Quantifying and Mitigating the Impact of Label Errors on Model Disparity Metrics

Julius Adebayo,Melissa Hall,Bowen Yu,Bobbie Chern

Errors in labels obtained via human annotation adversely affect a trained model's performance. Existing approaches propose ways to mitigate the effect of label error on a model's downstream accuracy, yet little is known about its impact on a model's group-based disparity metrics\footnote{Group-based disparity metrics like subgroup calibration, false positive rate, false negative rate, equalized odds, and equal opportunity are more often known, colloquially, as \textit{fairness metrics} in the literature. We use the term group-based disparity metrics in this work.}. Here we study the effect of label error on a model's group-based disparity metrics like group calibration. We empirically characterize how varying levels of label error, in both training and test data, affect these disparity metrics. We find that group calibration and other metrics are sensitive to train-time and test-time label error---particularly for minority groups. For the same level of label error, the percentage change in group calibration error for the minority group is on average 1.5 times larger than the change for the majority group. Towards mitigating the impact of training-time label error, we present an approach to estimate how changing a single training input's label affects a model's group disparity metric on a test set. We empirically assess the proposed approach on a variety of datasets and find a 10-40\% improvement, compared to alternative approaches, in identifying training inputs that improve a model's disparity metric. The proposed approach can help surface training inputs that may need to be corrected for improving a model's group-based disparity metrics.

Suppression helps: Lateral Inhibition-inspired Convolutional Neural Network for Image Classification

Chengyuan Zhuang,Xiaohui Yuan,XUAN GUO

Convolutional neural networks (CNNs) have become powerful and popular tools since deep learning emerged for image classification in the computer vision field. For better recognition, the dimensions of depth and width have been explored, leading to convolutional neural networks with more layers and more channels. In addition to these factors, neurobiology also suggests the widely existing lateral inhibition (e.g., Mach band effect), which increases the contrast of nearby neuron excitation in the lateral direction, to help recognition. However, such an important mechanism has not been well explored in modern convolutional neural networks. In this paper, we explicitly explore the filter dimension in the lateral direction and propose our lateral inhibition-inspired (LI) design. Our naive design incorporates the low-pass filter, while eliminating the central weight to mimic the inhibition strength decay. The inhibition value is computed from the filtering result of the input, with a simple learnable weight parameter per channel for multiplication to decide the strength. Then the inhibition value is subtracted from the input as suppression, which could increase the contrast to help recognition. We also suggest an alternative using depthwise convolution, as a general form. Our design could work on both the plain convolution and the convolutional block with residual connection, while being compatible with existing modules. Without any channel attention along the channel dimension, the preliminary results demonstrate an absolute improvement of 3.68\% and 0.69\% over AlexNet and ResNet-18, respectively, in the ImageNet data set, with little increase in parameters, indicating the merits of our design to help feature learning for image classification.

Factorized Fourier Neural Operators

Alasdair Tran,Alexander Mathews,Lexing Xie,Cheng Soon Ong

We propose the Factorized Fourier Neural Operator (F-FNO), a learning-based approach for simulating partial differential equations (PDEs). Starting from a recently proposed Fourier representation of flow fields, the F-FNO bridges the performance gap between pure machine learning approaches to that of the best numerical or hybrid solvers. This is achieved with new representations – separable spectral layers and improved residual connections – and a combination of training strategies such as the Markov assumption, Gaussian noise, and cosine learning rate d ecay. On several challenging benchmark PDEs on regular grids, structured meshes, and point clouds, the F-FNO can scale to deeper networks and outperform both the FNO and the geo-FNO, reducing the error by 83% on the Navier-Stokes problem, 31% on the elasticity problem, 57% on the airfoil flow problem, and 60% on the plastic forging problem. Compared to the state-of-the-art pseudo-spectral method, the F-FNO can take a step size that is an order of magnitude larger in time and achieve an order of magnitude speedup to produce the same solution quality.

DFPC: Data flow driven pruning of coupled channels without data.

Tanay Narshana,Chaitanya Murti,Chiranjib Bhattacharyya

Modern, multi-branched neural network architectures often possess complex interconnections between layers, which we call coupled channels (CCs). Structured pruning of CCs in these multi-branch networks is an under-researched problem, as most existing works are typically designed for pruning single-branch models like VGG-nets. While these methods yield accurate subnetworks, the improvements in inference times when applied to multi-branch networks are comparatively modest, as these methods do not prune CCs, which we observe contribute significantly to inference time. For instance, layers with CCs as input or output take more than 66% of the inference time in ResNet-50. Moreover, pruning in the data-free regime, where data is not used for pruning, is gaining traction owing to privacy concerns and computational costs associated with fine-tuning. Motivated by this, we study the problem of pruning CCs in the data-free regime. To facilitate the development of algorithms to prune CCs, we define Data Flow Couplings (DFCs) to enumerate the layers that constitute coupled connections and the associated transformation. Additionally, saliencies for pruning CCs cannot be gauged in isolation, as there may be discrepancies among the layerwise importance of CCs using conventional scoring strategies. This necessitates finding grouped saliencies to gauge the importance of all corresponding coupled elements in a network. We thus propose the Backwards Graph-based Saliency Computation (BGSC) algorithm, a data-free method that computes saliencies by estimating an upper bound to the reconstruction error of intermediate layers; we call this pruning strategy Data Flow driven Pruning of Coupled channels (DFPC). Finally, we show the efficacy of DFPC for models trained on standard datasets. Since we pruned coupled channels, we achieve up to 1.66x improvements in inference time for ResNet-101 trained on CIFAR-10 with a 5% accuracy drop without fine-tuning. With access to the ImageNet training set, we achieve significant improvements over the data-free method and see an improvement of at least 47.1% in speedup for a 2.3% accuracy drop for ResNet-50 against our baselines.

TVSPrune - Pruning Non-discriminative filters via Total Variation separability of intermediate representations without fine tuning

Chaitanya Murti,Tanay Narshana,Chiranjib Bhattacharyya

Achieving structured, data-free sparsity of deep neural networks (DNNs) remains an open area of research. In this work, we address the challenge of pruning filters without access to the original training set or loss function. We propose the discriminative filters hypothesis, that well-trained models possess discriminative filters, and any non-discriminative filters can be pruned without impacting the predictive performance of the classifier. Based on this hypothesis, we propose a new paradigm for pruning neural networks: distributional pruning, wherein we only require access to the distributions that generated the original datasets. Our approach to solving the problem of formalising and quantifying the discriminating ability of filters is through the total variation (TV) distance between the class-conditional distributions of the filter outputs. We present empirical results that, using this definition of discriminability, support our hypothesis on a variety of datasets and architectures. Next, we define the LDIFF score, a heuristic to quantify the extent to which a layer possesses a mixture of discriminative and non-discriminative filters. We empirically demonstrate that the LDIFF score is indicative of the performance of random pruning for a given layer, and thereby indicates the extent to which a layer may be pruned. Our main contribution is a novel one-shot pruning algorithm, called TVSPrune, that identifies non-discriminative filters for pruning. We extend this algorithm to IterTVSPrune, wherein we iteratively apply TVSPrune, thereby enabling us to achieve greater sparsity. Last, we demonstrate the efficacy of the TVSPrune on a variety of datasets , and show that in some cases, we can prune up to 60% of parameters with only a 2% loss of accuracy without any fine-tuning of the model, beating the nearest baseline by almost 10%.

Finding Actual Descent Directions for Adversarial Training
Fabian Latorre,Igor Krawczuk,Leello Tadesse Dadi,Thomas Pethick,Volkan Cevher

Adversarial Training using a strong first-order adversary (PGD) is the gold standard for training Deep Neural Networks that are robust to adversarial examples. We show that, contrary to the general understanding of the method, the gradient at an optimal adversarial example may increase, rather than decrease, the adversarially robust loss. This holds independently of the learning rate. More precisely, we provide a counterexample to a corollary of Danskin's Theorem presented in the seminal paper of Madry et al. (2018) which states that a solution of the inner maximization problem can yield a descent direction for the adversarially robust loss. Based on a correct interpretation of Danskin's Theorem, we propose Danskin's Descent Direction (DDi) and we verify experimentally that it provides better directions than those obtained by a PGD adversary. Using the CIFAR10 dataset we further provide a real world example showing that our method achieves a steeper increase in robustness levels in the early stages of training, and is more stable than the PGD baseline. As a limitation, PGD training of ReLU+BatchNorm networks still performs better, but current theory is unable to explain this.

A Study of Biologically Plausible Neural Network: the Role and Interactions of Brain-Inspired Mechanisms in Continual Learning
Fahad Sarfraz,Elahe Arani,Bahram Zonooz

Humans excel at continually acquiring, consolidating, and retaining information from an ever-changing environment, whereas artificial neural networks (ANNs) exhibit catastrophic forgetting. There are considerable differences in the complexity of synapses, the processing of information, and the learning mechanisms in biological neural networks and their artificial counterpart, which may explain the mismatch in performance. We consider a biologically plausible framework that constitutes separate populations of exclusively excitatory and inhibitory neurons which adhere to Dale's principle and the excitatory pyramidal neurons are augmented with dendritic-like structures for context-dependent processing of stimuli. We then conduct a comprehensive study on the role and interactions of different mechanisms inspired by the brain including sparse non-overlapping representations, Hebbian learning, synaptic consolidation, and replay of past activations that accompanied the learning event. Our study suggests that employing multiple complementary mechanisms in a biologically plausible architecture, similar to the brain, can be effective in enabling continual learning in ANNs.

Learning Continuous Normalizing Flows For Faster Convergence To Target Distribution via Ascent Regularizations
Shuangshuang Chen,Sihao Ding,Yiannis Karayiannidis,Mårten Björkman

Normalizing flows (NFs) have been shown to be advantageous in modeling complex distributions and improving sampling efficiency for unbiased sampling. In this work, we propose a new class of continuous NFs, ascent continuous normalizing flows (ACNFs), that makes a base distribution converge faster to a target distribution. As solving such a flow is non-trivial and barely possible, we propose a practical implementation to learn flexibly parametric ACNFs via ascent regularization and apply it in two learning cases: maximum likelihood learning for density estimation and minimizing reverse KL divergence for unbiased sampling and variational inference. The learned ACNFs demonstrate faster convergence towards the target distributions, therefore, achieving better density estimations, unbiased sampling and variational approximation at lower computational costs. Furthermore, the flows show to stabilize themselves to mitigate performance deterioration and are less sensitive to the choice of training flow length T.

pFedKT: Personalized Federated Learning via Knowledge Transfer
Liping Yi,Xiaorong Shi,Gang Wang,xiaoguang Liu
Federated learning (FL) has been widely studied as a new paradigm to achieve multi-party collaborative modelling on decentralized data with privacy protection. Unfortunately, traditional FL suffers from Non-IID data distribution, where clients' private models after FL are even inferior to models trained standalone. Existing approaches to tackle this challenge fall into two directions: a) pursuing a better global model through mitigating biases of private models, and b) improving personalized private models by personalized federated learning (PFL). Still, both of them have limited accuracy improvements in private models. To this end, \textit{we design pFedKT, a novel personalized federated learning framework with knowledge transfer, towards boosting the performances of personalized private models on Non-IID data}. It involves two types of knowledge transfer: a) transferring \textit{historical private knowledge} to new private models by local hypernetworks; b) transferring \textit{the global model's knowledge} to private models through contrastive learning. After absorbing the historical private knowledge and the latest global knowledge, the personalization and generalization of private models are both enhanced. Besides, we derive pFedKT's generalization and prove its convergence theoretically. Extensive experiments verify that pFedKT presents $0.31\%-3.46\%$ accuracy improvements of private models than the state-of-the-art baseline.

FARE: Provably Fair Representation Learning
Nikola Jovanovi■,Mislav Balunovic,Dimitar Iliev Dimitrov,Martin Vechev
Fair representation learning (FRL) is a popular class of methods aiming to produce fair classifiers via data preprocessing. However, recent work has shown that prior methods achieve worse accuracy-fairness tradeoffs than originally suggested by their results. This dictates the need for FRL methods that provide provable upper bounds on unfairness of any downstream classifier, a challenge yet unsolved. In this work we address this challenge and propose Fairness with Restricted Encoders (FARE), the first FRL method with provable fairness guarantees. Our key insight is that restricting the representation space of the encoder enables us to derive suitable fairness guarantees, while allowing empirical accuracy-fairness tradeoffs comparable to prior work. FARE instantiates this idea with a tree-based encoder, a choice motivated by inherent advantages of decision trees when applied in our setting. Crucially, we develop and apply a practical statistical procedure that computes a high-confidence upper bound on the unfairness of any downstream classifier. In our experimental evaluation on several datasets and settings we demonstrate that FARE produces tight upper bounds, often comparable with empirical results of prior methods, which establishes the practical value of our approach.

ONLINE RESTLESS BANDITS WITH UNOBSERVED STATES
Bowen Jiang,Bo Jiang,Jian Li,TAO LIN,Xinbing Wang,Chenghu Zhou
We study the online restless bandit problem, where each arm evolves according to a Markov chain independently, and the reward of pulling an arm depends on both the current state of the corresponding Markov chain and the action. The agent (decision maker) does not know the transition kernels and reward functions, and cannot observe the states of arms all the time. The goal is to sequentially choose which arms to pull so as to maximize the expected cumulative rewards collected. In this paper, we propose TSEETC, a learning algorithm based on Thompson Sampling with Episodic Explore-Then-Commit. The algorithm proceeds in episodes of increasing length and each episode is divided into exploration and exploitation phases. In the exploration phase in each episode, action-reward samples are collected in a round-robin way and then used to update the posterior as a mixture of Dirichlet distributions. At the beginning of the exploitation phase, TSEETC gene

rates a sample from the posterior distribution as true parameters. It then follows the optimal policy for the sampled model for the rest of the episode. We establish the Bayesian regret bound $\tilde {\mathcal{O}}(\sqrt{T})$ for TSEETC, where T is the time horizon. This is the first bound that is close to the lower bound of restless bandits, especially in an unobserved state setting. We show through simulations that TSEETC outperforms existing algorithms in regret.

Learning to aggregate: A parameterized aggregator to debias aggregation for cross-device federated learning

Tao Shen,Kun Kuang,Yaliang Li,Feng Wang,Zheqi Lv,Hongxia Yang,Chao Wu,Fei Wu

Federated learning (FL) emerged as a novel machine learning setting that enables collaboratively training deep models on decentralized private data. Due to the heterogeneity (non-iidness) of the decentralized data, FL methods (e.g. FedAvg) suffers from unstable and slow convergence. Recent works explain the non-iid problem in FL as the client drift, and deal with it by enforcing regularization at local updates. However, these works neglect the heterogeneity among different communication rounds: the data of sampled candidates at different communication rounds are also of non-iid distribution, and we term it as period drift, which as well as client drift can lead to aggregation bias that degrade convergence. To deal with it, we propose a novel aggregation strategy, named FedPA, that uses a Parameterized Aggregator, as an alternative of averaging. We frame FedPA within a meta-learning setting, and formulates the aggregator as a meta-learner, to learn to aggregate the model parameters of clients. FedPA can directly learn the aggregation bias and well calibrate and control the direction of aggregated parameters to a better direction towards the optimum. Experiments show that FedPA can achieve competitive performances compared with conventional baselines.

Deep Reinforcement Learning based Insight Selection Policy

Libio Goncalves Braz,Allmin Pradhap Singh Susaiyah,Milan Petkovic,Aki Härmä

We live in the era of ubiquitous sensing and computing. More and more data is being collected and processed from devices, sensors and systems. This opens up opportunities to discover patterns from these data that could help in gaining better understanding into the source that produces them. This is useful in a wide range of domains, especially in the area of personal health, in which such knowledge could help in allowing users to comprehend their behaviour and indirectly improve their lifestyle. Insight generators are systems that identify such patterns and verbalise them in a readable text format, referred to as insights. The selection of insights is done using a scoring algorithm which aims at optimizing this process based on multiple objectives, e.g., factual correctness, usefulness and interestingness of insights. In this paper, we propose a novel Reinforcement Learning (RL) framework for insight selection where the scoring model is trained by user feedback on interestingness and their lifestyle quality estimates. With the use of highly reusable and simple principles of automatic user simulation based on real data, we demonstrate in this preliminary study that the RL solution may improve the selection of insights towards multiple pre-defined objectives.

Data Leakage in Tabular Federated Learning

Mark Vero,Mislav Balunovic,Dimitar Iliev Dimitrov,Martin Vechev

While federated learning (FL) promises to preserve privacy in distributed training of deep learning models, recent work in the image and NLP domains showed that training updates leak private data of participating clients. At the same time, most high-stakes applications of FL (e.g., legal and financial) use tabular data. Compared to the NLP and image domains, reconstruction of tabular data poses several unique challenges: (i) categorical features introduce a significantly more difficult mixed discrete-continuous optimization problem, (ii) the mix of categorical and continuous features causes high variance in the final reconstructions, and (iii) structured data makes it difficult for the adversary to judge reconstruction quality. In this work, we tackle these challenges and propose the first comprehensive reconstruction attack on tabular data, called TabLeak. TabLeak is based on three key ingredients: (i) a softmax structural prior, implicitly conv erting the mixed discrete-continuous optimization problem into an easier fully continuous one, (ii) a way to reduce the variance of our reconstructions through a pooled ensembling scheme exploiting the structure of tabular data, and (iii) an entropy measure which can successfully assess reconstruction quality. Our experimental evaluation demonstrates the effectiveness of TabLeak, reaching a state-of-the-art on four popular tabular datasets. For instance, on the Adult dataset, we improve attack accuracy by 10% compared to the baseline on the practically relevant batch size of 32 and further obtain non-trivial reconstructions for batch sizes as large as 128. Our findings are important as they show that performing FL on tabular data, which often poses high privacy risks, is highly vulnerable.

Long-horizon video prediction using a dynamic latent hierarchy

Alexey Zakharov,Qinghai Guo,Zafeirios Fountas

The task of video prediction and generation is known to be notoriously difficult, with the research in this area largely limited to short-term predictions. Though plagued with noise and stochasticity, videos consist of features that are organised in a spatiotemporal hierarchy, different features possessing different temporal dynamics. In this paper, we introduce Dynamic Latent Hierarchy (DLH) -- a deep hierarchical latent model that represents videos as a hierarchy of latent states that evolve over separate and fluid timescales. Each latent state is a mixture distribution with two components, representing the immediate past and the predicted future, causing the model to learn transitions only between sufficiently dissimilar states, while clustering temporally persistent states closer together. Using this unique property, DLH naturally discovers the spatiotemporal structure of a dataset and learns disentangled representations across its hierarchy. We hypothesise that this simplifies the task of modeling temporal dynamics of a video, improves the learning of long-term dependencies, and reduces error accumulation. As evidence, we demonstrate that DLH outperforms state-of-the-art benchmarks in video prediction, is able to better represent stochasticity, as well as to dynamically adjust its hierarchical and temporal structure. Our paper shows, among other things, how progress in representation learning can translate into progress in prediction tasks.

****

SwinZS3: Zero-Shot Semantic Segmentation with a Swin Transformer

Tian YingJie,Wang YiQi

Zero-shot semantic segmentation (ZS3) aims at learning to classify the never-seen classes with zero training samples. Convolutional neural networks (CNNs) have recently achieved great success in this task. However, their limited attention ability constraints existing network architectures to reason based on word embeddings. In this light of the recent successes achieved by Swin Transformers, we propose SwinZS3, a new framework exploiting the visual embeddings and semantic embeddings on joint embedding space. The SwinZS3 combines a transformer image encoder with a language encoder. The image encoder is trained by pixel-text score maps using the dense language-guided semantic prototypes which are computed by the language encoder. This allows the SwinZS3 could recognize the unseen classes at test time without retraining. We experiment with our method on the ZS3 standard benchmarks (PASCAL VOC and PASCAL Context) and the results demonstrate the effectiveness of our method by showing the state-of-art performance.

Softened Symbol Grounding for Neuro-symbolic Systems

Zenan Li,Yuan Yao,Taolue Chen,Jingwei Xu,Chun Cao,Xiaoxing Ma,Jian L\"{u}

Neuro-symbolic learning generally consists of two separated worlds, i.e., neural network training and symbolic constraint solving,
whose success hinges on symbol grounding, a fundamental problem in AI. This paper presents a novel, softened symbol grounding process, bridging the gap between the two worlds, and resulting in an effective and efficient neuro-symbolic learning framework. Technically, the framework features (1) modeling of symbol solution states as a Boltzmann distribution, which avoids expensive state searching and facilitates mutually beneficial interactions between network training and symb

olic reasoning; (2) a new MCMC technique leveraging projection and SMT solvers, which efficiently samples from disconnected symbol solution spaces; (3) an annealing mechanism that can escape from sub-optimal symbol groundings. Experiments with three representative neuro-symbolic learning tasks demonstrate that, owing to its superior symbol grounding capability, our framework successfully solves problems well beyond the frontier of the existing proposals.

****

Encoding Recurrence into Transformers

Feiqing Huang,Kexin Lu,Yuxi CAI,Zhen Qin,Yanwen Fang,Guangjian Tian,Guodong Li

This paper novelly breaks down with ignorable loss an RNN layer into a sequence of simple RNNs, each of which can be further rewritten into a lightweight positional encoding matrix of a self-attention, named the Recurrence Encoding Matrix (REM). Thus, recurrent dynamics introduced by the RNN layer can be encapsulated into the positional encodings of a multihead self-attention, and this makes it possible to seamlessly incorporate these recurrent dynamics into a Transformer, leading to a new module, Self-Attention with Recurrence (RSA). The proposed module can leverage the recurrent inductive bias of REMs to achieve a better sample efficiency than its corresponding baseline Transformer, while the self-attention is used to model the remaining non-recurrent signals. The relative proportions of these two components are controlled by a data-driven gated mechanism, and the effectiveness of RSA modules are demonstrated by four sequential learning tasks.

Human-Guided Fair Classification for Natural Language Processing

Florian E. Dorner,Momchil Peychev,Nikola Konstantinov,Naman Goel,Elliott Ash,Martin Vechev

Text classifiers have promising applications in high-stake tasks such as resume screening and content moderation. These classifiers must be fair and avoid discriminatory decisions by being invariant to perturbations of sensitive attributes such as gender or ethnicity. However, there is a gap between human intuition about these perturbations and the formal similarity specifications capturing them. While existing research has started to address this gap, current methods are based on hardcoded word replacements, resulting in specifications with limited expressivity or ones that fail to fully align with human intuition (e.g., in cases of asymmetric counterfactuals). This work proposes novel methods for bridging this gap by discovering expressive and intuitive individual fairness specifications. We show how to leverage unsupervised style transfer and GPT-3's zero-shot capabilities to automatically generate expressive candidate pairs of semantically similar sentences that differ along sensitive attributes. We then validate the generated pairs via an extensive crowdsourcing study, which confirms that a lot of these pairs align with human intuition about fairness in the context of toxicity classification. Finally, we show how limited amounts of human feedback can be leveraged to learn a similarity specification that can be used to train downstream fairness-aware models.

Proper Scoring Rules for Survival Analysis

Hiroki Yanagisawa

Survival analysis is the problem of estimating probability distributions for future events, which can be seen as a problem in uncertainty quantification. Although there are fundamental theories on strictly proper scoring rules for uncertainty quantification, little is known about those for survival analysis. In this paper, we investigate extensions of four major strictly proper scoring rules for survival analysis. Through the extensions, we discuss and clarify the assumptions arising from the discretization of the estimation of probability distributions. We also discuss the relationship between the existing algorithms and extended scoring rules, and we propose new algorithms based on our extensions of the scoring rules for survival analysis.

Social Network Structure Shapes Innovation: Experience-sharing in RL with SAPIENS

Eleni Nisioti,Matéo Mahaut,Pierre-Yves Oudeyer,Ida Momennejad,Clément Moulin-Frier

The human cultural repertoire relies on innovation: our ability to continuously explore how existing elements can be combined to create new ones. Innovation is not solitary, it relies on collective accumulation and merging of previous solutions. Machine learning approaches commonly assume that fully connected multi-agent networks are best suited for innovation. However, human laboratory and field studies have shown that hierarchical innovation is more robustly achieved by dynamic social network structures. In dynamic settings, humans oscillate between innovating individually or in small clusters, and then sharing outcomes with others. To our knowledge, the role of multi-agent topology on innovation has not been systematically studied in machine learning. It remains unclear a) which social network topologies are optimal for which innovation tasks, and b) which properties of experience sharing improve multi-level innovation. Here we use a multi-level hierarchical problem setting (WordCraft), with three different innovation tasks. We systematically design networks of DQNs sharing experiences from their replay buffers in varying topologies (fully connected, small world, dynamic, ring). Comparing the level of innovation achieved by different experience-sharing topologies across different tasks shows that, first, consistent with human findings, experience sharing within a dynamic topology achieves the highest level of innovation across tasks. Second, experience sharing is not as helpful when there is a single clear path to innovation. Third, two metrics we propose, conformity and diversity of shared experience, can explain the success of different topologies on different tasks. These contributions can advance our understanding of optimal AI-AI, human-human, and human-AI collaborative networks, inspiring future tools for fostering collective innovation in large organizations.
****
Mini-batch k-means terminates within $O(d/\epsilon)$ iterations
Gregory Schwartzman
We answer the question: "Does \emph{local} progress (on batches) imply \emph{global} progress (on the entire dataset) for mini-batch k-means?". Specifically, we consider mini-batch k-means which terminates only when the improvement in the quality of the clustering on the sampled batch is below some threshold.

Although at first glance it appears that this algorithm might execute forever, we answer the above question in the affirmative and show that if the batch is of size $\tilde{\Omega}((d/\epsilon)^2)$, it must terminate within $O(d/\epsilon)$ iterations with high probability, where d is the dimension of the input, and ϵ is a threshold parameter for termination. This is true \emph{regardless} of how the centers are initialized. When the algorithm is initialized with the k-means++ initialization scheme, it achieves an approximation ratio of $O(\log k)$ (the same as the full-batch version).

Finally, we show the applicability of our results to the mini-batch k-means algorithm implemented in the scikit-learn (sklearn) python library.
****
Convergence is Not Enough: Average-Case Performance of No-Regret Learning Dynamics
Iosif Sakos,Stefanos Leonardos,William Overman,Stelios Andrew Stavroulakis,Ioannis Panageas,Georgios Piliouras
Learning in games involves two main challenges, even in settings in which agents seek to coordinate: convergence to equilibria and selection of good equilibria. Unfortunately, solving the issue of convergence, which is the focus of state-of-the-art models, conveys little information about the quality of the equilibria that are eventually reached, often none at all. In this paper, we study a class of games in which q-replicator (QRD), a widely-studied class of no-regret learning dynamics that include gradient descent, “standard” replicator, and log-barrier dynamics as special cases, can be shown to converge pointwise to Nash equilibria. This is the starting point for our main task, which is the mathematically ch

allenging problem of performance. In our main contribution, we quantify both conceptually and experimentally the outcome of optimal learning dynamics via average performance metrics, i.e., metrics that couple the regions of attraction with the quality of each attracting point. We provide an exhaustive comparison between gradient descent and “standard” replicator in a class of games with severe equilibrium selection problems and empirically extend our results to all dynamics in the QRD class. Our results combine tools from machine learning, game theory, and dynamical systems and provide a framework to initiate the systematic comparison of different optimal learning dynamics in arbitrary games.

Gene finding revisited: improved robustness through structured decoding from learning embeddings

Frederikke Isa Marin,Dennis Pultz,Wouter Boomsma

Gene finding is the task of identifying the locations of coding sequences within the vast amount of genetic code contained in the genome. With an ever increasing quantity of raw genome sequences, gene finding is an important avenue towards understanding the genetic information of (novel) organisms, as well as learning shared patterns across evolutionarily diverse species. The current state of the art are graphical models usually trained per organism and requiring manually curated data sets. However, these models lack the flexibility to incorporate deep learning representation learning techniques that have in recent years been transformative in the analysis of protein sequences, and which could potentially help gene finders exploit the growing number of sequenced genomes to expand performance across multiple organisms. Here, we propose a novel approach, combining learned embeddings of raw genetic sequences with exact
decoding using a latent conditional random field. We show that the model achieves performance matching the current state of the art, while increasing training robustness, and removing the need for manually fitted length distributions. As language models for DNA improve, this paves the way for more performant cross-organism gene-finders.

****

Learning Uncertainty for Unknown Domains with Zero-Target-Assumption

Yu Yu,Hassan Sajjad,Jia Xu

We introduce our Maximum-Entropy Rewarded Reinforcement Learning (MERRL) framework that selects training data for more accurate Natural Language Processing (NLP). Because conventional data selection methods select training samples based on the test domain knowledge and not on real life data, they frequently fail in unknown domains like patent and Twitter.

Our approach selects training samples that maximize information uncertainty measured by entropy, including observation entropy like empirical Shannon entropy, Min-entropy, R\'enyi entropy, and prediction entropy using mutual information, to cover more possible queries that may appear in unknown worlds. Our MERRL using regularized A2C and SAC achieves up to -99.7 perplexity decrease (-43.4\% relatively) in language modeling, +25.0 accuracy increase (+40.0\% relatively) in sentiment analysis, and +5.0 F1 score increase (+30.8\% relatively) in named entity recognition over various domains, demonstrating strong generalization power on unknown test sets.

Detecting Out-of-Distribution Data with Semi-supervised Graph “Feature" Networks

Debargha Ganguly,Debayan Gupta

Anomalous and out-of-distribution (OOD) data present a significant challenge to the robustness of decisions taken by deep neural networks, with myriad real-world consequences. State-of-the-art OOD detection techniques use embeddings learned by large pre-trained transformers. We demonstrate that graph structures and topological properties can be leveraged to detect both far-OOD and near-OOD data reliably, simply by characterising each data point (image) as a network of related features (visual concepts). Furthermore, we facilitate human-in-the-loop machine learning by expressing this data to comprise high-level domain-specific concepts. We obtained \textit{97.95\% AUROC} on far-OOD and \textit{98.79\% AUROC} on near-OOD detection tasks based on the LSUN dataset (comparable to the performanc e of state-of-the-art techniques).

****

Let Offline RL Flow: Training Conservative Agents in the Latent Space of Normalizing Flow

Dmitry Akimov,Vladislav Kurenkov,Alexander Nikulin,Denis Tarasov,Sergey Kolesnikov

Offline reinforcement learning aims to train a policy on a pre-recorded and fixed dataset without any additional environment interactions. There are two major challenges in this setting: (1) extrapolation error caused by approximating the value of state-action pairs not well-covered by the training data and (2) distributional shift between behavior and inference policies. One way to tackle these problems is to induce conservatism - i.e., keeping the learned policies closer to the behavioral ones. To achieve this, we build upon recent works on learning policies in latent action spaces and use a special form of normalizing flow for constructing a generative model, which we use as a conservative action encoder. This normalizing flow action encoder is pre-trained in a supervised manner on the offline dataset, and then an additional policy model - controller in the latent space - is trained via reinforcement learning. This approach avoids querying actions outside of the training dataset and therefore does not require additional regularization for out-of-dataset actions. We evaluate our method on various locomotion and navigation tasks, demonstrating that our approach outperforms recently proposed algorithms with generative action models on a large portion of datasets.

Towards a Complete Theory of Neural Networks with Few Neurons

Berfin Simsek,Valentin Schmutz,Wulfram Gerstner,Johanni Brea

Deep learning has seen unprecedented progress thanks to the deployment of models with millions of parameters.

On the theoretical side, an immense amount of effort has gone to understanding the dynamics of overparameterized networks.

Although now there is a well-developed theory of networks with infinitely many neurons, the classic problem of understanding how a neural network with a few neurons learns remains unsolved.

To attack this problem, we analytically study the landscapes of neural networks with few neurons.

We prove for the first time that a student network with one neuron has only one critical point --its global minimum-- when learning from a teacher network with arbitrarily many orthogonal neurons.

In addition, we prove how a neuron addition mechanism turns a minimum into a line of critical points with transitions from saddles to local minima via non-strict saddles.

Finally, we discuss how the insights we get from our novel proof techniques may shed light on the dynamics of neural networks with few neurons.

Machine Learning from Explanations

Jiashu Tao,Reza Shokri

Machine learning needs a huge amount of (labeled) data, as otherwise it might not learn the right model for different sub-populations, or even worse, they might pick up spurious correlations in the training data leading to brittle prediction mechanisms. Also, for small training datasets, there is a huge variability in the learned models on randomly sampled training datasets, which makes the whole process less reliable. But, collection of large amount of useful representative data, and training on large datasets, are very costly. In this paper, we present a technique to train reliable classification models on small datasets, assuming we have access to some simple explanations (e.g., subset of influential input features) on labeled data. We also propose a novel two stage training pipeline that optimizes the model's output and fine-tunes its attention in an interleaving manner, to help the model to agree with the provided explanation while learning from the data. We show that our training pipeline enables faster convergence to better models, especially when there is a severe class imbalance in the popu

lation or spurious features in the training data.

Functional Risk Minimization

Ferran Alet,Clement Gehring,Tomás Lozano-Pérez,Joshua B. Tenenbaum,Leslie Pack Kaelbling

In this work, we break the classic assumption of data coming from a single function $f_{\theta^*}(x)$ followed by some noise in output space $p(y|f_{\theta^*}(x))$. Instead, we model each data point (x_i,y_i) as coming from its own function f_{θ_i}. We show that this model subsumes Empirical Risk Minimization for many common loss functions, and provides an avenue for more realistic noise processes. We derive Functional Risk Minimization~(FRM), a general framework for scalable training objectives which results in better performance in small experiments in regression and reinforcement learning. We also show that FRM can be seen as finding the simplest model that memorizes the training data, providing an avenue towards understanding generalization in the over-parameterized regime.

Latent Linear ODEs with Neural Kalman Filtering for Irregular Time Series Forecasting

Randolf Scholz,Stefan Born,Nghia Duong-Trung,Mariano Nicolas Cruz-Bournazou,Lars Schmidt-Thieme

Over the past four years, models based on Neural Ordinary Differential Equations have become state of the art in the forecasting of irregularly sampled time series. Describing the data-generating process as a dynamical system in continuous time allows predictions at arbitrary time points. However, the numerical integration of Neural ODEs typically comes with a high computational burden or may even fail completely. We propose a novel Neural ODE model that embeds the observations into a latent space with dynamics governed by a linear ODE. Consequently, we do not require any specialized numerical integrator but only an implementation of the matrix exponential readily available in many numerical linear algebra libraries. We also introduce a novel state update component inspired by the classical Kalman filter, which, to our knowledge, makes our model the first Neural ODE variant to explicitly satisfy a specific self-consistency property. It allows forecasting irregularly sampled time series with missing values and comes with some numerical stability guarantees. We evaluate the performance on medical and climate benchmark datasets, where the model outperforms the state of the art by margins up to 30%.
****

Transformer-based model for symbolic regression via joint supervised learning

Wenqiang Li,Weijun Li,Linjun Sun,Min Wu,Lina Yu,Jingyi Liu,Yanjie Li,Songsong Tian

Symbolic regression (SR) is an important technique for discovering hidden mathematical expressions from observed data. Transformer-based approaches have been widely used for machine translation due to their high performance, and are recently highly expected to be used for SR. They input the data points, then output the expression skeleton, and finally optimize the coefficients. However, recent transformer-based methods for SR focus more attention on large scale training data and ignore the ill-posed problem: the lack of sufficient supervision, i.e., expressions that may be completely different have the same supervision because of their same skeleton, which makes it challenging to deal with data that may be from the same expression skeleton but with different coefficients. Therefore, we present a transformer-based model for SR with the ability to alleviate this problem. Specifically, we leverage a feature extractor based on pure residual MLP networks to obtain more information about data points. Furthermore, the core idea is that we propose a joint learning mechanism combining supervised contrastive learning, which makes features of data points from expressions with the same skeleton more similar so as to effectively alleviates the ill-posed problem. The benchmark results show that the proposed method is up to 25% higher with respect to the recovery rate of skeletons than typical transformer-based methods. Moreover, our method outperforms state-of-the-art SR methods based on reinforcement learning and genetic programming in terms of the coefficient of determination (R^2).

Gradient-Based Transfer Learning

Gustaf Tegnér,Alfredo Reichlin,Hang Yin,Hedvig Kjellstrom,Mårten Björkman,Danica Kragic

We formulate transfer learning as a meta-learning problem by extending upon the current meta-learning paradigm in that support and query data are drawn from different, but related distributions of tasks. Inspired by the success of Gradient-Based Meta-Learning (GBML), we propose to expand it to the transfer learning setting by constructing a general encoder-decoder architecture that learns a map between functionals of different domains. This is achieved by leveraging on the idea that the task-adapted parameters of a meta-learner can serve as an informative representation of the task itself. We demonstrate the proposed method on regression, prediction of dynamical systems and meta-imitation learning problems.

****

Coreset for Rational Functions

David Denisov,Ibrahim Jubran,Dan Feldman

We consider the problem of fitting a rational function $f:\mathbb{R}\to\mathbb{R}$ to a time-series $g:\{1,\cdots,n\}\to\mathbb{R}$. This is by minimizing the sum of distances (loss function) $\ell(f):=\sum_{i=1}^n |f(i)-g(i)|$, possibly with additional constraints and regularization terms that may depend on f. Our main motivation is to approximate such a time-series by a recursive sequence model $F_n=\sum_{i=1}^k \theta_i F_{n-i}$, e.g. a Fibonacci sequence, where $\theta\in \mathbb{R}^k$ are the model parameters, and $k\geq1$ is constant.

For $\varepsilon\in(0,1)$, an ε-coreset for this problem is a small data structure that approximates $\ell(g)$ up to $1\pm\varepsilon$ multiplicative factor, for every rational function g of constant degree.

We prove that every signal has an ε-coreset of size $O(n^{0.001}/\varepsilon^2)$, and provide a construction algorithm that computes it in $O(n^{1.001})$ time.

Open source code is provided, as well as extensive experimental results, on both real and synthetic datasets, which compare our method to existing solvers from Scipy.

Transformer needs NMDA receptor nonlinearity for long-term memory

Dong-Kyum Kim,Jea Kwon,Meeyoung Cha,C. Justin Lee

The NMDA receptor (NMDAR) in the hippocampus is essential for learning and memory. We find an interesting resemblance between deep models' nonlinear activation function and the NMDAR's nonlinear dynamics. In light of a recent study that compared the transformer architecture to the formation of hippocampal memory, this paper presents new findings that NMDAR-like nonlinearity may be essential for consolidating short-term working memory into long-term reference memory. We design a navigation task assessing these two memory functions and show that manipulating the activation function (i.e., mimicking the Mg^{2+}-gating of NMDAR) disrupts long-term memory formation. Our experimental data suggest that the concept of place cells and reference memory may reside in the feed-forward network layer of transformers and that nonlinearity plays a key role in these processes. Our findings propose that the transformer architecture and hippocampal spatial representation resemble by sharing the overlapping concept of NMDAR-like nonlinearity.

Simple Spectral Graph Convolution from an Optimization Perspective

Hao Zhu,Piotr Koniusz

Recent studies on SGC, PageRank and S^{2}GC have demonstrated that several graph diffusion techniques are straightforward, quick, and effective for tasks in the graph domain like node classification. Even though these techniques do not even need labels, they can nevertheless produce more discriminating features than raw attributes for downstream tasks with different classifiers. These methods are data-independent and thus primarily rely on some empirical parameters on polynomial bases (e.g., Monomial and Chebyshev), which ignore the homophily of graphs and the attribute distribution. They are more insensitive to heterophilous graphs due to the low-pass filtering. Although there are many approache s focusing on GNNs based on heterophilous graphs, these approaches are dependent on label information to learn model parameters. In this paper, we study the question: are labels a necessity for GNNs with heterophilous graphs? Based on this question, we propose a framework of self-representation on graphs related to the Least Squares problem. Specifically, we use Generalized Minimum RESidual (GMRES) method, which finds the least squares solution over Krylov subspaces. In theoretical analysis, without label information, we enjoy better features with graph convolution.

The proposed method, like previous data-independent methods, is not a deep model and is, therefore, quick, scalable, and simple. We also show performance guarantees for models on real and synthetic data. On a benchmark of real-world datasets, empirically, our method is competitive with existing deep models for node classification.

QAID: Question Answering Inspired Few-shot Intent Detection

Asaf Yehudai,Matan Vetzler,Yosi Mass,Koren Lazar,Doron Cohen,Boaz Carmeli

Intent detection with semantically similar fine-grained intents is a challenging task. To address it, we reformulate intent detection as a question-answering retrieval task by treating utterances and intent names as questions and answers. To that end, we utilize a question-answering retrieval architecture and adopt a two stages training schema with batch contrastive loss. In the pre-training stage, we improve query representations through self-supervised training. Then, in the fine-tuning stage, we increase contextualized token-level similarity scores between queries and answers from the same intent. Our results on three few-shot intent detection benchmarks achieve state-of-the-art performance.

Rethinking the Value of Prompt Learning for Vision-Language Models

Peisong Wang,Weihan Chen,Weixiang Xu,Qinghao Hu,Jian Cheng

Large-scale visual-language pre-training like CLIP has demonstrated great success in open-set visual concept learning that enables zero-shot transfer to downstream tasks through prompting. To automate prompt engineering, prompt learning is proposed to automatically learn the optimal task-relevant prompts. In this paper, we make some surprising observations that contradict common beliefs about prompts. We observe that even random prompts can achieve pretty good performance for zero-shot recognition. We also find that prompt learning gives comparable or worse performance than directly fine-tuning of the linear classifier. Moreover, prompt learning is no more than parameter-efficient learning, and is a trade-off between optimality and generalization. Our results highlight the need for the rethinking of existing prompt learning, more careful baseline evaluations in future research on prompt learning methods in vision-language models.

Disentangled Feature Swapping Augmentation for Weakly Supervised Semantic Segmentation

Junehyoung Kwon,Eunju Lee,YunSung Cho,YoungBin Kim

Weakly supervised semantic segmentation utilizes a localization map obtained from a classifier to generate a pseudo-mask. However, classifiers utilize background cues to predict class labels because of a biased dataset consisting of images, in which specific objects frequently co-occur with certain backgrounds. Consequently, the classifier confuses the background with the target objects, resulting in inaccurate localization maps. To this end, we propose DisEntangled FeaTure swapping augmentation(DEFT) to prevent the classifier from being biased by a misleading correlation. Our method first disentangles the foreground and background features. Then, we randomly swap the disentangled features within mini-batches via a two-way process. These features contain various contexts that do not appear in the biased dataset, but the class relevant representation is preserved. In addition, we introduce training schemes to obtain further performance gains. Experimental results showed that when our augmentation was used in various weakly supervised semantic segmentation methods trained on the Pascal VOC 2012 dataset, the performance of the localization maps and pseudo-mask as well as the segmentation results improved.

Distributed Least Square Ranking with Random Features
Rong Yin,Yong Liu,Weiping Wang,Dan Meng
In this paper, we study the statistical properties of pairwise ranking using distributed learning and random features (called DRank-RF) and establish its convergence analysis in probability. Theoretical analysis shows that DRank-RF remarkably reduces the computational requirements while preserving a satisfactory convergence rate. An extensive experiment verifies the effectiveness of DRank-RF. Furthermore, to improve the learning performance of DRank-RF, we propose an effective communication strategy for it and demonstrate the power of communications via theoretical assessments and numerical experiments.

Doing Fast Adaptation Fast: Conditionally Independent Deep Ensembles for Distribution Shifts
Wanqian Yang,Aahlad Manas Puli,Andrew Gordon Wilson,Rajesh Ranganath
Classifiers in a diverse ensemble capture distinct predictive signals, which is valuable for datasets containing multiple strongly predictive signals. Performing fast adaptation at test time allows us to generalize to distributions where certain signals are no longer predictive, or to avoid relying on sensitive or protected attributes. However, ensemble learning is often expensive, even more so when we need to enforce diversity constraints between the high-dimensional representations of the classifiers. Instead, we propose an efficient and fast method for learning ensemble diversity. We minimize conditional mutual information of the output distributions between classifiers, a quantity which can be cheaply and exactly computed from empirical data. The resulting ensemble contains individually strong predictors that are only dependent because they predict the label. We demonstrate the efficacy of our method on shortcut learning tasks. Performing fast adaptation on our ensemble selects shortcut-invariant models that generalize well to test distributions where the shortcuts are uncorrelated with the label.

Solving stochastic weak Minty variational inequalities without increasing batch size
Thomas Pethick,Olivier Fercoq,Puya Latafat,Panagiotis Patrinos,Volkan Cevher
This paper introduces a family of stochastic extragradient-type algorithms for a class of nonconvex-nonconcave problems characterized by the weak Minty variational inequality (MVI). Unlike existing results on extragradient methods in the monotone setting, employing diminishing stepsizes is no longer possible in the weak MVI setting. This has led to approaches such as increasing batch sizes per iteration which can however be prohibitively expensive. In contrast, our proposed methods involves two stepsizes and only requires one additional oracle evaluation per iteration. We show that it is possible to keep one fixed stepsize while it is only the second stepsize that is taken to be diminishing, making it interesting even in the monotone setting. Almost sure convergence is established and we provide a unified analysis for this family of schemes which contains a nonlinear generalization of the celebrated primal dual hybrid gradient algorithm.

****
Diversity Boosted Learning for Domain Generalization with a Large Number of Domains
XI LENG,Xiaoying Tang,Yatao Bian
Machine learning algorithms minimizing the average training loss typically suffer from poor generalization performance. It inspires various works for domain generalization (DG), among which a series of methods work by $O(n^2)$ pairwise domain operations with n domains, where each one is often costly. Moreover, while a common objective in the DG literature is to learn invariant representations against spurious correlations induced by domains, we point out the insufficiency of it and highlight the importance of alleviating spurious correlations caused by objects. Based on the observation that diversity helps mitigate spurious correlations, we propose a Diversity boosted twO-level saMplIng framework (DOMI) to effi

ciently sample the most informative ones among a large number of domains and data points. We show that DOMI helps train robust models against spurious correlations from both domain-side and object-side, substantially enhancing the performance of five backbone DG algorithms on Rotated MNIST and Rotated Fashion MNIST.

Towards Performance-maximizing Network Pruning via Global Channel Attention

Yingchun Wang,Linchuan Xu,Song Guo,Jingcai Guo,Weizhan Zhang,Jie Zhang,shuai chen

Network pruning has attracted increasing attention recently for its capability of transferring large-scale neural networks (e.g., CNNs) into resource-constrained devices. Such a transfer is typically achieved by removing redundant network parameters while retaining its generalization performance in a static or dynamic pruning manner. Concretely, static pruning usually maintains a larger and fit-to-all (samples) compressed network by removing the same channels for all samples, while dynamic pruning can adaptively remove (more) different channels for different samples and obtain state-of-the-art performance along with a higher compression ratio. However, since the system has to preserve the complete network information for sample-specific pruning, dynamic pruning methods are usually not memory-efficient. In this paper, our interest is to explore a static alternative, dubbed GlobalPru, to conventional static pruning methods that can take into account both compression ratio and model performance maximization. Specifically, a novel channel attention-based learn-to-rank algorithm is proposed to learn the global channel attention of the network for various samples, wherein, each sample-specific channel saliency is forced to reach an agreement on the global ranking. Hence, all samples can empirically share the same pruning priority of channels to achieve channel pruning with minimal performance loss. Extensive experiments demonstrate that the proposed GlobalPru can achieve better performance than state-of-the-art static and dynamic pruning methods by significant margins.

Adaptive Block-wise Learning for Knowledge Distillation

Tianyi Lei,Junyu Xie,Wang qian,Dezhong Peng,Xu Wang

Knowledge distillation allows the student network to improve its performance under the supervision of transferred knowledge. Existing knowledge distillation methods are implemented under the implicit hypothesis that knowledge from teacher and student contributes to each layer of the student network to the same extent. In this work, we argue that there should be different contributions of knowledge from the teacher and the student during training for each layer. Experimental results evidence this argument. To the end, we propose a novel Adaptive Block-wise Learning~(ABL) for Knowledge Distillation to automatically balance teacher-guided knowledge between self-knowledge in each block. Specifically, to solve the problem that the error backpropagation algorithm cannot assign weights to each block of the student network independently, we leverage the local error signals to approximate the global error signals on student objectives. Moreover, we utilize a set of meta variables to control the contribution of the student knowledge and teacher knowledge to each block during the training process. Finally, the extensive experiments prove the effectiveness of our method. Meanwhile, ABL provides an insightful view that in the shallow blocks, the weight of teacher guidance is greater, while in the deep blocks, student knowledge has more influence.

Curriculum-based Co-design of Morphology and Control of Voxel-based Soft Robots

Yuxing Wang,Shuang Wu,Haobo Fu,QIANG FU,Tiantian Zhang,Yongzhe Chang,Xueqian Wang

Co-design of morphology and control of a Voxel-based Soft Robot (VSR) is challenging due to the notorious bi-level optimization. In this paper, we present a Curriculum-based Co-design (CuCo) method for learning to design and control VSRs through an easy-to-difficult process. Specifically, we expand the design space from a small size to the target size gradually through a predefined curriculum. At each learning stage of the curriculum, we use reinforcement learning to simultaneously train the design policy and the control policy, which is enabled by incorporating the design process into the environment and using differentiable policy representations. The converged morphology and the learned policies from last stage are inherited and then serve as the starting point for the next stage. In empirical studies, we show that CuCo is more efficient in creating larger robots with better performance by reusing the practical design and control patterns learned within each stage, in comparison to prior approaches that learn from scratch in the space of target size.

****

Object-Centric Learning with Slot Mixture Models

Daniil Kirilenko,Alexey Kovalev,Aleksandr Panov

Object-centric architectures usually apply some differentiable module on the whole feature map to decompose it into sets of entities representations called slots. Some of these methods structurally resemble clustering algorithms, where the center of the cluster in latent space serves as slot representation. Slot Attention is an example of such a method as a learnable analog of the soft k-Means algorithm. In our work, we use the learnable clustering method based on Gaussian Mixture Model, unlike other approaches we represent slots not only as centers of clusters but we also use information about the distance between clusters and assigned vectors, which leads to more expressive slots representations. Our experiments demonstrate that using this approach instead of Slot Attention improves performance in different scenarios achieving state-of-the-art performance in the set property prediction task.

WiNeRT: Towards Neural Ray Tracing for Wireless Channel Modelling and Differentiable Simulations

Tribhuvanesh Orekondy,Pratik Kumar,Shreya Kadambi,Hao Ye,Joseph Soriaga,Arash Behboodi

In this paper, we work towards a neural surrogate to model wireless electro-magnetic propagation effects in indoor environments.

Such neural surrogates provide a fast, differentiable, and continuous representation of the environment and enables end-to-end optimization for downstream tasks (e.g., network planning). Specifically, the goal of the paper is to render the wireless signal (e.g., time-of-flights, power of each path) in an environment as a function of the sensor's spatial configuration (e.g., placement of transmit and receive antennas). NeRF-based approaches have shown promising results in the visual setting (RGB image signal, with a camera sensor), where the key idea is to algorithmically evaluate the 'global' signal (e.g., using volumetric rendering) by breaking it down in a sequence of 'local' evaluations (e.g., using co-ordinate neural networks). In a similar spirit, we model the time-angle channel impulse response (the global wireless signal) as a superposition of multiple paths. The wireless characteristics (e.g., power) of each path is a result of multiple evaluations of a neural network that learns implicit ray-surface interaction properties. We evaluate our approach in multiple indoor scenarios and demonstrate that our model achieves strong performance (e.g., $<$0.33ns error in time-of-flight predictions). Furthermore, we demonstrate that our neural surrogate whitens the `black-box' wireless simulators, and thus enables inverse rendering applications (e.g., user localization).

Pocket-specific 3D Molecule Generation by Fragment-based Autoregressive Diffusion Models

Xingang Peng,Jiaqi Guan,Jian Peng,Jianzhu Ma

Autoregressive model is widely adopted to generate 3D molecules which can fit any protein binding pocket. Current autoregressive model suffers from two major drawbacks. First, it is hard to capture local geometric patterns as only one atom is generated at each step. Second, most of the autoregressive models generate atoms and chemical bonds in two separate processes, which causes a number of problems such as incorrect counts of rings, a bias distribution of bond lengths, and inaccurate 3D molecular structures. To tackle this problem, we designed a model, named FragDiff, to generate 3D molecules fragment-by-fragment for pockets. In each generation step, FragDiff places a molecular fragment around the pocket by using E(3)-equivariant diffusion generative models to simultaneously predict the atom types, atom coordinates and the chemical bonds of the fragment. Extensive experimental results confirm our assumption that unifying the atoms and bonds generations could significantly improve the quality of the sampled 3D molecules in terms of more accurate distributions of 2D subgraphs and 3D substructures.

Towards scalable and non-IID robust Hierarchical Federated Learning via Label-driven Knowledge Aggregator

Duong Minh Nguyen,Viet Quoc Pham,Hoang Thai Dinh,Diep Nguyen,Long Tran-Thanh,Won-Joo Hwang

In real-world applications, Federated Learning (FL) meets two challenges: (1) scalability, especially when applied to massive IoT networks, and (2) how to be robust against an environment with heterogeneous data. Realizing the first problem, we aim to design a novel FL framework named Full-stack FL (F2L). More specifically, F2L utilizes a hierarchical network architecture, making extending the FL network accessible without reconstructing the whole network system. Moreover, leveraging the advantages of hierarchical network design, we propose a new label-driven knowledge distillation (LKD) technique at the global server to address the second problem. As opposed to current knowledge distillation techniques, LKD is capable of training a student model, which consists of good knowledge from all teachers' models. Therefore, our proposed algorithm can effectively extract the knowledge of the regions' data distribution (i.e., the regional aggregated models) to reduce the divergence between clients' models when operating under the FL system with non-independent identically distributed data. Extensive experiment results reveal that: (i) our F2L method can significantly improve the overall FL efficiency in all global distillations, and (ii) F2L rapidly achieves convergence as global distillation stages occur instead of increasing on each communication cycle.

LS-IQ: Implicit Reward Regularization for Inverse Reinforcement Learning

Firas Al-Hafez,Davide Tateo,Oleg Arenz,Guoping Zhao,Jan Peters

Recent methods for imitation learning directly learn a Q-function using an implicit reward formulation rather than an explicit reward function. However, these methods generally require implicit reward regularization to improve stability and often mistreat absorbing states. Previous works show that a squared norm regularization on the implicit reward function is effective, but do not provide a theoretical analysis of the resulting properties of the algorithms. In this work, we show that using this regularizer under a mixture distribution of the policy and the expert provides a particularly illuminating perspective: the original objective can be understood as squared Bellman error minimization, and the corresponding optimization problem minimizes a bounded χ^2-Divergence between the expert and the mixture distribution. This perspective allows us to address instabilities and properly treat absorbing states. We show that our method, Least Squares Inverse Q-Learning (LS-IQ), outperforms state-of-the-art algorithms, particularly in environments with absorbing states. Finally, we propose to use an inverse dynamics model to learn from observations only. Using this approach, we retain performance in settings where no expert actions are available.

****

Humanly Certifying Superhuman Classifiers

Qiongkai Xu,Christian Walder,Chenchen Xu

This paper addresses a key question in current machine learning research: if we believe that a model's predictions might be better than those given by human experts, how can we (humans) verify these beliefs? In some cases, this ``superhuman'' performance is readily demonstrated; for example by defeating top-tier human players in traditional two player games. On the other hand, it can be challenging to evaluate classification models that potentially surpass human performance. Indeed, human annotations are often treated as a ground truth, which implicitly assumes the superiority of the human over any models trained on human annotations. In reality, human annotators are subjective and can make mistakes. Evaluating the performance with respect to a genuine oracle is more objective and reliable, even when querying the oracle is more expensive or sometimes impossible. In th is paper, we first raise the challenge of evaluating the performance of both humans and models with respect to an oracle which is $\textit{unobserved}$. We develop a theory for estimating the accuracy compared to the oracle, using only imperfect human annotations for reference. Our analysis provides an executable recipe for detecting and certifying superhuman performance in this setting, which we believe will assist in understanding the stage of current research on classification. We validate the convergence of the bounds and the assumptions of our theory on carefully designed toy experiments with known oracles. Moreover, we demonstrate the utility of our theory by meta-analyzing large-scale natural language processing tasks, for which an oracle does not exist, and show that under our mild assumptions a number of models from recent years have already achieved superhuman performance with high probability---suggesting that our new oracle based performance evaluation metrics are overdue as an alternative to the widely used accuracy metrics that are naively based on imperfect human annotations.

Share Your Representation Only: Guaranteed Improvement of the Privacy-Utility Tradeoff in Federated Learning

Zebang Shen,Jiayuan Ye,Anmin Kang,Hamed Hassani,Reza Shokri

Repeated parameter sharing in federated learning causes significant information leakage about private data, thus defeating its main purpose: data privacy. Mitigating the risk of this information leakage, using state of the art differentially private algorithms, also does not come for free. Randomized mechanisms can prevent convergence of models on learning even the useful representation functions, especially if there is more disagreement between local models on the classification functions (due to data heterogeneity). In this paper, we consider a representation federated learning objective that encourages various parties to collaboratively refine the consensus part of the model, with differential privacy guarantees, while separately allowing sufficient freedom for local personalization (without releasing it). We prove that in the linear representation setting, while the objective is non-convex, our proposed new algorithm \DPFEDREP\ converges to a ball centered around the \emph{global optimal} solution at a linear rate, and the radius of the ball is proportional to the reciprocal of the privacy budget. With this novel utility analysis, we improve the SOTA utility-privacy trade-off for this problem by a factor of $\sqrt{d}$, where d is the input dimension. We empirically evaluate our method with the image classification task on CIFAR10, CIFAR100, and EMNIST, and observe a significant performance improvement over the prior work under the same small privacy budget. The code can be found in this link, https://github.com/shenzebang/CENTAUR-Privacy-Federated-Representation-Learning.

Quantized Disentangled Representations for Object-Centric Visual Tasks

Daniil Kirilenko,Alexandr Korchemnyi,Alexey Kovalev,Aleksandr Panov

Recently, the pre-quantization of image features into discrete latent variables has helped to achieve remarkable results in image modeling. In this paper, we propose a method to learn discrete latent variables applied to object-centric tasks. In our approach, each object is assigned a slot which is represented as a vector generated by sampling from non-overlapping sets of low-dimensional discrete variables.

We empirically demonstrate that embeddings from the learned discrete latent spaces have the disentanglement property. The model is trained with a set prediction and object discovery as downstream tasks. It achieves the state-of-the-art results on the CLEVR dataset among a class of object-centric methods for set prediction task. We also demonstrate manipulation of individual objects in a scene with controllable image generation in the object discovery setting.

Supervised Random Feature Regression via Projection Pursuit

Jingran Zhou,Ling Zhou,shaogao lv

Random feature methods and neural network models are two popular nonparametric modeling methods, which are regarded as representatives of shallow learning and Neural Network, respectively. In practice random feature methods are short of th

e capacity of feature learning, while neural network methods lead to computationally heavy problems. This paper aims at proposing a flexible but computational efficient method for general nonparametric problems. Precisely, our proposed method is a feed-forward two-layer nonparametric estimation, and the first layer is used to learn a series of univariate basis functions for each projection variable, and then search for their optimal linear combination for each group of these learnt functions. Based on all the features derived in the first layer, the second layer attempts at learning a single index function with an unknown activation function. Our nonparametric estimation takes advantage of both random features and neural networks, and can be seen as an intermediate bridge between them.
****
Graph Spline Networks for Efficient Continuous Simulation of Dynamical Systems
Chuanbo Hua,Federico Berto,Michael Poli,Stefano Massaroli,Jinkyoo Park
While complex simulations of physical systems have been widely studied in engineering and scientific computing, lowering their often prohibitive computational requirements has only recently been tackled by deep learning approaches. In this paper, we present GraphSplineNets, a novel deep learning approach to speed up simulation of physical systems with spatio-temporal continuous outputs by exploiting the synergy between graph neural networks (GNN) and orthogonal spline collocation (OSC). Two differentiable time-oriented OSC and spatial-oriented OSC are applied to bridge the gap between discrete GNN outputs and generate continuous solutions at any location in space and time without explicit prior knowledge of underlying differential equations. Moreover, we introduce an adaptive collocation strategy in space to enable the model to sample from the most important regions. Our model improves on widely used graph neural networks for physics simulation on both efficiency and solution accuracy. We demonstrate SplineGraphNets in predicting complex dynamical systems such as the heat equation, damped wave propagation and the Navier-Stokes equations for incompressible flow, where they improve accuracy of more than 25% while providing at least 60% speedup.
****
Online black-box adaptation to label-shift in the presence of conditional-shift
Faruk Ahmed,Aaron Courville
We consider an out-of-distribution setting where trained predictive models are deployed online in new locations (inducing conditional-shift), such that these locations are also associated with differently skewed target distributions (label-shift). While approaches for online adaptation to label-shift have recently been discussed by Wu et al. (2021), the potential presence of concurrent conditional-shift has not been considered in the literature, although one might anticipate such distributional shifts in realistic deployments. In this paper, we empirically explore the effectiveness of online adaptation methods in such situations on three synthetic and two realistic datasets, comprising both classification and regression problems. We show that it is possible to improve performance in these settings by learning additional hyper-parameters to account for the presence of conditional-shift by using appropriate validation sets.
****
RuDar: Weather Radar Dataset for Precipitation Nowcasting with Geographical and Seasonal Variability
Petr Vytovtov,Eugenia Elistratova,Evgenii Tsymbalov,Alexander Ganshin,Yuri Pavlyukov
Precipitation nowcasting, a short-term (up to six hours) rain prediction, is arguably one of the most demanding weather forecasting tasks.
To achieve accurate predictions, a forecasting model should consider miscellaneous meteorological and geographical data sources.
Currently available datasets provide information only about precipitation intensity, vertically integrated liquid (VIL), or maximum reflectivity on the vertical section.
Such single-level or aggregated data lacks description of the reflectivity change in vertical dimension, simplifying or distorting the corresponding models.

To fill this gap, we introduce an additional dimension of the precipitation meas urements in the RuDar dataset that incorporates 3D radar echo observations.

Measurements are collected from 30 weather radars located mostly in the European part of Russia, covering multiple climate zones.

Radar product updates every 10 minutes with a 2 km spatial resolution.

The measurements include precipitation intensity (mm/h) at an altitude of 600 m, reflectivity (dBZ) and radial velocity (m/s) at 10 altitude levels from 1 km to 10 km with 1 km step.

We also add the orography information as it affects the intensity and distribution of precipitation.

The dataset includes over 50 000 timestamps over a two-year period from 2019 to 2021, totalling in roughly 100 GB of data.

We evaluate several baselines, including optical flow and neural network models, for precipitation nowcasting on the proposed data. We also evaluate the uncertainty quantification for the ensemble scenario and show that the corresponding estimates do correlate with the ensemble errors on different sections of data.

We believe that RuDar dataset will become a reliable benchmark for precipitation nowcasting models and also will be used in other machine learning tasks, e.g., in data shift studying, anomaly detection, or uncertainty estimation.

Both dataset and code for data processing and model preparation are publicly available.

Learning Representations for Reinforcement Learning with Hierarchical Forward Models

Trevor McInroe,Lukas Schäfer,Stefano V Albrecht

Learning control from pixels is difficult for reinforcement learning (RL) agents because representation learning and policy learning are intertwined. Previous approaches remedy this issue with auxiliary representation learning tasks, but they either do not consider the temporal aspect of the problem or only consider single-step transitions, which may miss relevant information if important environmental changes take many steps to manifest. We propose Hierarchical k-Step Latent (HKSL), an auxiliary task that learns representations via a hierarchy of forward models that operate at varying magnitudes of step skipping while also learning to communicate between levels in the hierarchy. We evaluate HKSL in a suite of 30 robotic control tasks with and without distractors and a task of our creation. We find that HKSL either converges to higher episodic returns or optimal performance more quickly than several current baselines. Furthermore, we find that HKSL's representations capture task-relevant details accurately across timescales (even in the presence of distractors) and that communication channels between hierarchy levels organize information based on both sides of the communication process, both of which improve sample efficiency.

xTrimoABFold: Improving Antibody Structure Prediction without Multiple Sequence Alignments

Yining Wang,Xumeng Gong,Shaochuan Li,Bing Yang,YiWu Sun,Chuan Shi,Hui Li,Yangang Wang,Cheng Yang,Le Song

Antibody, used by the immune system to identify and neutralize foreign objects such as pathogenic bacteria and viruses, plays an important role in immune system . In the field of drug engineering, the essential task is designing a novel antibody to make sure its paratope (substructures in the antibody) binds to the epitope of the specific antigen with high precision. Also, understanding the structure of antibody and its paratope can facilitate a mechanistic understanding of the function. Therefore, antibody structure prediction has always been a highly valuable problem for drug discovery. AlphaFold2, a breakthrough in the field of structural biology, provides a feasible solution to predict protein structure based on protein sequences and computationally expensive coevolutionary multiple sequence alignments (MSAs). However, the computational efficiency and undesirable prediction accuracy on antibody, especially on the complementarity-determining regions (CDRs) of antibody limit its applications on the industrially high-throughput drug design. In this paper, we present a novel method named xTrimoABFold to

predict antibody structure from antibody sequence based on a pretrained antibody language model (ALM) as well as homologous templates, which are searched from protein database (PDB) via fast and cheap algorithms. xTrimoABFold outperforms the MSA-based AlphaFold2 and the protein language model based SOTAs, e.g., OmegaFold, HelixFold-Single and IgFold with a large significant margin (30+% improvement on RMSD) while performs 151x faster than AlphaFold2. To the best of our knowledge, xTrimoABFold is the best antibody structure predictor to date in the world.

Thresholded Lexicographic Ordered Multi-Objective Reinforcement Learning

Alperen Tercan,Vinayak Prabhu

Lexicographic multi-objective problems, which impose a lexicographic importance order over the objectives, arise in many real-life scenarios. Existing Reinforcement Learning work directly addressing lexicographic tasks has been scarce. The few proposed approaches were all noted to be heuristics without theoretical guarantees as the Bellman equation is not applicable to them. Additionally, the practical applicability of these prior approaches also suffers from various issues such as not being able to reach the goal state. While some of these issues have been known before, in this work we investigate further shortcomings, and propose fixes for improving practical performance in many cases. We also present a policy optimization approach using our Lexicographic Projection Optimization (LPO) algorithm that has the potential to address these theoretical and practical concerns. Finally, we demonstrate our proposed algorithms on benchmark problems.

HOW SAMPLING AFFECTS TRAINING: AN EFFECTIVE SAMPLING THEORY STUDY FOR LONG-TAILED IMAGE CLASSIFICATION

Gong Zhang,Yongqiang Gao,Liu Haijing

The long-tailed image classification problem has been very challenging for a longtime. Suffered from the unbalanced distribution of categories, many deep vision classification methods perform well in the head classes while poor in the tail ones. This paper proposes an effective sampling theory, attempting to provide a theoretical explanation for the decoupling representation and classifier for long-tailed image classification. To apply the above sampling theory in practice, a general jitter sampling strategy is proposed. Experiments show that variety of long-tailed distribution algorithms exhibit better performance based on the effective sampling theory. The code will be released soon later.
****

EquiMod: An Equivariance Module to Improve Visual Instance Discrimination

Alexandre DEVILLERS,Mathieu Lefort

Recent self-supervised visual representation methods are closing the gap with supervised learning performance. Most of these successful methods rely on maximizing the similarity between embeddings of related synthetic inputs created through data augmentations. This can be seen as a task that encourages embeddings to leave out factors modified by these augmentations, i.e. to be invariant to them. However, this only considers one side of the trade-off in the choice of the augmentations: they need to strongly modify the images to avoid simple solution shortcut learning (e.g. using only color histograms), but on the other hand, augmentations-related information may be lacking in the representations for some downstream tasks (e.g. literature shows that color is important for bird and flower classification). Few recent works proposed to mitigate this problem of using only an invariance task by exploring some form of equivariance to augmentations. This has been performed by learning additional embeddings space(s), where some augmentation(s) cause embeddings to differ, yet in a non-controlled way. In this work, we introduce EquiMod a generic equivariance module that structures the learned latent space, in the sense that our module learns to predict the displacement in the embedding space caused by the augmentations. We show that applying that module to state-of-the-art invariance models, such as BYOL and SimCLR, increases the performances on the usual CIFAR10 and ImageNet datasets. Moreover, while our model could collapse to a trivial equivariance, i.e. invariance, we observe that it instead automatically learns to keep some augmentations-related information beneficial to the representations.

Manipulating Multi-agent Navigation Task via Emergent Communications

Han Yu,Hengtong Lu,Caixia Yuan,Xiaojie Wang

Multi-agent corporations struggle to efficiently sustain grounded communications with a specific task goal. Existing approaches are limited in their simple task settings and single-turn communications. This work describes a multi-agent communication scenario via emergent language in a navigation task. This task involves two agents with unequal abilities: the tourist (agent A) who can only observe the surroundings and the guide (agent B) who has a holistic view but does not know the initial position of agent A. They communicate with the emerged language grounded through the environment and a common task goal: to help the tourist find the target place. We release a new dataset of 3000 scenarios that involve multi-agent visual and language navigation. We also seek to address the multi-agent emergent communications by proposing a collaborative learning framework that enables the agents to generate and understand emergent language and solve tasks. The framework is trained with reinforcement learning by maximizing the task success rate in an end-to-end manner. Results show that the proposed framework achieves competing performance in both the accuracy of language understanding and the task success rate. We also discuss the explanations of the emerged language.

****

Task-Aware Information Routing from Common Representation Space in Lifelong Learning

Prashant Shivaram Bhat,Bahram Zonooz,Elahe Arani

Intelligent systems deployed in the real world suffer from catastrophic forgetting when exposed to a sequence of tasks. Humans, on the other hand, acquire, consolidate, and transfer knowledge between tasks that rarely interfere with the consolidated knowledge. Accompanied by self-regulated neurogenesis, continual learning in the brain is governed by the rich set of neurophysiological processes that harbor different types of knowledge which are then integrated by the conscious processing. Thus, inspired by Global Workspace Theory of conscious information access in the brain, we propose TAMiL, a continual learning method that entails task-attention modules to capture task-specific information from the common representation space. We employ simple, undercomplete autoencoders to create a communication bottleneck between the common representation space and the global workspace, allowing only the task-relevant information to the global workspace, thereby greatly reducing task interference. Experimental results show that our method outperforms state-of-the-art rehearsal-based and dynamic sparse approaches and bridges the gap between fixed capacity and parameter isolation approaches while being scalable. We also show that our method effectively mitigates catastrophic forgetting while being well-calibrated with reduced task-recency bias.

CodeBPE: Investigating Subtokenization Options for Large Language Model Pretraining on Source Code

Nadezhda Chirkova,Sergey Troshin

Recent works have widely adopted large language model pretraining for source code, suggested source code-specific pretraining objectives and investigated the applicability of various Transformer-based language model architectures for source code. This work investigates another important aspect of such models, the effect of different subtokenization options, and aims at identifying most effective and length-efficient subtokenizations, taking into account source code specifics. We propose subtokenziation that reduces average length by 17--40% without downstream performance drop, and show that a carefully chosen subtokenization may improve quality by 0.5-2%, possibly with some length increase.

****

Transport with Support: Data-Conditional Diffusion Bridges

Ella Tamir,Martin Trapp,Arno Solin

The dynamic Schrödinger bridge problem provides an appealing setting for posing optimal transport problems as learning non-linear diffusion processes and enables efficient iterative solvers. Recent works have demonstrated state-of-the-art results (eg, in modelling single-cell embryo RNA sequences or sampling from compl ex posteriors) but are typically limited to learning bridges with only initial and terminal constraints. Our work extends this paradigm by proposing the Iterative Smoothing Bridge (ISB). We combine learning diffusion models with Bayesian filtering and optimal control, allowing for constrained stochastic processes governed by sparse observations at intermediate stages and terminal constraints. We assess the effectiveness of our method on synthetic and real-world data and show that the ISB generalises well to high-dimensional data, is computationally efficient, and provides accurate estimates of the marginals at intermediate and terminal times.

****

Randomized Sharpness-Aware Training for Boosting Computational Efficiency in Deep Learning

Yang Zhao

By driving optimizers to converge to flat minima, sharpness-aware learning algorithms (such as SAM) have shown the power to achieve state-of-art performances. However, these algorithms will generally incur one extra forward-backward propagation at each training iteration, which largely burdens the computation especially for scalable models. To this end, we propose an efficient training scheme, called Randomized Sharpness-Aware Training (RST). Optimizers in RST would perform a Bernoulli trial at each iteration to choose randomly from base algorithms (SGD) and sharpness-aware algorithms (SAM) with a probability arranged by a predefined scheduling function. Due to the mixture of base algorithms, the overall count of propagation pairs could be largely reduced. Also, we give theoretical analysis on the convergence of RST. Then, we empirically study the computation cost and effect of various types of scheduling functions, and give directions on setting appropriate scheduling functions. Further, we extend the RST to a general framework (G-RST), where we can adjust regularization degree on sharpness freely for any scheduling function. We show that G-RST can outperform SAM in most cases while saving 50\% extra computation cost.

****

Self-Supervised Off-Policy Ranking via Crowd Layer

Pengjie Gu,Mengchen Zhao,Jianye HAO,Bo An

Off-policy evaluation (OPE) aims to estimate the online performance of target policies given dataset collected by some behavioral policies. OPE is crucial in many applications where online policy evaluation is expensive. However, existing OPE methods are far from reliable. Fortunately, in many real-world scenarios, we care only about the ranking of the evaluating policies, rather than their exact online performance. Existing works on off-policy ranking (OPR) adopt a supervised training paradigm, which assumes that there are plenty of deployed policies and the labels of their performance are available. However, this assumption does not apply to most OPE scenarios because collecting such training data might be highly expensive. In this paper, we propose a novel OPR framework called SOCCER, where the existing OPE methods are modeled as workers in a crowdsourcing system. SOCCER can be trained in a self-supervised way as it does not require any ground-truth labels of policies. Moreover, in order to capture the relative discrepancies between policies, we propose a novel transformer-based architecture to learn effective pairwise policy representations. Experimental results show that SOCCER achieves significantly high accuracy in a variety of OPR tasks. Surprisingly, SOCCER even performs better than baselines trained in a supervised way using additional labeled data, which further demonstrates the superiority of SOCCER in OPR tasks.

Geometry Problem Solving based on Counterfactual Evolutionary Reasoning

SONG Bing,Xiong Gang,Fenghua Zhu,Lv Yisheng,Peijun Ye

As a representative topic in natural language processing and automated theorem proving, geometry problem solving requires an abstract problem understanding and symbolic reasoning. A major challenge here is to find a feasible reasoning sequence that is consistent with given axioms and the theorems already proved. Most recent methods have exploited neural network-based techniques to automatically di scover eligible solving steps. Such a kind of methods, however, is greatly impacted by the expert solutions for training. To improve the accuracy, this paper proposes a new method called counterfactual evolutionary reasoning, which uses a generative adversarial network to generate initial reasoning sequences and then introduces counterfactual reasoning to explore potential solutions. By directly exploring theorem candidates rather than the neural network selection, the new method can sufficiently extend the searching space to get a more appropriate reasoning step. Through comparative experiments on the recent proposed geometry3k, the largest geometry problem solving dataset, our method generally achieves a higher accuracy than most previous methods, bringing an overall improvement about 4.4% compared with the transformer models.

Few-Shot Domain Adaptation For End-to-End Communication

Jayaram Raghuram,Yijing Zeng,Dolores Garcia,Rafael Ruiz,Somesh Jha,Joerg Widmer,Suman Banerjee

The problem of end-to-end learning of a communication system using an autoencoder -- consisting of an encoder, channel, and decoder modeled using neural networks -- has recently been shown to be an effective approach. A challenge faced in the practical adoption of this learning approach is that under changing channel conditions (e.g. a wireless link), it requires frequent retraining of the autoencoder in order to maintain a low decoding error rate. Since retraining is both time consuming and requires a large number of samples, it becomes impractical when the channel distribution is changing quickly. We propose to address this problem using a fast and sample-efficient (few-shot) domain adaptation method that does not change the encoder and decoder networks. Different from conventional training-time unsupervised or semi-supervised domain adaptation, here we have a trained autoencoder from a source distribution that we want to adapt (at test time) to a target distribution using only a small labeled dataset, and no unlabeled data. We focus on a generative channel model based on the Gaussian mixture density network (MDN), and propose a regularized, parameter-efficient adaptation of the MDN using a set of affine transformations. The learned affine transformations are then used to design an optimal transformation at the decoder input to compensate for the distribution shift, and effectively present to the decoder inputs close to the source distribution. Experiments on many simulated distribution changes common to the wireless setting, and a real mmWave FPGA testbed demonstrate the effectiveness of our method at adaptation using very few target domain samples~\footnote{Code for our work: \url{https://github.com/jayaram-r/domain-adaptation-autoencoder}}.

HyPHEN: A Hybrid Packing Method and Optimizations for Homomorphic Encryption-Based Neural Network

Jaiyoung Park,Donghwan Kim,Jung Ho Ahn

Private Inference (PI) enables users to enjoy secure AI inference services while companies comply with regulations. Fully Homomorphic Encryption (FHE) based Convolutional Neural Network (CNN) inference is promising as users can offload the whole computation process to the server while protecting the privacy of sensitive data. Recent advances in AI research have enabled HE-friendly deep CNN like ResNet. However, FHE-based CNN (HCNN) suffers from high computational overhead.
Prior HCNN approaches rely on dense packing techniques that aggregate as many channels into the ciphertext to reduce element-wise operations like multiplication and bootstrapping.
However, these approaches require performing an excessive amount of homomorphic rotations to accumulate channels and maintain dense data organization, which takes up most of the runtime.
To overcome this limitation, we present HyPHEN, a deep HCNN implementation that drastically reduces the number of homomorphic rotations.
HyPHEN utilizes a novel convolution algorithm, RAConv, utilizing replication-based data organization, which leads to a significant reduction in rotation count.
Furthermore, we propose hybrid gap packing method for HyPHEN, which gathers sparse convolution results into a dense data organization with a marginal increase i

n the number of rotations.
HyPHEN explores the trade-off between the computational costs of rotations and other operations, and finds the optimal point minimizing the execution time.
With these optimizations, HyPHEN takes 3.8-4.9$\times$ less execution time than the state-of-the-art HCNN implementation and brings the runtimes of ResNet inference down to 1.38-14.86s using a GPU-accelerated HEAAN library.

Causal Inference for Knowledge Graph Completion

Changyi Xiao,Xiangnan He,Yixin Cao

The basis of existing knowledge graph completion (KGC) models is to learn the correlations in data, such as the correlation between entities or relations and scores of triplets. Since the world is driven by causality rather than correlation, correlation-driven KGC models are weak in interpretation and suffer from the data bias issue. In this paper, we propose causal KGC models to alleviate the issues by leveraging causal inference framework. Our models are intuitive and interpretable by utilizing causal graphs, controllable by using intervention techniques and model-agnostic. Causal graphs allow us to explain the causal relationships between variables and the data generation process. Under the causal graph, data bias can be seen as confounders. Then we block the bad effect of confounders by intervention operators to mitigate the data bias issue. Due to the difficulty of obtaining randomized data, causal KGC models pose unique challenges for evaluation. Thus, we show a method that makes evaluation feasible. Finally, we show a group theory view for KGC, which is equivalent to the view of causal but further reveals the relationships between causal graphs. Experimental results show that our causal KGC models achieve better performance than traditional KGC models.

Formal Specifications from Natural Language

Christopher Hahn,Frederik Schmitt,Julia Janice Tillman,Niklas Metzger,Julian Siber,Bernd Finkbeiner

We study the generalization abilities of language models when translating natural language into formal specifications with complex semantics. In particular, we fine-tune language models on three datasets consisting of English sentences and their corresponding formal representation: 1) regular expressions (regex), frequently used in programming and search; 2) First-order logic (FOL), commonly used in software verification and theorem proving; and 3) linear-time temporal logic (LTL), which forms the basis for industrial hardware specification languages. Our experiments show that, in these diverse domains, the language models maintain their generalization capabilities from pre-trained knowledge of natural language to generalize, e.g., to new variable names or operator descriptions. Additionally, they achieve competitive performance, and even outperform the state-of-the-art for translating into regular expressions, with the benefits of being easy to access, efficient to fine-tune, and without a particular need for domain-specific reasoning.

****

DELTA: Diverse Client Sampling for Fasting Federated Learning

Lin Wang,Yongxin Guo,Tao Lin,Xiaoying Tang

Partial client participation has been widely adopted in Federated Learning (FL) to efficiently reduce the communication burden. However, an improper client sampling scheme will select unrepresentative subsets, which will cause a large variance in the model update and slows down the convergence. Existing sampling methods are either biased or can be further improved to accelerate the convergence. In this paper, we propose an unbiased sampling scheme, termed DELTA, to alleviate this problem. In particular, DELTA characterizes the impact of client diversity and local variance and samples the representative clients who carry valuable information for global model updates. Moreover, DELTA is a provably optimal unbiased sampling scheme that minimizes the variance caused by partial client participation and achieves better convergence than other unbiased sampling schemes. We corroborate our results with experiments on both synthetic and real data sets.

Incremental Predictive Coding: A Parallel and Fully Automatic Learning Algorithm

Tommaso Salvatori,Yuhang Song,Beren Millidge,Zhenghua Xu,Lei Sha,Cornelius Emde,Rafal Bogacz,Thomas Lukasiewicz

Neuroscience-inspired models, such as predictive coding, have the potential to play an important role in the future of machine intelligence. However, they are not yet used in industrial applications due to some limitations, such as efficiency. In this work, we propose incremental predictive coding (iPC), a variation of the original model derived from the incremental expectation maximization algorithm, where every operation can be performed in parallel without external control. We show both theoretically and empirically that iPC is more efficient than the original algorithm by Rao and Ballard, with performances comparable to those of backpropagation in image classification tasks. This work impacts several areas, as it has general applications in computational neuroscience and machine learning, and specific applications in scenarios where automatization and parallelization are important, such as distributed computing and implementations of deep learning models on analog and neuromorphic chips.

****

Learning Geometric Representations of Interactive Objects

Alfredo Reichlin,Giovanni Luca Marchetti,Hang Yin,Anastasia Varava,Danica Kragic

We address the problem of learning geometric representations from observations perceived by an agent operating within an environment and interacting with an external object. To this end, we propose a representation learning framework that extracts the state of both the agent and the object from unstructured observations of arbitrary nature (e.g., images). Supervision comes from the performed actions alone, while the dynamics of the object is assumed to be unknown. We provide a theoretical foundation and formally prove that an ideal learner is guaranteed to infer an isometric representation, disentangling the agent from the object. Finally, we investigate empirically our framework on a variety of scenarios. Results show that our model reliably infers the correct representation and outperforms vision-based approaches such as a state-of-the-art keypoint extractor.

****

Improve distance metric learning by learning positions of class centers

Kun Song,Lantian Chu,Junwei Han,Fakhri Karray

Deep metric learning aims at learning a deep neural network by letting similar samples have small distances while dissimilar samples have large distances. To achieve this goal, the current DML algorithms mainly focus on pulling similar samples in each class as closely as possible. However, pulling similar samples only considers the local distribution of the data samples and ignores the global distribution of the data set, i.e., the center positions of different classes. The global distribution helps the distance metric learning. For example, expanding the distance between centers can increase the discriminant ability of the extracted features. However, how to increase the distance between centers is a challenging task. In this paper, we design a genius function named the skewed mean function, which only considers the most considerable distances of a set of samples. So maximizing the value of the skewed mean function can make the largest distance larger. We also prove that the current energy functions used for uniformity regularization on centers are special cases of our skewed mean function. At last, we conduct extensive experiments to illustrate the superiority of our methods.

****

The guide and the explorer: smart agents for resource-limited iterated batch reinforcement learning

Othman Gaizi,Albert Thomas,Balázs Kégl,Gabriel Hurtado

Iterated (a.k.a growing) batch reinforcement learning (RL) is a growing subfield fueled by the demand from systems engineers for intelligent control solutions that they can apply within their technical and organizational constraints. Model-based RL (MBRL) suits this scenario well for its sample efficiency and modularity. Recent MBRL techniques combine efficient neural system models with classical planning (like model predictive control; MPC). In this paper we add two components to this classical setup. The first is a Dyna-style policy learned on the system model using model-free techniques. We call it the guide since it guides the p lanner. The second component is the explorer, a strategy to expand the limited knowledge of the guide during planning. Through a rigorous ablation study we show that combination of these two ingredients is crucial for optimal performance and better data efficiency. We apply this approach with an off-policy guide and a heating explorer to improve the state of the art of benchmark systems addressing both discrete and continuous action spaces.

FairGBM: Gradient Boosting with Fairness Constraints
André Cruz,Catarina G Belém,João Bravo,Pedro Saleiro,Pedro Bizarro

Tabular data is prevalent in many high-stakes domains, such as financial services or public policy. Gradient Boosted Decision Trees (GBDT) are popular in these settings due to their scalability, performance, and low training cost. While fairness in these domains is a foremost concern, existing in-processing Fair ML methods are either incompatible with GBDT, or incur in significant performance losses while taking considerably longer to train. We present FairGBM, a dual ascent learning framework for training GBDT under fairness constraints, with little to no impact on predictive performance when compared to unconstrained GBDT. Since observational fairness metrics are non-differentiable, we propose smooth convex error rate proxies for common fairness criteria, enabling gradient-based optimization using a ``proxy-Lagrangian'' formulation. Our implementation shows an order of magnitude speedup in training time relative to related work, a pivotal aspect to foster the widespread adoption of FairGBM by real-world practitioners.

****

How (Un)Fair is Text Summarization?
Hannah Brown,Reza Shokri

Creating a good summary requires carefully choosing details from the original text to accurately represent it in a limited space. If a summary contains biased information about a group, it risks passing this bias off to readers as fact. These risks increase if we consider not just one biased summary, but rather a biased summarization algorithm. Despite this, little work has measured whether these summarizers demonstrate biased performance. Rather, most work in summarization focuses on improving performance, ignoring questions of bias. In this paper we demonstrate that automatic summarizers both amplify and introduce bias towards information about under-represented groups. Additionally, we show that summarizers are highly sensitive to document structure, making the summaries they generate unstable under changes that are semantically meaningless to humans, which poses a further fairness risk. Given these results, and the large scale potential for harm presented by biased summarization, we recommend that bias analysis be performed and reported on summarizers to ensure that new automatic summarization methods do not introduce bias to the summaries they generate.

Simulating Task-Free Continual Learning Streams From Existing Datasets
Aristotelis Chrysakis,Marie-Francine Moens

Task-free continual learning is the subfield of machine learning that focuses on learning online from a stream whose distribution changes continuously over time. However, previous works evaluate task-free continual learning using streams with distributions that change only at a few distinct points in time. In order to address the discrepancy between the definition and evaluation of task-free continual learning, we propose a principled algorithm that can permute any labeled dataset into a stream that is continuously nonstationary. We empirically show that the streams generated by our algorithm are less structured than the ones conventionally used in the literature. Moreover, we use our simulated task-free streams to benchmark multiple methods applicable to the task-free setting. We hope that our work will make it more likely that task-free continual learning methods are able to better generalize to real-world problems.

****

Online Bias Correction for Task-Free Continual Learning
Aristotelis Chrysakis,Marie-Francine Moens

Task-free continual learning is the machine-learning setting where a model is trained online with data generated by a nonstationary stream. Conventional wisdom suggests that, in this setting, models are trained using an approach called experience replay, where the risk is computed both with respect to current stream observations and to a small subset of past observations. In this work, we explain both theoretically and empirically how experience replay biases the outputs of the model towards recent stream observations. Moreover, we propose a simple approach to mitigate this bias online, by changing how the output layer of the model is optimized. We show that our approach improves significantly the learning performance of experience-replay approaches over different datasets. Our findings suggest that, when performing experience replay, the output layer of the model should be optimized separately from the preceding layers.

A Simple Contrastive Learning Objective for Alleviating Neural Text Degeneration

Shaojie Jiang,Ruqing Zhang,Svitlana Vakulenko,Maarten de Rijke

The cross-entropy objective has proved to be an all-purpose training objective for autoregressive language models (LMs). However, without distinguishing problematic tokens, LMs trained using cross-entropy exhibit text degeneration problems. To address this, unlikelihood training has been proposed to reduce the probability of unlikely tokens predicted by LMs. But unlikelihood does not explicitly consider the relationship between the label tokens and unlikely token candidates, thus showing marginal improvements in degeneration. We propose a new contrastive token learning objective that inherits the advantages of cross-entropy and unlikelihood training and avoids their limitations. The key idea is to teach a LM to generate high probabilities for label tokens and low probabilities for negative candidates. Comprehensive experiments on language modeling and open-domain dialogue generation tasks show that the proposed contrastive token objective yields much less repetitive texts, with a higher generation quality than baseline approaches, achieving the new state-of-the-art performance on text degeneration.

Enriching Online Knowledge Distillation with Specialist Ensemble

Mincheol Park,Woojeong Kim,Junsik Bang,Won Woo Ro,Suhyun Kim

Online Knowledge Distillation (KD) has an advantage over traditional KD works in that it removes the necessity for a pre-trained teacher. Indeed, an ensemble of small teachers has become typical guidance for a student's learning trajectory. Previous works emphasized diversity to create helpful ensemble knowledge and further argued that the size of diversity should be significant to prevent homogenization. This paper proposes a well-founded online KD framework with naturally derived specialists. In supervised learning, the parameters of a classifier are optimized by stochastic gradient descent based on a training dataset distribution. If the training dataset is shifted, the optimal point and corresponding parameters change accordingly, which is natural and explicit.

We first introduce a label prior shift to induce evident diversity among the same teachers, which assigns a skewed label distribution to each teacher and simultaneously specializes them through importance sampling. Compared to previous works, our specialization achieves the highest level of diversity and maintains it throughout training. Second, we propose a new aggregation that uses post-compensation in specialist outputs and conventional model averaging. The aggregation empirically exhibits the advantage of ensemble calibration even if applied to previous diversity-eliciting methods. Finally, through extensive experiments, we demonstrate the efficacy of our framework on top-1 error rate, negative log-likelihood, and notably expected calibration error.

Improved Gradient Descent Optimization Algorithm based on Inverse Model-Parameter Difference

Ayushya Pare,Zhichun Lei

A majority of deep learning models implement first-order optimization algorithms like the stochastic gradient descent (SGD) or its adaptive variants for training large neural networks. However, slow convergence due to complicated geometry of the loss function is one of the major challenges faced by the SGD. The currently popular optimization algorithms incorporate an accumulation of past gradients to improve the gradient descent convergence via either the accelerated gradient

scheme (including Momentum, NAG, etc.) or the adaptive learning-rate scheme (including Adam, AdaGrad, etc.). Despite their general popularity, these algorithms often display suboptimal convergence owing to extreme scaling of the learning-rate due to the accumulation of past gradients. In this paper, a novel approach to gradient descent optimization is proposed which utilizes the difference in the model-parameter values from the preceding iterations to adjust the learning-rate of the algorithm. More specifically, the learning-rate for each model-parameter is adapted inversely proportional to the displacement of the model-parameter from the previous iterations. As the algorithm utilizes the displacement of model-parameters, poor convergence caused due to the accumulation of past gradients is avoided. A convergence analysis based on the regret bound approach is performed and the theoretical bounds for a stable convergence are determined. An Empirical analysis evaluates the proposed algorithm applied on the CIFAR 10/100 and the ImageNet datasets and compares it with the currently popular optimizers. The experimental results demonstrate that the proposed algorithm shows better performance than the popular optimization algorithms.
****
Variational Learning ISTA
Fabio Valerio Massoli,Christos Louizos,Arash Behboodi
Compressed sensing combines the power of convex optimization techniques with a sparsity inducing prior on the signal space to solve an underdetermined system of equations. For many problems, the sparsifying dictionary is not directly given, nor its existence can be assumed. Besides, the sensing matrix can change across different scenarios. Addressing these issues requires solving a sparse representation learning problem, namely dictionary learning, taking into account the epistemic uncertainty on the learned dictionaries and, finally, jointly learning sparse representations and reconstructions under varying sensing matrix conditions.

We propose a variant of the LISTA architecture that incorporates the sensing matrix into the architecture. In particular, we propose to learn a distribution over dictionaries via a variational approach, dubbed \ac{VLISTA}, which approximates a posterior distribution over the dictionaries as part of an unfolded LISTA-based recovery network. Such a variational posterior distribution is updated after each iteration, and thereby adapts the dictionary according to the optimization dynamics. As a result, \ac{VLISTA} provides a probabilistic way to jointly learn the dictionary distribution and the reconstruction algorithm with varying sensing matrices. We provide theoretical and experimental support for our architecture and show that it learns calibrated uncertainties.
****
Moment Distributionally Robust Probabilistic Supervised Learning
Yeshu Li,Brian D Ziebart
Probabilistic supervised learning assumes the groundtruth itself is a distribution instead of a single label, as in classic settings. Common approaches learn with a proper composite loss and obtain probability estimates via an invertible link function. Typical links such as the softmax yield restrictive and problematic uncertainty certificates. In this paper, we propose to make direct prediction of conditional label distributions from first principles in distributionally robust optimization based on an ambiguity set defined by feature moment divergence. We derive its generalization bounds under mild assumptions. We illustrate how to manipulate penalties for underestimation and overestimation. Our method can be easily incorporated into neural networks for end-to-end representation learning. Experimental results on datasets with probabilistic labels illustrate the flexibility, effectiveness, and efficiency of this learning paradigm.
****
CLEP: Exploiting Edge Partitioning for Graph Contrastive Learning
Yilin He,Chaojie Wang,Hao Zhang,Bo Chen,Bo An,Mingyuan Zhou
Generative and contrastive are two fundamental unsupervised approaches to model graph information. The graph generative models extract intra-graph information whereas the graph contrastive learning methods focus on inter-graph information. Combining these complementary sources of information can potentially enhance the

expressiveness of graph representations, which, nevertheless, is underinvestigated by existing methods. In this work, we introduce a probabilistic framework called contrastive learning with edge partitioning (CLEP) that integrates generative modeling and graph contrastive learning. CLEP models edge generation by cumulative latent node interactions over multiple mutually independent hidden communities. Inspired by the ``assembly'' behavior of communities in graph generation, CEGCL learns community-specific graph embeddings and assemble them together to represent the entire graph, which are further used to predict the graph's identity via a contrastive objective. To relate each embedding to one hidden community, we define a set of community-specific weighted edges for node feature aggregation by partitioning the observed edges according to the latent node interactions associated with the corresponding hidden community. With these unique designs, CLEP is able to model the statistical dependency among hidden communities, graph structures as well as the identity of each graph; it can also be trained end-to-end via variational inference. We evaluate CLEP on real-world benchmarks under self-supervised and semi-supervised settings and achieve promising results, which demostrate the effectiveness of our method. Various exploratory studies are also conducted to highlight the characteristics of the inferred hidden communities and the potential benefits they bring to representation learning.

Meta-Learning the Inductive Biases of Simple Neural Circuits

Will Dorrell,Maria Yuffa,Peter E. Latham

Animals receive noisy and incomplete information, from which we must learn how to react in novel situations. A fundamental problem is that training data is always finite, making it unclear how to generalise to unseen data. But, animals do react appropriately to unseen data, wielding Occam's razor to select a parsimonious explanation of the observations. How they do this is called their inductive bias, and it is implicitly built into the operation of animals' neural circuits. This relationship between an observed circuit and its inductive bias is a useful explanatory window for neuroscience, allowing design choices to be understood normatively. However, it is generally very difficult to map circuit structure to inductive bias. In this work we present a neural network tool to bridge this gap. The tool allows us to meta-learn the inductive bias of neural circuits by learning functions that a neural circuit finds easy to generalise, since easy-to-generalise functions are exactly those the circuit chooses to explain incomplete data. We show that in systems where the inductive bias is known analytically, i.e. linear and kernel regression, our tool recovers it. Then, we show it is able to flexibly extract inductive biases from differentiable circuits, including spiking neural networks. This illustrates the intended use case of our tool: understanding the role of otherwise opaque pieces of neural functionality, such as non-linearities, learning rules, or connectomic data, through the inductive bias they induce.

Accelerating spiking neural network training using the d-block model

Luke Taylor,Andrew J King,Nicol Spencer Harper

There is a growing interest in using spiking neural networks (SNNs) to study the brain \textit{in silico} and in emulating them on neuromorphic computers due to their lower energy consumption compared to artificial neural networks (ANNs). Significant progress has been made in directly training SNNs to perform on a par with ANNs in terms of accuracy. However, these methods are slow due to their sequential nature and require careful network regularisation to avoid overfitting. We propose a new SNN model, the d-block model, with stochastic absolute refractory periods and recurrent conductance latencies, which reduces the number of sequential computations using fast vectorised operations. Our model obtains accelerated training speeds and state-of-the-art performance across various neuromorphic datasets without the need for any regularisation and using fewer spikes compared to standard SNNs.

****

RG: OUT-OF-DISTRIBUTION DETECTION WITH REACTIVATE GRADNORM

Mingyu Xu,Kexin Wang,Zheng Lian,Licai Sun,Bin Liu,Jianhua Tao

Detecting out-of-distribution (OOD) data is critical to building reliable machine learning systems in the open world. Previous works mainly perform OOD detection in feature space or output space. Recently, researchers have achieved promising results using gradient information, which combines the information in both feature and output space for OOD detection. However, existing works still suffer from the problem of overconfidence. To address this problem, we propose a novel method called ``Reactivate Gradnorm (RG)'', which exploits the norm of the clipped feature vector and the energy in the output space for OOD detection. To verify the effectiveness of our method, we conduct experiments on four benchmark datasets. Experimental results demonstrate that our RG outperforms existing state-of-the-art approaches by 2.06\% in average AUROC. Meanwhile, RG is easy to implement and does not require additional OOD data or fine-tuning process. We can realize OOD detection in only one forward pass of any pretrained model.

Don’t fear the unlabelled: safe semi-supervised learning via debiasing

Hugo Schmutz,Olivier HUMBERT,Pierre-Alexandre Mattei

Semi-supervised learning (SSL) provides an effective means of leveraging unlabelled data to improve a model’s performance. Even though the domain has received a considerable amount of attention in the past years, most methods present the common drawback of lacking theoretical guarantees. Our starting point is to notice that the estimate of the risk that most discriminative SSL methods minimise is biased, even asymptotically. This bias impedes the use of standard statistical learning theory and can hurt empirical performance. We propose a simple way of removing the bias. Our debiasing approach is straightforward to implement and applicable to most deep SSL methods. We provide simple theoretical guarantees on the trustworthiness of these modified methods, without having to rely on the strong assumptions on the data distribution that SSL theory usually requires. In particular, we provide generalisation error bounds for the proposed methods. We evaluate debiased versions of different existing SSL methods, such as the Pseudo-label method and Fixmatch, and show that debiasing can compete with classic deep SSL techniques in various settings by providing better calibrated models. Additionally, we provide a theoretical explanation of the intuition of the popular SSL methods. An implementation of a debiased version of Fixmatch is available at https://github.com/HugoSchmutz/DeFixmatch

Gandalf : Data Augmentation is all you need for Extreme Classification

Siddhant Kharbanda,Devaansh Gupta,Erik Schultheis,Atmadeep Banerjee,Vikas Verma,Rohit Babbar

Extreme Multi-label Text Classification (XMC) involves learning a classifier that can assign an input with a subset of most relevant labels from millions of label choices. Recent works in this domain have increasingly focused on the problem setting with short-text input data, and labels endowed with short textual descriptions called label features. Short-text XMC with label features has found numerous applications in areas such as prediction of related searches, title-based product recommendation, bid-phrase suggestion, amongst others. In this paper, we propose Gandalf, a graph induced data augmentation based on label features, such that the generated data-points can supplement the training distribution. By exploiting the characteristics of the short-text XMC problem, it leverages the label features to construct valid training instances, and uses the label graph for generating the corresponding soft-label targets, hence effectively capturing the label-label correlations. While most recent advances (such as SiameseXML and ECLARE) in XMC have been algorithmic, mainly aimed towards developing novel deep-learning architectures, our data-centric augmentation approach is orthogonal to these methodologies. We demonstrate the generality and effectiveness of Gandalf by showing up to 30% relative improvements for 5 state-of-the-art algorithms across 4 benchmark datasets consisting of up to 1.3 million labels.

Learning a Data-Driven Policy Network for Pre-Training Automated Feature Engineering

Liyao Li,Haobo Wang,Liangyu Zha,Qingyi Huang,Sai Wu,Gang Chen,Junbo Zhao

Feature engineering is widely acknowledged to be pivotal in tabular data analysis and prediction. Automated feature engineering (AutoFE) emerged to automate this process managed by experienced data scientists and engineers conventionally. In this area, most — if not all — prior work adopted an identical framework from the neural architecture search (NAS) method. While feasible, we posit that the NAS framework very much contradicts the way how human experts cope with the data since the inherent Markov decision process (MDP) setup differs. We point out that its data-unobserved setup consequentially results in an incapability to generalize across different datasets as well as also high computational cost. This paper proposes a novel AutoFE framework Feature Set Data-Driven Search (FETCH), a pipeline mainly for feature generation and selection. Notably, FETCH is built on a brand-new data-driven MDP setup using the tabular dataset as the state fed into the policy network. Further, we posit that the crucial merit of FETCH is its transferability where the yielded policy network trained on a variety of datasets is indeed capable to enact feature engineering on unseen data, without requiring additional exploration. To the best of our knowledge, this is a pioneer attempt to build a tabular data pre-training paradigm via AutoFE. Extensive experiments show that FETCH systematically surpasses the current state-of-the-art AutoFE methods and validates the transferability of AutoFE pre-training.

Attention Flows for General Transformers
Niklas Metzger,Christopher Hahn,Julian Siber,Frederik Schmitt,Bernd Finkbeiner

In this paper, we study the computation of how much an input token in a Transformer model influences its prediction. We formalize a method to construct a flow network out of the attention values of encoder-only Transformer models and extend it to general Transformer architectures, including an auto-regressive decoder. We show that running a maxflow algorithm on the flow network construction yields Shapley values, which determine a player's impact in cooperative game theory. By interpreting the input tokens in the flow network as players, we can compute their influence on the total attention flow leading to the decoder's decision. Additionally, we provide a library that computes and visualizes the attention flow of arbitrary Transformer models. We show the usefulness of our implementation on various models trained on natural language processing and reasoning tasks.

****

Making Substitute Models More Bayesian Can Enhance Transferability of Adversarial Examples
Qizhang Li,Yiwen Guo,Wangmeng Zuo,Hao Chen

The transferability of adversarial examples across deep neural networks (DNNs) is the crux of many black-box attacks. Many prior efforts have been devoted to improving the transferability via increasing the diversity in inputs of some substitute models. In this paper, by contrast, we opt for the diversity in substitute models and advocate to attack a Bayesian model for achieving desirable transferability. Deriving from the Bayesian formulation, we develop a principled strategy for possible finetuning, which can be combined with many off-the-shelf Gaussian posterior approximations over DNN parameters. Extensive experiments have been conducted to verify the effectiveness of our method, on common benchmark datasets, and the results demonstrate that our method outperforms recent state-of-the-arts by large margins (roughly 19% absolute increase in average attack success rate on ImageNet), and, by combining with these recent methods, further performance gain can be obtained. Our code: https://github.com/qizhangli/MoreBayesian-attack.

Learning Group Importance using the Differentiable Hypergeometric Distribution
Thomas M. Sutter,Laura Manduchi,Alain Ryser,Julia E Vogt

Partitioning a set of elements into subsets of a priori unknown sizes is essential in many applications. These subset sizes are rarely explicitly learned - be it the cluster sizes in clustering applications or the number of shared versus independent generative latent factors in weakly-supervised learning. Probability distributions over correct combinations of subset sizes are non-differentiable due to hard constraints, which prohibit gradient-based optimization. In this work, we propose the differentiable hypergeometric distribution. The hypergeometric distribution models the probability of different group sizes based on their relative importance. We introduce reparameterizable gradients to learn the importance between groups and highlight the advantage of explicitly learning the size of subsets in two typical applications: weakly-supervised learning and clustering. In both applications, we outperform previous approaches, which rely on suboptimal heuristics to model the unknown size of groups.

****

Convergence Rate of Primal-Dual Approach to Constrained Reinforcement Learning with Softmax Policy

Long Yang,Li Shen,Pengfei Li,Yaodong Yang,Zhouchen Lin,Gang Pan

In this paper, we consider primal-dual approach to solve constrained reinforcement learning (RL) problems, where we formulate constrained reinforcement learning under constrained Markov decision process (CMDP). We propose the primal-dual policy gradient (PD-PG) algorithm with softmax policy. Although the constrained RL involves a non-concave maximization problem over the policy parameter space, we show that for both exact policy gradient and model-free learning, the proposed PD-PG needs iteration complexity of $\mathcal{O}\left(\epsilon^{-2}\right)$ to achieve its optimal policy for both constraint and reward performance. Such an iteration complexity outperforms or matches most constrained RL algorithms. For the learning with exact policy gradient, the main challenge is to show the positivity of deterministic optimal policy (at the optimal action) is independent on both state space and iteration times.

For the model-free learning, since we consider the discounted infinite-horizon setting, and the simulator can not rollout with an infinite-horizon sequence; thus one of the main challenges lies in how to design unbiased value function estimators with finite-horizon trajectories. We consider the unbiased estimators with finite-horizon trajectories that involve geometric distribution horizons, which is the key technique for us to obtain the theoretical results for model-free learning.

Cross-Layer Retrospective Retrieving via Layer Attention

Yanwen Fang,Yuxi CAI,Jintai Chen,Jingyu Zhao,Guangjian Tian,Guodong Li

More and more evidence has shown that strengthening layer interactions can enhance the representation power of a deep neural network, while self-attention excels at learning interdependencies by retrieving query-activated information. Motivated by this, we devise a cross-layer attention mechanism, called multi-head recurrent layer attention (MRLA), that sends a query representation of the current layer to all previous layers to retrieve query-related information from different levels of receptive fields. A light-weighted version of MRLA is also proposed to reduce the quadratic computation cost. The proposed layer attention mechanism can enrich the representation power of many state-of-the-art vision networks, including CNNs and vision transformers. Its effectiveness has been extensively evaluated in image classification, object detection and instance segmentation tasks, where improvements can be consistently observed. For example, our MRLA can improve 1.6% Top-1 accuracy on ResNet-50, while only introducing 0.16M parameters and 0.07B FLOPs. Surprisingly, it can boost the performances by a large margin of 3-4% box AP and mask AP in dense prediction tasks. Our code is available at https://github.com/joyfang1106/MRLA.

Decision S4: Efficient Sequence-Based RL via State Spaces Layers

Shmuel Bar David,Itamar Zimerman,Eliya Nachmani,Lior Wolf

Recently, sequence learning methods have been applied to the problem of off-policy
Reinforcement Learning, including the seminal work on Decision Transformers,
which employs transformers for this task. Since transformers are parameter-heavy,
cannot benefit from history longer than a fixed window size, and are not computed
using recurrence, we set out to investigate the suitability of the S4 family of

models, which are based on state-space layers and have been shown to outperform transformers, especially in modeling long-range dependencies. In this work, we present two main algorithms: (i) an off-policy training procedure that works with trajectories, while still maintaining the training efficiency of the S4 model. (ii) An on-policy training procedure that is trained in a recurrent manner, benefits from long-range dependencies, and is based on a novel stable actor-critic mechanism. Our results indicate that our method outperforms multiple variants of decision transformers, as well as the other baseline methods on most tasks, while reducing the latency, number of parameters, and training time by several orders of magnitude, making our approach more suitable for real-world RL

****

Deep autoregressive density nets vs neural ensembles for model-based offline reinforcement learning

Abdelhakim Benechehab,Albert Thomas,Balázs Kégl

We consider the problem of offline reinforcement learning where only a set of system transitions is made available for policy optimization. Following recent advances in the field, we consider a model-based reinforcement learning algorithm that infers the system dynamics from the available data and performs policy optimization on imaginary model rollouts. This approach is vulnerable to exploiting model errors which can lead to catastrophic failures on the real system. The standard solution is to rely on ensembles for uncertainty heuristics and to avoid exploiting the model where it is too uncertain. We challenge the popular belief that we must resort to ensembles by showing that better performance can be obtained with a single well-calibrated autoregressive model on the D4RL benchmark. We also analyze static metrics of model-learning and conclude on the important model properties for the final performance of the agent.

Unveiling the sampling density in non-uniform geometric graphs

Raffaele Paolino,Aleksandar Bojchevski,Stephan Günnemann,Gitta Kutyniok,Ron Levie

A powerful framework for studying graphs is to consider them as geometric graphs: nodes are randomly sampled from an underlying metric space, and any pair of nodes is connected if their distance is less than a specified neighborhood radius. Currently, the literature mostly focuses on uniform sampling and constant neighborhood radius. However, real-world graphs are likely to be better represented by a model in which the sampling density and the neighborhood radius can both vary over the latent space. For instance, in a social network communities can be modeled as densely sampled areas, and hubs as nodes with larger neighborhood radius. In this work, we first perform a rigorous mathematical analysis of this (more general) class of models, including derivations of the resulting graph shift operators. The key insight is that graph shift operators should be corrected in order to avoid potential distortions introduced by the non-uniform sampling. Then, we develop methods to estimate the unknown sampling density in a self-supervised fashion. Finally, we present exemplary applications in which the learnt density is used to 1) correct the graph shift operator and improve performance on a variety of tasks, 2) improve pooling, and 3) extract knowledge from networks. Our experimental findings support our theory and provide strong evidence for our model.

Boosting Causal Discovery via Adaptive Sample Reweighting

An Zhang,Fangfu Liu,Wenchang Ma,Zhibo Cai,Xiang Wang,Tat-Seng Chua

Under stringent model type and variable distribution assumptions, score-based causal discovery methods learn the directed acyclic graph (DAG) from observational data by evaluating candidate graphs over an averaged score function. Despite the great success in low-dimensional linear systems, it has been observed that the se approaches overly exploits easier-to-fit samples, thus inevitably learning spurious edges. Worse still, the common homogeneity assumption of most causal discovery methods can be easily violated due to the widespread existence of heterogeneous data in the real world, resulting in performance vulnerability when noise distributions vary. We propose a simple yet effective model-agnostic framework to boost causal discovery performance by dynamically learning the adaptive weights for the Reweighted Score function, ReScore for short, where the learned weights tailors quantitatively to the important degree of each samples. Intuitively, we leverage the bilevel optimization scheme to alternatively train a standard DAG learner first, then upweight the samples that the DAG learner fails to fit well and downweight the samples that the DAG learner easily extracts the causation information from. Extensive experiments on both synthetic and real-world datasets are carried out to validate the effectiveness of ReScore. We observe consistent and significant boosts in structure learning performance. We further visualize that ReScore concurrently mitigates the influence of spurious edges and generalizes to heterogeneous data. Finally, we perform theoretical analysis to guarantee the structure identifiability and the weight adaptive properties of ReScore. Our codes are available at https://github.com/anzhang314/ReScore.

Robust Training through Adversarially Selected Data Subsets

Hitvarth Diwanji,Divyanshu Shende,Rishi Agarwal,Swaprava Nath,Abir De

Robustness to adversarial perturbations often comes at the cost of a drop in accuracy on unperturbed or clean instances. Most existing defense mechanisms attempt to defend the learner from attack on all possible instances, which often degrades the accuracy on clean instances significantly. However, in practice, an attacker might only select a small subset of instances to attack, $e.g.$, in facial recognition systems an adversary might aim to target specific faces. Moreover, the subset selection strategy of the attacker is seldom known to the defense mechanism a priori, making it challenging to attune the mechanism beforehand. This motivates designing defense mechanisms which can (i) defend against attacks on subsets instead of all instances to prevent degradation of clean accuracy and, (ii) ensure good overall performance for attacks on any selected subset. In this work, we take a step towards solving this problem. We cast the training problem as a min-max game involving worst-case subset selection along with optimization of model parameters, rendering the problem NP-hard. To tackle this, we first show that, for a given learner's model, the objective can be expressed as a difference between a γ-weakly submodular and a modular function. We use this property to propose ROGET, an iterative algorithm, which admits approximation guarantees for a class of loss functions. Our experiments show that ROGET obtains better overall accuracy compared to several state-of-the-art defense methods for different adversarial subset selection techniques.

Beyond Reward: Offline Preference-guided Policy Optimization

Yachen Kang,Diyuan Shi,Jinxin Liu,Li He,Donglin Wang

In this work, we study offline preference-based reinforcement learning (PbRL), which relaxes the two fundamental supervisory signals in standard reinforcement learning (online accessible transition dynamics and rewards). In other words, the agent is provided with fixed offline trajectory transitions and human preferences between pairs of trajectories. Due to the orthogonality property of rewards and dynamics, one common practice is combining prior PbRL-based reward learning objectives with off-the-shelf offline RL algorithms to bridge preference modeling and offline learning. However, such two isolated optimizations require learning a separate reward function and thus place an information bottleneck on reward learning (the bridge). As an alternative, we propose offline preference-guided policy optimization (OPPO), an end-to-end offline PbRL formulation, which jointly learns to model the preference (for finding the optimal task policy) and the offline data (for eliminating OOD). In particular, OPPO introduces an offline hindsight information matching objective and a preference modeling objective. Then, iterating the two objectives over, we can directly extract a well-performing decision policy, avoiding a separate reward learning. We empirically show that OPPO can effectively model the offline preference and outperform prior competing baselines (including the offline RL algorithms performed over the true reward function).

****

Iterative Circuit Repair Against Formal Specifications

Matthias Cosler,Frederik Schmitt,Christopher Hahn,Bernd Finkbeiner

We present a deep learning approach for repairing sequential circuits against formal specifications given in linear-time temporal logic (LTL). Given a defective circuit and its formal specification, we train Transformer models to output circuits that satisfy the corresponding specification. We propose a separated hierarchical Transformer for multimodal representation learning of the formal specification and the circuit. We introduce a data generation algorithm that enables generalization to more complex specifications and out-of-distribution datasets. In addition, our proposed repair mechanism significantly improves the automated synthesis of circuits from LTL specifications with Transformers. It improves the state-of-the-art by 6.8 percentage points on held-out instances and 11.8 percentage points on an out-of-distribution dataset from the annual reactive synthesis competition.

Neural Probabilistic Logic Programming in Discrete-Continuous Domains

Lennert De Smet,Pedro Zuidberg Dos Martires,Robin Manhaeve,Giuseppe Marra,Angelika Kimmig,Luc De Raedt

Neural-symbolic AI (NeSy) methods allow neural networks to exploit symbolic background knowledge. NeSy has been shown to aid learning in the limited data regime and to facilitate inference on out-of-distribution data. Neural probabilistic logic programming (NPLP) is a popular NeSy approach that integrates probabilistic models with neural networks and logic programming. A major limitation of current NPLP systems, such as DeepProbLog, is their restriction to discrete and finite probability distributions, e.g., binary random variables. To overcome this limitation, we introduce DeepSeaProbLog, an NPLP language that supports discrete and continuous random variables on (possibly) infinite and even uncountable domains. Our main contributions are 1) the introduction of DeepSeaProbLog and its semantics, 2) an implementation of DeepSeaProbLog that supports inference and gradient-based learning, and 3) an experimental evaluation of our approach.

****

Can BERT Refrain from Forgetting on Sequential Tasks? A Probing Study

Mingxu Tao,Yansong Feng,Dongyan Zhao

Large pre-trained language models have helped to achieve state of the art on a variety of NLP tasks, nevertheless, they still suffer from forgetting when incrementally learning a series of sequential tasks. To alleviate this problem, recent works propose several models enhanced by sparse experience replay and local adaption, which yield satisfactory performance. However, in this paper we find that pre-trained language models like BERT have a potential ability to learn sequentially, even without any sparse memory replay. To verify the ability of BERT to maintain old knowledge, we adopt and re-finetune single-layer probe networks with the parameters of BERT fixed. We investigate the models on two typical kinds of NLP tasks, text classification and extractive question answering. And our experiments reveal that BERT can actually generate high quality representations for previous tasks in a long term, under extremely sparse replay or even no replay. We further introduce a series of methods to interpret the mechanism of forgetting and how memory rehearsal plays a significant role in task incremental learning, which bridges the gap between our new discovery and previous studies about catastrophic forgetting. Additionally, we provide both quantified and visualized results demonstrating that the representation space of BERT is always topologically organised, which guarantees its performance.

****

Behavior Proximal Policy Optimization

Zifeng Zhuang,Kun LEI,Jinxin Liu,Donglin Wang,Yilang Guo

Offline reinforcement learning (RL) is a challenging setting where existing off-policy actor-critic methods perform poorly due to overestimating of out-of-distr ibution state-action pairs. Thus, various additional augmentations are proposed to keep the learned policy close to the offline dataset (or the behavior policy). In this work, starting from the analysis of offline monotonic policy improvement, we reach a surprising conclusion that online on-policy algorithms are naturally able to solve offline RL. Specifically, the inherent conservatism of these on-policy algorithms is exactly what the offline RL method needs to overcome the overestimation. Based on this, we propose Behavior Proximal Policy Optimization (BPPO), which solves offline RL without any extra constraint or regularization introduced compared to PPO. Extensive experiments on the D4RL benchmark empirically show this extremely succinct method outperforms state-of-the-art offline RL algorithms. Our implementation is available at https://github.com/Dragon-Zhuang/BPPO.

FedGC: An Accurate and Efficient Federated Learning under Gradient Constraint for Heterogeneous Data

Peng Liu,Jie Du,Chi Man VONG

Federated Learning (FL) is an important paradigm in large-scale distributed machine learning, which enables multiple clients to jointly learn a unified global model without transmitting their local data to a central server. FL has attracted growing attentions in many real-world applications, such as multi-center cardiovascular disease diagnosis and autonomous driving. Practically, the data across clients are always heterogeneous, i.e., not independently and identically distributed (Non-IID), making the local models suffer from catastrophic forgetting of the initial (or global) model. To mitigate this forgetting issue, existing FL methods may require additional regularization terms or generates pseudo data, resulting to 1) limited accuracy; 2) long training time and slow convergence rate for real-time applications; and 3) high communication cost. In this work, an accurate and efficient Federated Learning algorithm under Gradient Constraints (FedGC) is proposed, which provides three advantages: i) High accuracy is achieved by the proposed Client-Gradient-Constraint based projection method (CGC) to alleviate the forgetting issue occurred in clients, and the proposed Server-Gradient-Constraint based projection method (SGC) to effectively aggregate the gradients of clients; ii) Short training time and fast convergence rate are enabled by the proposed fast Pseudo-gradient-based mini-batch Gradient Descent (PGD) method and SGC; iii) Low communication cost is required due to the fast convergence rate and only gradients are necessary to be transmitted between server and clients. In the experiments, four real-world image datasets with three Non-IID types are evaluated, and five popular FL methods are used for comparison. The experimental results demonstrate that our FedGC not only significantly improves the accuracy and convergence rate on Non-IID data, but also drastically decreases the training time. Compared to the state-of-art FedReg, our FedGC improves the accuracy by up to 14.28% and speeds up the local training time by 15.5 times while decreasing 23% of the communication cost.

Actionable Neural Representations: Grid Cells from Minimal Constraints

Will Dorrell,Peter E. Latham,Timothy E. J. Behrens,James C. R. Whittington

To afford flexible behaviour, the brain must build internal representations that mirror the structure of variables in the external world. For example, 2D space obeys rules: the same set of actions combine in the same way everywhere (step north, then south, and you won't have moved, wherever you start). We suggest the brain must represent this consistent meaning of actions across space, as it allows you to find new short-cuts and navigate in unfamiliar settings. We term this representation an `actionable representation'. We formulate actionable representations using group and representation theory, and show that, when combined with biological and functional constraints - non-negative firing, bounded neural activity, and precise coding - multiple modules of hexagonal grid cells are the optimal representation of 2D space. We support this claim with intuition, analytic justification, and simulations. Our analytic results normatively explain a set of surprising grid cell phenomena, and make testable predictions for future experiments. Lastly, we highlight the generality of our approach beyond just understan ding 2D space. Our work characterises a new principle for understanding and designing flexible internal representations: they should be actionable, allowing animals and machines to predict the consequences of their actions, rather than just encode.

Compression-aware Training of Neural Networks using Frank-Wolfe

Max Zimmer,Christoph Spiegel,Sebastian Pokutta

Many existing Neural Network pruning approaches either rely on retraining to compensate for pruning-caused performance degradation or they induce strong biases to converge to a specific sparse solution throughout training. A third paradigm, ’compression-aware’ training, obtains state-of-the-art dense models which are robust to a wide range of compression ratios using a single dense training run while also avoiding retraining. In that vein, we propose a constrained optimization framework centered around a versatile family of norm constraints and the Stochastic Frank-Wolfe (SFW) algorithm which together encourage convergence to well-performing solutions while inducing robustness towards convolutional filter pruning and low-rank matrix decomposition. Comparing our novel approaches to compression methods in these domains on benchmark image-classification architectures and datasets, we find that our proposed scheme is able to yield competitive results, often outperforming existing compression-aware approaches. In the case of low-rank matrix decomposition, our approach can require much less computational resources than nuclear-norm regularization based approaches by requiring only a fraction of the singular values in each iteration. As a special case, our proposed constraints can be extended to include the unstructured sparsity-inducing constraint proposed constraint by Pokutta et al. (2020) and Miao et al. (2022), which we improve upon. Our findings also indicate that the robustness of SFW-trained models largely depends on the gradient rescaling of the learning rate and we establish a theoretical foundation for that practice.

Modeling content creator incentives on algorithm-curated platforms

Jiri Hron,Karl Krauth,Michael Jordan,Niki Kilbertus,Sarah Dean

Content creators compete for user attention. Their reach crucially depends on algorithmic choices made by developers on online platforms. To maximize exposure, many creators adapt strategically, as evidenced by examples like the sprawling search engine optimization industry. This begets competition for the finite user attention pool. We formalize these dynamics in what we call an exposure game, a model of incentives induced by modern algorithms including factorization and (deep) two-tower architectures. We prove that seemingly innocuous algorithmic choices—e.g., non-negative vs. unconstrained factorization—significantly affect the existence and character of (Nash) equilibria in exposure games. We proffer use of creator behavior models like ours for an (ex-ante) pre-deployment audit. Such an audit can identify misalignment between desirable and incentivized content, and thus complement post-hoc measures like content filtering and moderation. To this end, we propose tools for numerically finding equilibria in exposure games, and illustrate results of an audit on the MovieLens and LastFM datasets. Among else, we find that the strategically produced content exhibits strong dependence between algorithmic exploration and content diversity, and between model expressivity and bias towards gender-based user and creator groups.

MBrain: A Multi-channel Self-Supervised Learning Framework for Brain Signals

Donghong Cai,Junru Chen,Yang Yang,Teng Liu,Yafeng Li

Brain signals are important quantitative data for understanding physiological activities and diseases of human brain. Meanwhile, rapidly developing deep learning methods offer a wide range of opportunities for better modeling brain signals, which has attracted considerable research efforts recently. Most existing studies pay attention to supervised learning methods, which, however, require high-cost clinical labels. In addition, the huge difference in the clinical patterns of brain signals measured by invasive (e.g., SEEG) and non-invasive (e.g., EEG) methods leads to the lack of a unified method. To handle the above issues, in this paper, we propose to study the self-supervised learning (SSL) framework for bra in signals that can be applied to pre-train either SEEG or EEG data. Intuitively, brain signals, generated by the firing of neurons, are transmitted among different connecting structures in human brain. Inspired by this, we propose to learn implicit spatial and temporal correlations between different channels (i.e., contacts of the electrode, corresponding to different brain areas) as the cornerstone for uniformly modeling different types of brain signals. Specifically, we capture the temporal correlation by designing the delayed-time-shift prediction task; we represent the spatial correlation by a graph structure, which is built with the goal to maximize the mutual information of each channel and its correlated ones. We further theoretically prove that our design can lead to a better predictive representation. Extensive experiments of seizure detection on both EEG and SEEG large-scale real- world datasets demonstrate our model outperforms several state-of-the-art time series SSL and unsupervised models.

****

Group-Disentangling Conditional Shift

Dan Andrei Iliescu,Damon Wischik

We propose a novel group disentanglement method called the Context-Aware Variational Autoencoder (CxVAE). Our model can learn disentangled representations on datasets with conditional shift. This phenomenon occurs when the conditional distribution of the instance-level latent variable $\mathbf{z}$ given the input observation $\mathbf{x}$ changes from one group to another (i.e. $p_i(\mathbf{z}|\mathbf{x}) \neq p_j(\mathbf{z}|\mathbf{x})$, where i,j are two different groups). We show that existing methods fail to learn disentangled representations under this scenario because they infer the group $\mathbf{u}$ and instance $\mathbf{z}$ variables separately. CxVAE overcomes this limitation by conditioning the instance inference on the group variable $q(\mathbf{z}|\mathbf{x},\mathbf{u})$. Our model has the novel ability to disentangle ambiguous observations (those with incomplete information about the generative factors), which we evaluate on the task of fair comparisons between student test scores. Additionally, we demonstrate empirically that conditional shift is the cause of our model's improved performance.

When and Why Is Pretraining Object-Centric Representations Good for Reinforcement Learning?

Jaesik Yoon,Yi-Fu Wu,Sungjin Ahn

Unsupervised object-centric representation (OCR) learning has recently been drawing a lot of attention as a new paradigm of visual representation. This is because of its potential of being an effective pretraining technique for various downstream tasks in terms of sample efficiency, systematic generalization, and reasoning. Although image-based reinforcement learning (RL) is one of the most important and thus frequently mentioned such downstream tasks, the benefit in RL has surprisingly not been investigated systematically thus far. Instead, most of the evaluations have focused on rather indirect metrics such as segmentation quality and object property prediction accuracy. In this paper, we investigate the effectiveness of OCR pretraining for image-based reinforcement learning via empirical experiments. For systematic evaluation, we introduce a simple object-centric visual RL benchmark and verify a series of hypotheses answering questions such as "Does OCR pretraining provide better sample efficiency?", "Which types of RL tasks benefit most from OCR pretraining?", and "Can OCR pretraining help with out-of-distribution generalization?". The results suggest that OCR pretraining is particularly effective in tasks where the relationship between objects is important, improving both task performance and sample efficiency when compared to single-vector representations. Furthermore, OCR models facilitate generalization to out-of-distribution tasks such as changing the number of objects or the appearance of the objects in the scene.

Face reconstruction from facial templates by learning latent space of a generator network

Hatef Otroshi Shahreza,Sébastien Marcel

Face recognition systems are increasingly deployed in different applications. In these systems, a feature vector (also called facial embeddings or templates) is typically extracted from each face image and is stored in the system's database during the enrollment stage, which is later used for comparison during the recognition stage. In this paper, we focus on the template inversion attack against face recognition systems and propose a new method to reconstruct face images from facial templates. Within a generative adversarial network (GAN)-based framework, we learn a mapping from facial templates to the intermediate latent space of a pre-trained face generation network, from which we can generate high-resolution realistic reconstructed face images. We show that our proposed method can be applied in whitebox and blackbox attacks against face recognition systems. Furthermore, we evaluate the transferability of our attack when the adversary uses the reconstructed face image to impersonate the underlying subject in an attack against another face recognition system. Considering the adversary's knowledge and the target face recognition system, we define five different attacks and evaluate the vulnerability of state-of-the-art face recognition systems. Our experiments show that our proposed method achieves high success attack rates in whitebox and blackbox scenarios. Furthermore, the reconstructed face images are transferable and can be used to enter target face recognition systems with a different feature extractor model.

Mole-BERT: Rethinking Pre-training Graph Neural Networks for Molecules

Jun Xia,Chengshuai Zhao,Bozhen Hu,Zhangyang Gao,Cheng Tan,Yue Liu,Siyuan Li,Stan Z. Li

Recent years have witnessed the prosperity of pre-training graph neural networks (GNNs) for molecules. Typically, following the Masked Language Modeling (MLM) task of BERT~\citep{devlin2019bert}, \cite{hu2020strategies} first randomly mask the atom types and then pre-train the GNNs to predict them. However, unlike MLM, this pre-training task named AttrMask is too simple to learn informative molecular representations due to the extremely small and unbalanced atom vocabulary. As a remedy, we adopt the encoder of a variant of VQ-VAE~\citep{van2017neural} as a context-aware tokenizer to encode atoms as meaningful discrete values, which can enlarge the atom vocabulary size and mitigate the quantitative divergence between dominant (e.g., carbons) and rare atoms (e.g., phosphorus). With the enlarged atom vocabulary, we propose a novel node-level pre-training task, dubbed Masked Atoms Modeling (\textbf{MAM}), to randomly mask the discrete values and pre-train GNNs to predict them. MAM mitigates the negative transfer issue of AttrMask and can be combined with various pre-training tasks to advance their performance. Furthermore, for graph-level pre-training, we propose triplet masked contrastive learning (\textbf{TMCL}) to model varying degrees of semantic similarity between molecules, which is especially effective for molecule retrieval. MAM and TMCL constitute a novel pre-training framework, \textbf{Mole-BERT}, which can match or outperform state-of-the-art methods that require expensive domain knowledge as guidance. The codes, the tokenizer, and the pre-trained models will be released.

A sparse, fast, and stable representation for multiparameter topological data analysis

David Loiseaux,Mathieu Carrière,Andrew Blumberg

Topological data analysis (TDA) is a new area of geometric data analysis that focuses on using invariants from algebraic topology to provide multiscale shape descriptors for point clouds. One of the most important shape descriptors is persistent homology, which studies the topological variations as a filtration parameter changes; a typical parameter is the feature scale.

For many data sets, it is useful to consider varying multiple filtration parameters at once, for example scale and density. While the theoretical properties of one-parameter persistent homology are well understood, less is known about the multiparameter case. Of particular interest is the problem of representing multiparameter persistent homology by elements of a vector space for integration with traditional machine learning.

Existing approaches to this problem either ignore most of the multiparameter information to reduce to the one-parameter case or are heuristic and potentially unstable in the face of noise. In this article, we introduce a general representation framework for multiparameter persistent homology that encompasses previous approaches. We establish theoretical stability guarantees under this framework as well as efficient algorithms for practical computation, making this framework an applicable and versatile tool for TDA practitioners. We validate our stability results and algorithms with numerical experiments that demonstrate statistical convergence, prediction accuracy, and fast running times on several real data sets.

Improving Protein Interaction Prediction using Pretrained Structure Embedding

Chunchen Wang,YiWu Sun,Bing Yang,Shaochuan Li,Cheng Yang,Hui Li,Chuan Shi,Le Song

The prediction of protein-protein interactions (PPIs) is a critical problem because the knowledge of PPIs unravels the cellular behavior and its functionality. So far most previous works on PPI predictions mainly focused on sequence and network information and ignored the structural information of protein physical binding. We design a novel method, called xxx, which can leverage pretrained structure embedding and can be transferred to new ppi predictions. Experimental results on PPi predictions show that our pretrained structure embedding leads to significant improvement in PPI prediction comparing to sequence and network based methods. Furthermore, we show that embeddings pretrained based on ppi from different species can be transferred to improve the prediction for human proteins.

Batch Normalization and Bounded Activation Functions

Dongjin Kim,Woojeong Kim,TaeJoo Park,Suhyun Kim

Since Batch Normalization was proposed, it has been commonly located in front of activation functions, as proposed by the original paper. Swapping the order, i.e., using Batch Normalization after activation functions, has also been attempted, but it is generally not much different from the conventional order when ReLU is used. However, in the case of bounded activation functions like Tanh, we discovered that the swapped order achieves considerably better performance on various benchmarks and architectures than the conventional order. We report this remarkable phenomenon and closely examine what contributes to this performance improvement in this paper. One noteworthy thing about swapped models is the extreme saturation of activation values, which is usually considered harmful. Looking at the output distribution of individual activation functions, we found that many of them are highly asymmetrically saturated. The experiments inducing a different degree of asymmetric saturation support the hypothesis that asymmetric saturation helps improve performance. In addition, we found that Batch Normalization after bounded activation functions has another important effect: it relocates the asymmetrically saturated output of activation functions near zero. This enables the swapped model to have higher sparsity, further improving performance. Extensive experiments with Tanh, LeLecun Tanh, and Softsign show that the swapped models achieve improved performance with a high degree of asymmetric saturation.

MEDOE: A Multi-Expert Decoder and Output Ensemble Framework for Long-tailed Semantic Segmentation

Junao Shen,Long Chen,Tian Feng,Zhang Wei,Fei Wu,Kun Kuang

Long-tailed distribution of semantic categories, which has been often ignored in conventional methods, causes unsatisfactory performance in semantic segmentation on tail categories. In this paper, we focus on the problem of long-tailed semantic segmentation. Although some long-tailed recognition methods (e.g., re-sampling/re-weighting) have been proposed in other problems, they are likely to compromise crucial contextual information in semantic segmentation. Therefore, these methods are hardly adaptable to the problem of long-tailed semantic segmentation. To address this problem, we propose a novel method, named MEDOE, by ensembling and grouping contextual information. Specifically, our MEDOE is a two-sage fram ework comprising a multi-expert decoder (MED) and a multi-expert output ensemble (MOE). The MED includes several ``experts", each of which takes as input the dataset masked according to the specific categories based on frequency distribution and generates contextual information self-adaptively for classification. The MOE then ensembles the experts' outputs with learnable decision weights. As a model-agnostic framework, MEDOE can be flexibly and efficiently coupled with various popular deep neural networks (e.g., Deeplabv3+, OCRNet, and PSPNet) to improve the performance in long-tailed semantic segmentation. Experimental results show that the proposed framework outperforms the current methods on both Cityscapes and ADE20K datasets by up to 2\% in mIoU and 6\% in mAcc.

Concept-level Debugging of Part-Prototype Networks
Andrea Bontempelli,Stefano Teso,Katya Tentori,Fausto Giunchiglia,Andrea Passerini

Part-prototype Networks (ProtoPNets) are concept-based classifiers designed to achieve the same performance as black-box models without compromising transparency. ProtoPNets compute predictions based on similarity to class-specific part-prototypes learned to recognize parts of training examples, making it easy to faithfully determine what examples are responsible for any target prediction and why. However, like other models, they are prone to picking up confounders and shortcuts from the data, thus suffering from compromised prediction accuracy and limited generalization. We propose ProtoPDebug, an effective concept-level debugger for ProtoPNets in which a human supervisor, guided by the model’s explanations, supplies feedback in the form of what part-prototypes must be forgotten or kept, and the model is fine-tuned to align with this supervision. Our experimental evaluation shows that ProtoPDebug outperforms state-of-the-art debuggers for a fraction of the annotation cost. An online experiment with laypeople confirms the simplicity of the feedback requested to the users and the effectiveness of the collected feedback for learning confounder-free part-prototypes. ProtoPDebug is a promising tool for trustworthy interactive learning in critical applications, as suggested by a preliminary evaluation on a medical decision making task.

Geometrically regularized autoencoders for non-Euclidean data
Cheongjae Jang,Yonghyeon Lee,Yung-Kyun Noh,Frank C. Park

Regularization is almost {\it de rigueur} when designing autoencoders that are sparse and robust to noise. Given the recent surge of interest in machine learning problems involving non-Euclidean data, in this paper we address the regularization of autoencoders on curved spaces. We show that by ignoring the underlying geometry of the data and applying standard vector space regularization techniques, autoencoder performance can be severely degraded, or worse, training can fail to converge. Assuming that both the data space and latent space can be modeled as Riemannian manifolds, we show how to construct regularization terms in a coordinate-invariant way, and develop geometric generalizations of the denoising autoencoder and reconstruction contractive autoencoder such that the essential properties that enable the estimation of the derivative of the log-probability density are preserved. Drawing upon various non-Euclidean data sets, we show that our geometric autoencoder regularization techniques can have important performance advantages over vector-spaced methods while avoiding other breakdowns that can result from failing to account for the underlying geometry.

TransFool: An Adversarial Attack against Neural Machine Translation Models
Sahar Sadrizadeh,Pascal Frossard,Ljiljana Dolamic

Deep neural networks have been shown to be vulnerable to small perturbations of their inputs known as adversarial attacks. In this paper, we consider the particular task of Neural Machine Translation (NMT), where security is often critical. We investigate the vulnerability of NMT models to adversarial attacks and propose a new attack algorithm called TransFool. It builds on a multi-term optimization problem and a gradient projection step to compute adversarial examples that fool NMT models. By integrating the embedding representation of a language model in the proposed attack, we generate fluent adversarial examples in the source la

nguage that maintain a high level of semantic similarity with the clean samples and render the attack largely undetectable. Experimental results demonstrate that, for multiple translation tasks and different NMT architectures, our white-box attack can severely degrade the translation quality for more than 60% of the sentences while the semantic similarity between the original sentence and the adversarial example stays very high. Moreover, we show that the proposed attack is transferable to unknown target models and can fool those quite easily. Finally, our method leads to improvement in terms of success rate, semantic similarity, and fluency compared to the existing attack strategies both in white-box and black-box settings. Hence, TransFool permits to better characterize the vulnerability of NMT systems and outlines the necessity to design strong defense mechanisms and more robust NMT systems for real-life applications.

Protein Sequence Design in a Latent Space via Model-based Reinforcement Learning
Minji Lee,Luiz Felipe Vecchietti,Hyunkyu Jung,Hyunjoo Ro,Meeyoung Cha,Ho Min Kim
Proteins are complex molecules responsible for different functions in the human body. Enhancing the functionality of a protein and/or cellular fitness can significantly impact various industries. However, their optimization remains challenging, and sequences generated by data-driven methods often fail in wet lab experiments. This study investigates the limitations of existing model-based sequence design methods and presents a novel optimization framework that can efficiently traverse the latent representation space instead of the protein sequence space. Our framework generates proteins with higher functionality and cellular fitness by modeling the sequence design task as a Markov decision process and applying model-based reinforcement learning. We discuss the results in a comprehensive evaluation of two distinct proteins, GPF and His3, along with the predicted structure of optimized sequences using deep learning-based structure prediction.

The GANfather: Controllable generation of malicious activity to expose detection weaknesses and improve defence systems.
Ricardo Ribeiro Pereira,Jacopo Bono,João Tiago Ascensão,David Oliveira Aparicio,Pedro Manuel Pinto Ribeiro,Pedro Bizarro
Criminal activities are typically adversarial in nature, where an attacker and a defence system are constantly adapting to each other's behaviour. If the defence systems are helped by automated detection methods, then those methods need to be updated frequently. In practice, this means that the defence systems are always one step behind the attackers. For example, in anti-money laundering systems, new labels representing suspicious activity are frequently delayed by weeks or months and some money laundering activity may never be found, leading to detection systems that are inaccurate and resulting in an estimated undetected €0.7-3 trillion being laundered annually.

To tackle the problem of missing or delayed labels in adversarial settings, we propose The GANfather, an adversarial and label-free method to both (1) generate a variety of meaningful attacks, as guided by a custom, user-defined objective function; and (2) train a defence system to detect such attacks. Optionally, we can ensure that the generated attacks escape an existing detection system, revealing current weaknesses which the new defence system actively corrects. Our method is inspired by generative adversarial networks (GANs), but unlike GANs we nudge our generator to produce out-of-distribution data using a loss function that characterises criminal activity. Importantly, our method does not require any labelled examples.

We test our framework in two real-world use-cases, namely injection attacks in recommendation systems and anti-money laundering. In the former, we show how an injection attack with a limited number of generated fake profiles is sufficient to successfully recommend an item to a large number of users. These generated injection attacks are more effective in recommending the target item than naive ‘bombing’ strategies and harder to detect. In the latter, the generated attacks are able to simulate money laundering and move cumulative amounts close to 250 thou sand dollars through a network of accounts without being detected by existing systems. We also show how we can train a new defence system that captures all these synthetic attacks, potentially saving millions of dollars in detected criminal activity. Our method is generic and applicable in a variety of adversarial domains, exposing current liabilities with the generated data and strengthening the defence systems against current and future malicious attacks.

Proximal Validation Protocol

MingFeng Ou,Yiming Zhang,Sai Wu,Gang Chen,Junbo Zhao

Modern machine learning algorithms are generally built upon a train/validation/test split protocol. In particular, with the absence of accessible testing set in real-world ML development, how to split out a validation set becomes crucial for reliable model evaluation, selection and etc. Concretely, under a randomized splitting setup, the split ratio of the validation set generally acts as a vital meta-parameter; that is, with more data picked and used for validation, it would cost model performance due to the less training data, and vice versa. Unfortunately, this implies a vexing trade-off between performance enhancement against trustful model evaluation. However, to date, the research conducted on this line remains very few. We reason this could be due to a workflow gap between the academic and ML production which we may attribute to a form of technical debt of ML. In this article, we propose a novel scheme --- dubbed Proximal Validation Protocol (PVP) --- which is targeted to resolve this problem of validation set construction. Core to PVP is to assemble a \emph{proximal set} as a substitution for the traditional validation set while avoiding the valuable data wasted by the training procedure. The construction of the proximal validation set is established with dense data augmentation followed by a novel distributional-consistent sampling algorithm. With extensive empirical findings, we prove that PVP works (much) better than all the other existing validation protocols on three data modalities (images, text, and tabular data), demonstrating its feasibility towards ML production.

A Message Passing Perspective on Learning Dynamics of Contrastive Learning

Yifei Wang,Qi Zhang,Tianqi Du,Jiansheng Yang,Zhouchen Lin,Yisen Wang

In recent years, contrastive learning achieves impressive results on self-supervised visual representation learning, but there still lacks a rigorous understanding of its learning dynamics. In this paper, we show that if we cast a contrastive objective equivalently into the feature space, then its learning dynamics admits an interpretable form. Specifically, we show that its gradient descent corresponds to a specific message passing scheme on the corresponding augmentation graph. Based on this perspective, we theoretically characterize how contrastive learning gradually learns discriminative features with the alignment update and the uniformity update. Meanwhile, this perspective also establishes an intriguing connection between contrastive learning and Message Passing Graph Neural Networks (MP-GNNs). This connection not only provides a unified understanding of many techniques independently developed in each community, but also enables us to borrow techniques from MP-GNNs to design new contrastive learning variants, such as graph attention, graph rewiring, jumpy knowledge techniques, etc. We believe that our message passing perspective not only provides a new theoretical understanding of contrastive learning dynamics, but also bridges the two seemingly independent areas together, which could inspire more interleaving studies to benefit from each other. The code is available at https://github.com/PKU-ML/Message-Passing-Contrastive-Learning.

Help Me Explore: Combining Autotelic and Social Learning via Active Goal Queries

Ahmed Akakzia,Hugo Caselles-Dupré,Olivier Serris,Mohamed CHETOUANI,Olivier Sigaud,Cédric Colas

Most approaches to open-ended skill learning train a single agent in a purely sensorimotor environment. But because no human child learns everything on their own, we argue that sociality will be a key component of open-ended learning systems. This paper enables learning agents to blend individual and socially-guided sk ill learning through a new interaction protocol named Help Me Explore (HME). In social episodes triggered at the agent's demand, a social partner suggests a goal at the frontier of the agent's capabilities and, when the goal is reached, follows up with a new adjacent goal just beyond. In individual episodes, the agent practices skills autonomously by pursuing goals it already discovered through either its own experience or social suggestions. The idea of augmenting an individual goal exploration with social goal suggestions is simple, general and powerful. We demonstrate its efficiency on two notoriously hard exploration benchmarks: continuous mazes and a 5-block robotic manipulation task. With minimal social interventions, an HME-agent outperforms the purely social agent deprived of its autonomy, and the purely individual agent which fails to solve hard exploration problems.

AUTOMATIC CURRICULUM FOR UNSUPERVISED REIN- FORCEMENT LEARNING

Yucheng Yang,Tianyi Zhou,Tianhong Dai,Meng Fang,Mykola Pechenizkiy

Recent unsupervised reinforcement learning (URL) can learn meaningful skills without task rewards by carefully designed training objectives. However, most existing works lack quantitative evaluation metrics for URL but mainly rely on visualizations of trajectories to compare the performance. Moreover, each URL method only focuses on a single training objective, which can hinder further learning progress and the development of new skills. To bridge these gaps, we first propose multiple evaluation metrics for URL that can cover different preferred properties. We show that balancing these metrics leads to what a “good” trajectory visualization embodies. Next, we use these metrics to develop an automatic curriculum that can change the URL objective across different learning stages in order to improve and balance all metrics. Specifically, we apply a non-stationary multi-armed bandit algorithm to select an existing URL objective for each episode according to the metrics evaluated in previous episodes. Extensive experiments indifferent environments demonstrate the advantages of our method on achieving promising and balanced performance over all URL metrics.

Filtered Semi-Markov CRF

Urchade Zaratiana,Nadi Tomeh,Niama Elkhbir,Pierre Holat,Thierry Charnois

Semi-Markov CRF \citep{semicrf} has been proposed as an alternative to the traditional Linear Chain CRF\citep{crf} for text segmentation tasks such as Named Entity Recognition. In contrast to CRF, which treats text segmentation as token-level prediction, Semi-CRF considers spans as the task's basic unit, which makes it more expressive. However, Semi-CRF has two major drawbacks: (1) it has quadratic complexity over sequence length as it operates on every span of the input sequence, and (2) empirically, it performs worse than classical CRF for sequence labeling tasks such as NER. In our work, we propose Filtered Semi-Markov CRF, a Semi-CRF variant that addresses the aforementioned issues. Our model extends Semi-CRF by incorporating a filtering step for eliminating irrelevant segments, which helps in reducing the complexity and allows to dramatically reduce the search space. On a variety of NER benchmarks, we find that our approach outperforms both CRF and Semi-CRF models while being significantly faster. We will make our code available to the public.

Zeroth-Order Optimization with Trajectory-Informed Derivative Estimation

Yao Shu,Zhongxiang Dai,Weicong Sng,Arun Verma,Patrick Jaillet,Bryan Kian Hsiang Low

Zeroth-order (ZO) optimization, in which the derivative is unavailable, has recently succeeded in many important machine learning applications. Existing algorithms rely on finite difference (FD) methods for derivative estimation and gradient descent (GD)-based approaches for optimization. However, these algorithms suffer from query inefficiency because many additional function queries are required for derivative estimation in their every GD update, which typically hinders their deployment in real-world applications where every function query is expensive. To this end, we propose a trajectory-informed derivative estimation method which only employs the optimization trajectory (i.e., the history of function queri es during optimization) and hence can eliminate the need for additional function queries to estimate a derivative. Moreover, based on our derivative estimation, we propose the technique of dynamic virtual updates, which allows us to reliably perform multiple steps of GD updates without reapplying derivative estimation. Based on these two contributions, we introduce the zeroth-order optimization with trajectory-informed derivative estimation (ZoRD) algorithm for query-efficient ZO optimization. We theoretically demonstrate that our trajectory-informed derivative estimation and our ZoRD algorithm improve over existing approaches, which is then supported by our real-world experiments such as black-box adversarial attack, non-differentiable metric optimization, and derivative-free reinforcement learning.

Distance VS. Coordinate: Distance Based Embedding Improves Model Generalization for Routing Problems

Hongsen Liao,Ruiyuan Wu,Yuyang Han,Yuncong Hu,Ke Xing,Jinghua Hao,Renqing He

Routing problems, such as traveling salesman problem (TSP) and vehicle routing problem, are among the most classic research topics in combinatorial optimization and operations research (OR). In recent years, with the rapid development of online service platforms, there has been renewed interest in applying this study to facilitate emerging industrial applications, such as food delivery and logistics services. While OR methods remain the mainstream technique, increasing efforts have been put into exploiting deep learning (DL) models for tackling routing problems. The existing ML methods often consider the embedding of the route point coordinate as a key model input and are capable of delivering competing performance in synthetic or simplified settings. However, it is empirically noted that this line of work appears to lack robustness and generalization ability that are crucial for real-world applications. In this paper, we demonstrate that the coordinate can unexpectedly lead to these problems. There are two factors that make coordinate rather `poisonous' for DL models: i) the definition of distance between route points is far more complex than what coordinate can depict; ii) the coordinate can hardly be sufficiently `traversed' by the training data. To circumvent these limitations, we propose to abandon the coordinate and instead use the relative distance for route point embedding. We show in both synthetic TSP and real-world food pickup and delivery route prediction problem that our design can significantly improve model's generalization ability, and deliver competitive or better performance with existing models.

****

Towards biologically plausible Dreaming and Planning

Cristiano Capone,Pier Stanislao Paolucci

Humans and animals can learn new skills after practicing for a few hours, while current reinforcement learning algorithms require a large amount of data to achieve good performances.

Recent model-based approaches show promising results by reducing the number of necessary interactions with the environment to learn a desirable policy. However, these methods require biological implausible ingredients, such as the detailed storage of older experiences, and long periods of offline learning. The optimal way to learn and exploit word-models is still an open question.

Taking inspiration from biology, we suggest that dreaming might be an efficient expedient to use an inner model. We propose a two-module (agent and model) neural network in which "dreaming" (living new experiences in a model-based simulated environment) significantly boosts learning. We also explore "planning", an online alternative to dreaming, that shows comparable performances. Importantly, our model does not require the detailed storage of experiences, and learns online the world-model. This is a key ingredient for biological plausibility and implementability (e.g., in neuromorphic hardware).

Extracting Meaningful Attention on Source Code: An Empirical Study of Developer and Neural Model Code Exploration

Matteo Paltenghi,Rahul Pandita,Austin Henley,Albert Ziegler

The high effectiveness of neural models of code, such as OpenAI Codex and AlphaC ode, suggests coding capabilities of models that are at least comparable to those of humans. However, previous work has only used these models for their raw completion, ignoring how the model reasoning, in the form of attention weights, can be used for other downstream tasks. Disregarding the attention weights means discarding a considerable portion of what those models compute when queried. To profit more from the knowledge embedded in these large pre-trained models, this work compares multiple approaches to post-process these valuable attention weights for supporting code exploration. Specifically, we compare to which extent the transformed attention signal of CodeGen, a large and publicly available pre-trained neural model, agrees with how developers look at and explore code when each answering the same sense-making questions about code. At the core of our experimental evaluation, we collect, manually annotate, and open-source a novel eye-tracking dataset comprising 25 developers answering sense-making questions on code over 92 sessions. We empirically evaluate five attention-agnostic heuristics and ten attention-based post processing approaches of the attention signal against our ground truth of developers exploring code, including the novel concept of follow-up attention which exhibits the highest agreement. Beyond the dataset contribution and the empirical study, we also introduce a novel practical application of the attention signal of pre-trained models with completely analytical solutions, going beyond how neural models’ attention mechanisms have traditionally been used.

Neuroevolution is a Competitive Alternative to Reinforcement Learning for Skill Discovery

Felix Chalumeau,Raphael Boige,Bryan Lim,Valentin Macé,Maxime Allard,Arthur Flajolet,Antoine Cully,Thomas PIERROT

Deep Reinforcement Learning (RL) has emerged as a powerful paradigm for training neural policies to solve complex control tasks. However, these policies tend to be overfit to the exact specifications of the task and environment they were trained on, and thus do not perform well when conditions deviate slightly or when composed hierarchically to solve even more complex tasks. Recent work has shown that training a mixture of policies, as opposed to a single one, that are driven to explore different regions of the state-action space can address this shortcoming by generating a diverse set of behaviors, referred to as skills, that can be collectively used to great effect in adaptation tasks or for hierarchical planning. This is typically realized by including a diversity term - often derived from information theory - in the objective function optimized by RL. However these approaches often require careful hyperparameter tuning to be effective. In this work, we demonstrate that less widely-used neuroevolution methods, specifically Quality Diversity (QD), are a competitive alternative to information-theory-augmented RL for skill discovery. Through an extensive empirical evaluation comparing eight state-of-the-art algorithms (four flagship algorithms from each line of work) on the basis of (i) metrics directly evaluating the skills' diversity, (ii) the skills' performance on adaptation tasks, and (iii) the skills' performance when used as primitives for hierarchical planning; QD methods are found to provide equal, and sometimes improved, performance whilst being less sensitive to hyperparameters and more scalable. As no single method is found to provide near-optimal performance across all environments, there is a rich scope for further research which we support by proposing future directions and providing optimized open-source implementations.

Scrunch: Preventing sensitive property inference through privacy-preserving representation learning

Vittorio Prodomo,Roberto González-Sánchez,Marco Gramaglia

Many tasks that are commonly performed by devices attached to the Internet are currently being offloaded to the cloud, using the Machine Learning as a Service (MLaaS) paradigm. While this paradigm is motivated by the reduced capacity of mobile terminals, it also hinders privacy associated with the data exchanged over the network. Thus, the data exchanged among parties shall be conveniently anonymi zed to prevent possible confidentiality and privacy issues. While many privacy-enhancing algorithms have been proposed in the past, they are usually relying on very complex models that make difficult their applicability to real-world systems or envision too friendly attacker models. In this paper, we propose a deep learning system that creates anonymized representations for the data, while keeping the accuracy for the targeted MLaaS task high, assuming that the attacker can re-train an adversarial model. Our results show that the proposed algorithm i) is effective yet it uses a lighter approach than state-of-the-art ii) considers less friendly attacker models, and iii) outperforms the benchmark under different privacy metrics.

Uniform-in-time propagation of chaos for the mean field gradient Langevin dynamics

Taiji Suzuki,Atsushi Nitanda,Denny Wu

The mean-field Langevin dynamics is characterized by a stochastic differential equation that arises from (noisy) gradient descent on an infinite-width two-layer neural network, which can be viewed as an interacting particle system. In this work, we establish a quantitative weak propagation of chaos result for the system, with a finite-particle discretization error of $\mathcal{O}(1/N)$ \textit{uniformly over time}, where N is the width of the neural network. This allows us to directly transfer the optimization guarantee for infinite-width networks to practical finite-width models without excessive overparameterization. On the technical side, our analysis differs from most existing studies on similar mean field dynamics in that we do not require the interaction between particles to be sufficiently weak to obtain a uniform propagation of chaos, because such assumptions may not be satisfied in neural network optimization. Instead, we make use of a logarithmic Sobolev-type condition which can be verified in appropriate regularized risk minimization settings.

****

GM-VAE: Representation Learning with VAE on Gaussian Manifold

Seunghyuk Cho,Juyong Lee,Dongwoo Kim

We propose a Gaussian manifold variational auto-encoder (GM-VAE) whose latent space consists of a set of diagonal Gaussian distributions. It is known that the set of the diagonal Gaussian distributions with the Fisher information metric forms a product hyperbolic space, which we call a Gaussian manifold. To learn the VAE endowed with the Gaussian manifold, we first propose a pseudo Gaussian manifold normal distribution based on the Kullback-Leibler divergence, a local approximation of the squared Fisher-Rao distance, to define a density over the latent space. With the newly proposed distribution, we introduce geometric transformations at the last and the first of the encoder and the decoder of VAE, respectively to help the transition between the Euclidean and Gaussian manifolds. Through the empirical experiments, we show competitive generalization performance of GM-VAE against other variants of hyperbolic- and Euclidean-VAEs. Our model achieves strong numerical stability, which is a common limitation reported with previous hyperbolic-VAEs.

****

Improving Adversarial Robustness by Putting More Regularizations on Less Robust Samples

Dongyoon Yang,Insung Kong,Yongdai Kim

Adversarial training, which is to enhance robustness against adversarial attacks, has received much attention because it is easy to generate human-imperceptible perturbations of data to deceive a given deep neural network. In this paper, we propose a new adversarial training algorithm that is theoretically well motivated and empirically superior to other existing algorithms. A novel feature of the proposed algorithm is to apply more regularization to data vulnerable to adversarial attacks than other existing regularization algorithms do. Theoretically, we show that our algorithm can be understood as an algorithm of minimizing a newly derived upper bound of the robust risk. Numerical experiments illustrate that our proposed algorithm improves the generalization (accuracy on examples) and ro bustness (accuracy on adversarial attacks) simultaneously to achieve the state-of-the-art performance.

****

Causal Explanations of Structural Causal Models

Matej Ze■evi■,Devendra Singh Dhami,Constantin A. Rothkopf,Kristian Kersting

In explanatory interactive learning (XIL) the user queries the learner, then the learner explains its answer to the user and finally the loop repeats. XIL is attractive for two reasons, (1) the learner becomes better and (2) the user's trust increases. For both reasons to hold, the learner's explanations must be useful to the user and the user must be allowed to ask useful questions. Ideally, both questions and explanations should be grounded in a causal model since they avoid spurious fallacies. Ultimately, we seem to seek a causal variant of XIL. The question part on the user's end we believe to be solved since the user's mental model can provide the causal model. But how would the learner provide causal explanations? In this work we show that existing explanation methods are not guaranteed to be causal even when provided with a Structural Causal Model (SCM). Specifically, we use the popular, proclaimed causal explanation method CXPlain to illustrate how the generated explanations leave open the question of truly causal explanations. Thus as a step towards causal XIL, we propose a solution to the lack of causal explanations. We solve this problem by deriving from first principles an explanation method that makes full use of a given SCM, which we refer to as SC$\textbf{E}$ ($\textbf{E}$ standing for explanation). Since SCEs make use of structural information, any causal graph learner can now provide human-readable explanations. We conduct several experiments including a user study with 22 participants to investigate the virtue of SCE as causal explanations of SCMs.

Asynchronous Distributed Bilevel Optimization

Yang Jiao,Kai Yang,Tiancheng Wu,Dongjin Song,Chengtao Jian

Bilevel optimization plays an essential role in many machine learning tasks, ranging from hyperparameter optimization to meta-learning. Existing studies on bilevel optimization, however, focus on either centralized or synchronous distributed setting. The centralized bilevel optimization approaches require collecting massive amount of data to a single server, which inevitably incur significant communication expenses and may give rise to data privacy risks. Synchronous distributed bilevel optimization algorithms, on the other hand, often face the straggler problem and will immediately stop working if a few workers fail to respond. As a remedy, we propose Asynchronous Distributed Bilevel Optimization (ADBO) algorithm. The proposed ADBO can tackle bilevel optimization problems with both nonconvex upper-level and lower-level objective functions, and its convergence is theoretically guaranteed. Furthermore, it is revealed through theoretic analysis that the iteration complexity of ADBO to obtain the ϵ-stationary point is upper bounded by $\mathcal{O}(\frac{1}{{{\epsilon ^2}}})$. Thorough empirical studies on public datasets have been conducted to elucidate the effectiveness and efficiency of the proposed ADBO.

Multi-Agent Reinforcement Learning with Shared Resources for Inventory Management

Yuandong Ding,Mingxiao Feng,Guozi Liu,Wei Jiang,Chuheng Zhang,Li Zhao,Lei Song,Houqiang Li,Yan Jin,Jiang Bian

In this paper, we consider the inventory management (IM) problem where we need to make replenishment decisions for a large number of stock keeping units (SKUs) to balance their supply and demand. In our setting, the constraint on the shared resources (such as the inventory capacity) couples the otherwise independent control for each SKU. We formulate the problem with this structure as Shared-Resource Stochastic Game (SRSG) and propose an efficient algorithm called Context-aware Decentralized PPO (CD-PPO). Through extensive experiments, we demonstrate that CD-PPO can accelerate the learning procedure compared with standard MARL algorithms.

Confidence-Based Feature Imputation for Graphs with Partially Known Features

Daeho Um,Jiwoong Park,Seulki Park,Jin young Choi

This paper investigates a missing feature imputation problem for graph learning tasks. Several methods have previously addressed learning tasks on graphs with missing features. However, in cases of high rates of missing features, they were unable to avoid significant performance degradation. To overcome this limitation, we introduce a novel concept of channel-wise confidence in a node feature, which is assigned to each imputed channel feature of a node for reflecting the certainty of the imputation. We then design pseudo-confidence using the channel-wise shortest path distance between a missing-feature node and its nearest known-feature node to replace unavailable true confidence in an actual learning process. Based on the pseudo-confidence, we propose a novel feature imputation scheme that performs channel-wise inter-node diffusion and node-wise inter-channel propagation. The scheme can endure even at an exceedingly high missing rate (e.g., 99.5\%) and it achieves state-of-the-art accuracy for both semi-supervised node classification and link prediction on various datasets containing a high rate of missing features. Codes are available at https://github.com/daehoum1/pcfi.

Explicitly Maintaining Diverse Playing Styles in Self-Play

Yuan Liu,Ruimin Shen,Miqing Li,Yingfeng Chen,Juan Zou,Changjie Fan

Self-play has proven to be an effective training schema to obtain a high-level agent in complex games through iteratively playing against an opponent from its historical versions. However, its training process may prevent it from generating a well-generalised policy since the trained agent rarely encounters diversely-behaving opponents along its own historical path. In this paper, we aim to improve the generalisation of the policy by maintaining a population of agents with diverse playing styles and high skill levels throughout the training process. Specifically, we propose a bi-objective optimisation model to simultaneously optimise the agents' skill level and playing style. A feature of this model is that we do not regard the skill level and playing style as two objectives to maximise directly since they are not equally important (i.e., agents with diverse playing styles but low skill levels are meaningless). Instead, we create a meta bi-objective model to enable high-level agents with diverse playing styles more likely to be incomparable (i.e. Pareto non-dominated), thereby playing against each other through the training process. We then present an evolutionary algorithm working with the proposed model. Experiments in a classic table tennis game Pong and a commercial role-playing game Justice Online show that our algorithm can learn a well generalised policy and at the same time is able to provide a set of high-level policies with various playing styles.

Toward Learning Geometric Eigen-Lengths Crucial for Robotic Fitting Tasks

Yijia Weng,Kaichun Mo,Ruoxi Shi,Yanchao Yang,Leonidas Guibas

Some extremely low-dimensional yet crucial geometric eigen-lengths often determine whether an object can be fitted in the environment or not. For example, the {\em height} of an object is important to measure to check if it can fit between the shelves of a cabinet, while the {\em width} of a couch is crucial when trying to move it through a doorway. Humans have materialized such crucial geometric eigen-lengths in common sense since they are very useful in serving as succinct yet effective, highly interpretable, and universal object representations. However, it remains obscure and underexplored if learning systems can be equipped with similar capabilities of automatically discovering such key geometric quantities in doing robotic fitting tasks. In this work, we therefore for the first time formulate and propose a novel learning problem on this question and set up a benchmark suite including the tasks, the data, and the evaluation metrics for studying the problem. We explore potential solutions and demonstrate the feasibility of learning such eigen-lengths from simply observing successful and failed fitting trials. We also attempt geometric grounding for more accurate eigen-length measurement and study the reusability of the learned geometric eigen-lengths across multiple tasks. Our work marks the first exploratory step toward learning crucial geometric eigen-lengths and we hope it can inspire future research in tackling this important yet underexplored problem.

LiftedCL: Lifting Contrastive Learning for Human-Centric Perception

Ziwei Chen,Qiang Li,Xiaofeng Wang,Wankou Yang

Human-centric perception targets for understanding human body pose, shape and segmentation. Pre-training the model on large-scale datasets and fine-tuning it on specific tasks has become a well-established paradigm in human-centric perception. Recently, self-supervised learning methods have re-investigated contrastive learning to achieve superior performance on various downstream tasks. When handling human-centric perception, there still remains untapped potential since 3D human structure information is neglected during the task-agnostic pre-training. In this paper, we propose the Lifting Contrastive Learning (LiftedCL) to obtain 3D-aware human-centric representations which absorb 3D human structure information. In particular, to induce the learning process, a set of 3D skeletons is randomly sampled by resorting to 3D human kinematic prior. With this set of generic 3D samples, 3D human structure information can be learned into 3D-aware representations through adversarial learning. Empirical results demonstrate that LiftedCL outperforms state-of-the-art self-supervised methods on four human-centric downstream tasks, including 2D and 3D human pose estimation (0.4% mAP and 1.8 mm MPJPE improvement on COCO 2D pose estimation and Human3.6M 3D pose estimation), human shape recovery and human parsing.

Individual Privacy Accounting with Gaussian Differential Privacy

Antti Koskela,Marlon Tobaben,Antti Honkela

Individual privacy accounting enables bounding differential privacy (DP) loss individually for each participant involved in the analysis. This can be informative as often the individual privacy losses are considerably smaller than those indicated by the DP bounds that are based on considering worst-case bounds at each data access. In order to account for the individual losses in a principled manner, we need a privacy accountant for adaptive compositions of mechanisms, where the loss incurred at a given data access is allowed to be smaller than the worst-case loss. This kind of analysis has been carried out for the Rényi differential privacy by Feldman and Zrnic (2021), however not yet for the so-called optimal privacy accountants. We make first steps in this direction by providing a careful analysis using the Gaussian differential privacy which gives optimal bounds for the Gaussian mechanism, one of the most versatile DP mechanisms. This approach is based on determining a certain supermartingale for the hockey-stick divergence and on extending the Rényi divergence-based fully adaptive composition results by Feldman and Zrnic (2021). We also consider measuring the individual (ε,δ)-privacy losses using the so-called privacy loss distributions. Using the Blackwell theorem, we can then use the results of Feldman and Zrnic (2021) to construct an approximative individual (ε,δ)-accountant. We also show how to speed up the FFT-based individual DP accounting using the Plancherel theorem.

Evolving Populations of Diverse RL Agents with MAP-Elites

Thomas PIERROT,Arthur Flajolet

Quality Diversity (QD) has emerged as a powerful alternative optimization paradigm that aims at generating large and diverse collections of solutions, notably with its flagship algorithm MAP-ELITES (ME) which evolves solutions through mutations and crossovers. While very effective for some unstructured problems, early ME implementations relied exclusively on random search to evolve the population of solutions, rendering them notoriously sample-inefficient for high-dimensional problems, such as when evolving neural networks. Follow-up works considered exploiting gradient information to guide the search in order to address these shortcomings through techniques borrowed from either Black-Box Optimization (BBO) or Reinforcement Learning (RL). While mixing RL techniques with ME unlocked state-of-the-art performance for robotics control problems that require a good amount of exploration, it also plagued these ME variants with limitations common among R

L algorithms that ME was free of, such as hyperparameter sensitivity, high stochasticity as well as training instability, including when the population size increases as some components are shared across the population in recent approaches. Furthermore, existing approaches mixing ME with RL tend to be tied to a specific RL algorithm, which effectively prevents their use on problems where the corresponding RL algorithm fails. To address these shortcomings, we introduce a flexible framework that allows the use of any RL algorithm and alleviates the aforementioned limitations by evolving populations of agents (whose definition include hyperparameters and all learnable parameters) instead of just policies. We demonstrate the benefits brought about by our framework through extensive numerical experiments on a number of robotics control problems, some of which with deceptive rewards, taken from the QD-RL literature. We open source an efficient JAX-based implementation of our algorithm in the QDax library.

Implicit Bias in Leaky ReLU Networks Trained on High-Dimensional Data
Spencer Frei,Gal Vardi,Peter Bartlett,Nathan Srebro,Wei Hu

The implicit biases of gradient-based optimization algorithms are conjectured to be a major factor in the success of modern deep learning. In this work, we investigate the implicit bias of gradient flow and gradient descent in two-layer fully-connected neural networks with leaky ReLU activations when the training data are nearly-orthogonal, a common property of high-dimensional data. For gradient flow, we leverage recent work on the implicit bias for homogeneous neural networks to show that asymptotically, gradient flow produces a neural network with rank at most two. Moreover, this network is an ℓ_2-max-margin solution (in parameter space), and has a linear decision boundary that corresponds to an approximate-max-margin linear predictor. For gradient descent, provided the random initialization variance is small enough, we show that a single step of gradient descent suffices to drastically reduce the rank of the network, and that the rank remains small throughout training. We provide experiments which suggest that a small initialization scale is important for finding low-rank neural networks with gradient descent.

Learning Test Time Augmentation with Cascade Loss Prediction
Siyang Pan,Jiaqian Yu,Dongwook Lee,Qiang Wang,ChangBeom Park,ByungIn Yoo

Data augmentation has been a successful common practice for improving the performance of deep neural network during training stage. In recent years, studies on test time augmentation (TTA) have also been promising due to its effectiveness on improving the robustness against out-of-distribution data at inference. Instead of simply adopting pre-defined handcrafted geometric operations such as croping and flipping, recent TTA methods learn predictive transformations which are supposed to provide the best performance gain on each test sample. However, the desired iteration number of transformation is proportional to the inference time of the predictor, and the gain by ensembling multiple augmented inputs still requires additional forward pass of the target model. In this paper, we propose a cascade method for test time augmentation prediction. It only requires a single forward pass of the transformation predictor, while can output multiple desirable transformations iteratively. These transformations will then be adopted sequentially on the test sample at once before the target model inference. The experimental results show that our method provides a better trade-off between computational cost and overall performance at test time, and shows significant improvement compared to existing methods.

Adaptive Computation with Elastic Input Sequence
Fuzhao Xue,Valerii Likhosherstov,Anurag Arnab,Neil Houlsby,Yi Tay,Mostafa Dehghani,Yang You

When solving a problem, human beings have the adaptive ability in terms of the type of information they use, the procedure they take, and the amount of time they spend approaching and solving the problem. However, most standard neural networks have the same function type and fixed computation budget on different samples regardless of their nature and difficulty. Adaptivity is a powerful paradigm a s it not only imbues practitioners with flexibility pertaining to the downstream usage of these models but can also serve as a powerful inductive bias for solving certain challenging classes of problems. In this work, we propose a new strategy, AdaTape, that enables dynamic computation in neural networks via adaptive tape tokens. AdaTape employs an elastic input sequence by equipping an existing architecture with a dynamic read and write tape. Specifically, we adaptively generate input sequences using tape tokens obtained from a tape bank that can either be trainable or generated from input data. We analyze the challenges and requirements to obtain dynamic sequence content and length, and propose the Adaptive Tape Reader (ATR) algorithm to achieve both objectives. Via extensive experiments on image recognition tasks, we show that AdaTape can achieve better performance while maintaining the computational cost.

Optimizing Data-Flow in Binary Neural Networks

Lorenzo Vorabbi,Davide Maltoni,Stefano Santi

Binary Neural Networks (BNNs) can significantly accelerate the inference time of a neural network by replacing its expensive floating-point arithmetic with bit-wise operations. Most existing solutions, however, do not fully optimize data flow through the BNN layers, and intermediate conversions from 1 to 16/32 bits often further hinder efficiency. We propose a novel training scheme that can increase data flow and parallelism in the BNN pipeline; specifically, we introduce a clipping block that decreases the data-width from 32 bits to 8. Furthermore, we reduce the internal accumulator size of a binary layer, usually kept using 32-bit to prevent data overflow without losing accuracy. Additionally, we provide an optimization of the Batch Normalization layer that both reduces latency and simplifies deployment. Finally, we present an optimized implementation of the Binary Direct Convolution for ARM instruction sets. Our experiments show a consistent improvement of the inference speed (up to 1.77 and $1.9 \times$ compared to two state-of-the-art BNNs frameworks) with no drop in accuracy for at least one full-precision model.

****

Gray-Box Gaussian Processes for Automated Reinforcement Learning

Gresa Shala,André Biedenkapp,Frank Hutter,Josif Grabocka

Despite having achieved spectacular milestones in an array of important real-world applications, most Reinforcement Learning (RL) methods are very brittle concerning their hyperparameters. Notwithstanding the crucial importance of setting the hyperparameters in training state-of-the-art agents, the task of hyperparameter optimization (HPO) in RL is understudied. In this paper, we propose a novel gray-box Bayesian Optimization technique for HPO in RL, that enriches Gaussian Processes with reward curve estimations based on generalized logistic functions. In a very large-scale experimental protocol, comprising 5 popular RL methods (DDPG, A2C, PPO, SAC, TD3), dozens of environments (Atari, Mujoco), and 7 HPO baselines, we demonstrate that our method significantly outperforms current HPO practices in RL.

****

Protein Sequence and Structure Co-Design with Equivariant Translation

Chence Shi,Chuanrui Wang,Jiarui Lu,Bozitao Zhong,Jian Tang

Proteins are macromolecules that perform essential functions in all living organisms. Designing novel proteins with specific structures and desired functions has been a long-standing challenge in the field of bioengineering. Existing approaches generate both protein sequence and structure using either autoregressive models or diffusion models, both of which suffer from high inference costs. In this paper, we propose a new approach capable of protein sequence and structure co-design, which iteratively translates both protein sequence and structure into the desired state from random initialization, based on context features given a priori. Our model consists of a trigonometry-aware encoder that reasons geometrical constraints and interactions from context features, and a roto-translation equivariant decoder that translates protein sequence and structure interdependently. Notably, all protein amino acids are updated in one shot in each translation step, which significantly accelerates the inference process. Experimental results across multiple tasks show that our model outperforms previous state-of-the-art baselines by a large margin, and is able to design proteins of high fidelity as regards both sequence and structure, with running time orders of magnitude less than sampling-based methods.

****

SGD Through the Lens of Kolmogorov Complexity

Gregory Schwartzman

We initiate a thorough study of the dynamics of stochastic gradient descent (SGD) under minimal assumptions using the tools of entropy compression. Specifically, we characterize a quantity of interest which we refer to as the \emph{accuracy discrepancy}. Roughly speaking, this measures the average discrepancy between the model accuracy on batches and large subsets of the entire dataset. We show that if this quantity is sufficiently large, then SGD finds a model which achieves perfect accuracy on the data in $O(1)$ epochs. On the contrary, if the model cannot perfectly fit the data, this quantity must remain below a \emph{global} threshold, which only depends on the size of the dataset and batch.

We use the above framework to lower bound the amount of randomness required to allow (non stochastic) gradient descent to escape from local minimas using perturbations. We show that even if the model is \emph{extremely overparameterized}, at least a linear (in the size of the dataset) number of random bits are required to guarantee that GD escapes local minimas in polynomial time.

Learning in temporally structured environments

Matt Jones,Tyler R. Scott,Mengye Ren,Gamaleldin Fathy Elsayed,Katherine Hermann,David Mayo,Michael Curtis Mozer

Natural environments have temporal structure at multiple timescales. This property is reflected in biological learning and memory but typically not in machine learning systems. We advance a multiscale learning method in which each weight in a neural network is decomposed as a sum of subweights with different learning and decay rates. Thus knowledge becomes distributed across different timescales, enabling rapid adaptation to task changes while avoiding catastrophic interference. First, we prove previous models that learn at multiple timescales, but with complex coupling between timescales, are equivalent to multiscale learning via a reparameterization that eliminates this coupling. The same analysis yields a new characterization of momentum learning, as a fast weight with a negative learning rate. Second, we derive a model of Bayesian inference over $1/f$ noise, a common temporal pattern in many online learning domains that involves long-range (power law) autocorrelations. The generative side of the model expresses $1/f$ noise as a sum of diffusion processes at different timescales, and the inferential side tracks these latent processes using a Kalman filter. We then derive a variational approximation to the Bayesian model and show how it is an extension of the multiscale learner. The result is an optimizer that can be used as a drop-in replacement in an arbitrary neural network architecture. Third, we evaluate the ability of these methods to handle nonstationarity by testing them in online prediction tasks characterized by $1/f$ noise in the latent parameters. We find that the Bayesian model significantly outperforms online stochastic gradient descent and two batch heuristics that rely preferentially or exclusively on more recent data. Moreover, the variational approximation performs nearly as well as the full Bayesian model, and with memory requirements that are linear in the size of the network.

Identifying Phase Transition Thresholds of Permuted Linear Regression via Message Passing

Hang Zhang,Ping Li

This paper considers the permuted linear regression, i.e., ${\mathbf{Y}} = {\mathbf{\Pi}}^{\natural}{\mathbf{X}}{\mathbf{B}}^{\natural} + {\mathbf{W}}$, where ${\mathbf{Y}} \in \mathbb{R}^{n\times m}, {\mathbf{\Pi}}^{\natural}\in\mathbb{R}^{n\times n}, {\mathbf{X}} \in \mathbb{R}^{n\times p}, {\mathbf{B}}^{\natural}\in

\mathbb{R}^{p\times m}$, and ${\mathbf{W}}\in \mathbb{R}^{n\times m}$ represent the observations, missing (or incomplete) information about ordering, sensing matrix, signal of interests, and additive sensing noise, respectively. As is shown in the previous work, there exists phase transition phenomena in terms of the \emph{signal-to-noise ratio} ($\mathsf{snr}$), number of permuted rows, etc. While all existing works only concern the convergence rates without specifying the associate constants in front of them, we give a precise identification of the phase transition thresholds via the message passing algorithm. Depending on whether the signal ${\mathbf{B}}^{\natural}$ is known or not, we separately identify the corresponding critical points around the phase transition regimes. Moreover, we provide numerical experiments and show the empirical phase transition points are well aligned with theoretical predictions.

RandProx: Primal-Dual Optimization Algorithms with Randomized Proximal Updates

Laurent Condat,Peter Richtárik

Proximal splitting algorithms are well suited to solving large-scale nonsmooth optimization problems, in particular those arising in machine learning. We propose a new primal–dual algorithm, in which the dual update is randomized; equivalently, the proximity operator of one of the function in the problem is replaced by a stochastic oracle. For instance, some randomly chosen dual variables, instead of all, are updated at each iteration. Or, the proximity operator of a function is called with some small probability only. A nonsmooth variance-reduction technique is implemented so that the algorithm finds an exact minimizer of the general problem involving smooth and nonsmooth functions, possibly composed with linear operators. We derive linear convergence results in presence of strong convexity; these results are new even in the deterministic case, when our algorithms reverts to the recently proposed Primal–Dual Davis–Yin algorithm. Some randomized algorithms of the literature are also recovered as particular cases (e.g., Point-SAGA). But our randomization technique is general and encompasses many unbiased mechanisms beyond sampling and probabilistic updates, including compression. Since the convergence speed depends on the slowest among the primal and dual contraction mechanisms, the iteration complexity might remain the same when randomness is used. On the other hand, the computation complexity can be significantly reduced. Overall, randomness helps getting faster algorithms. This has long been known for stochastic-gradient-type algorithms, and our work shows that this fully applies in the more general primal–dual setting as well.

****

Preserving Pre-trained Features Helps Calibrate Fine-tuned Language Models

Guande He,Jianfei Chen,Jun Zhu

Large pre-trained language models (PLMs) have demonstrated strong performance on natural language understanding (NLU) tasks through fine-tuning. However, fine-tuned models still suffer from overconfident predictions, especially in out-of-domain settings. In this paper, we tackle the problem of calibrating fine-tuned language models. We demonstrate that the PLMs are well-calibrated on the masked language modeling task with robust predictive confidence under domain shift, yet the fine-tuned models fail to retain such property due to catastrophic forgetting, which impacts the calibration on the downstream classification task. In light of these observations, we evaluate the calibration of several methods that preserve pre-trained features and show that preserving pre-trained features can improve the calibration of fine-tuned language models. Among these methods, our proposed method that encourages the fine-tuned model to learn generative representations with auxiliary language modeling objective achieves competitive accuracy and the lowest expected calibration error compared to several strong baselines under both in-domain and out-of-domain settings on three downstream NLU tasks.

****

A Hierarchical Bayesian Approach to Federated Learning

Minyoung Kim,Timothy Hospedales

We propose a novel hierarchical Bayesian approach to Federated learning (FL), where our models reasonably describe the generative process of clients' local data via hierarchical Bayesian modeling: constituting random variables of local mode

ls for clients that are governed by a higher-level global variate. Interestingly, the variational inference in our Bayesian model leads to an optimization problem whose block-coordinate descent solution becomes a distributed algorithm that is separable over clients and allows them not to reveal their own private data at all, thus fully compatible with FL. We also highlight that our block-coordinate algorithm has particular forms that subsume the well-known FL algorithms including Fed-Avg and Fed-Prox as special cases. That is, we not only justify the previous Fed-Avg and Fed-Prox algorithms whose learning protocols look intuitive but theoretically less underpinned, but also generalise them even further via principled Bayesian approaches. Beyond introducing novel modeling and derivations, we also offer convergence analysis showing that our block-coordinate FL algorithm converges to an (local) optimum of the objective at the rate of $O(1/\sqrt{t})$, the same rate as regular (centralised) SGD, as well as the generalisation error analysis where we prove that the test error of our model on unseen data is guaranteed to vanish as we increase the training data size, thus asymptotically optimal.

Neural Representations in Multi-Task Learning guided by Task-Dependent Contexts
Santiago Galella,Salva Ardid
The ability to switch between tasks effectively in response to external stimuli is a hallmark of cognitive control. Our brain is able to filter and to integrate external information to accomplish goal-directed behavior. Task switching occurs rapidly and efficiently, allowing us to perform multiple tasks with ease. In a similar way, deep learning models can be tailored to exhibit multi-task capabilities and achieve high performance across domains. Still, understanding how neural networks make predictions is crucial in many real-world applications.

In this study, we delve into neural representations learned by multi-tasking architectures. Concretely, we compare individual and parallel networks with task switching networks. Task-switching networks leverage task-dependent contexts to learn disentangled representations without hurting the overall task accuracy. We show that task-switching networks operate in an intermediate regime between individual and parallel. In addition, we show that shared representations are produced by the emergence neurons encoding multiple tasks. Furthermore, we study the role of contexts across network processing and show its role at aligning the task with the relevant features. Finally, we investigate how the magnitude of contexts affects the performance in task-switching networks.
****
MCTransformer: Combining Transformers And Monte-Carlo Tree Search For Offline Reinforcement Learning
Gur Yaari,Lior Rokach,Rami Puzis,Gilad Katz
Recent studies explored the framing of reinforcement learning as a sequence modeling problem, and then using Transformers to generate effective solutions. In this study, we introduce MCTransformer, a framework that combines Monte-Carlo Tree Search (MCTS) with Transformers. Our approach uses an actor-critic setup, where the MCTS component is responsible for navigating previously-explored states, aided by input from the Transformer. The Transformer controls the exploration and evaluation of new states, enabling an effective and efficient evaluation of various strategies. In addition to the development of highly effective strategies, our setup enables the use of more efficient sampling compared to existing MCTS-based solutions. MCTransformer is therefore able to perform a small number of evaluations for each newly-explored node, and to do so without degrading its performance. Our evaluation, conducted on the challenging and well-known problem of SameGame, shows that our approach outperforms both Transformer-based and MCTS-based solutions.
****
One-Step Estimator for Permuted Sparse Recovery
Hang Zhang,Ping Li
This paper considers the unlabeled sparse recovery under multiple measurements, i.e., ${\mathbf{Y}} = {\mathbf{\Pi}}^{\natural}{\mathbf{X}} {\mathbf{B}}^{\natur

al} + {\mathbf{W}}$, where ${\mathbf{Y}} \in \mathbb{R}^{n\times m}, {\mathbf{\Pi}}^{\natural}\in \mathbb{R}^{n\times n}, {\mathbf{X}} \in \mathbb{R}^{n\times p}, {\mathbf{B}}^{\natural}\in \mathbb{R}^{p\times m}, {\mathbf{W}}\in \mathbb{R}^{n\times m}$ represents the observations, missing (or incomplete) correspondence information, sensing matrix, sparse signals, and additive sensing noise, respectively. Different from the previous works on multiple measurements ($m > 1$) which all focus on the sufficient samples regime, namely, $n > p$, we consider a sparse matrix $\mathbf{B}^{\natural}$ and investigate the insufficient samples regime (i.e., $n \ll p$) for the first time. To begin with, we establish the lower bound on the sample number and \emph{signal-to-noise ratio} (${\mathsf{SNR}}$) for the correct permutation recovery. Moreover, we present a simple yet effective estimator. Under mild conditions, we show that our estimator can restore the correct correspondence information with high probability. Numerical experiments are presented to corroborate our theoretical claims.

Scaling Laws vs Model Architectures: How does Inductive Bias Influence Scaling?

Yi Tay,Mostafa Dehghani,Samira Abnar,Hyung Won Chung,William Fedus,Jinfeng Rao,Sharan Narang,Vinh Q. Tran,Dani Yogatama,Donald Metzler

There have been a lot of interest in the scaling properties of Transformer models \citep{kaplan2020scaling}. However, not much has been done on the front of investigating the effect of scaling properties of different inductive biases and model architectures. Do model architectures scale differently? If so, how does inductive bias affect scaling behaviour? How does this influence upstream (pretraining) and downstream (transfer)? This paper conducts a systematic study of scaling behaviour of ten diverse model architectures such as Transformers, Switch Transformers, Universal Transformers, Dynamic convolutions, Performers, and recently proposed MLP-Mixers. Via extensive experiments, we show that (1) architecture is an indeed an important consideration when performing scaling and (2) the best performing model can fluctuate at different scales. We believe that the findings outlined in this work has significant implications to how model architectures are currently evaluated in the community.

Guarded Policy Optimization with Imperfect Online Demonstrations

Zhenghai Xue,Zhenghao Peng,Quanyi Li,Zhihan Liu,Bolei Zhou

The Teacher-Student Framework (TSF) is a reinforcement learning setting where a teacher agent guards the training of a student agent by intervening and providing online demonstrations. Assuming optimal, the teacher policy has the perfect timing and capability to intervene in the learning process of the student agent, providing safety guarantee and exploration guidance. Nevertheless, in many real-world settings it is expensive or even impossible to obtain a well-performing teacher policy. In this work, we relax the assumption of a well-performing teacher and develop a new method that can incorporate arbitrary teacher policies with modest or inferior performance. We instantiate an Off-Policy Reinforcement Learning algorithm, termed Teacher-Student Shared Control (TS2C), which incorporates teacher intervention based on trajectory-based value estimation. Theoretical analysis validates that the proposed TS2C algorithm attains efficient exploration and substantial safety guarantee without being affected by the teacher's own performance. Experiments on various continuous control tasks show that our method can exploit teacher policies at different performance levels while maintaining a low training cost. Moreover, the student policy surpasses the imperfect teacher policy in terms of higher accumulated reward in held-out testing environments. Code is available at https://metadriverse.github.io/TS2C.

Fast Nonlinear Vector Quantile Regression

Aviv A. Rosenberg,Sanketh Vedula,Yaniv Romano,Alexander Bronstein

$$
\newcommand{\rvar}[1]{\mathrm {#1}}
\newcommand{\rvec}[1]{\boldsymbol{\mathrm{#1}}}
$$

Quantile regression (QR) is a powerful tool for estimating one or more condition

al quantiles of a target variable $\rvar{Y}$ given explanatory features $\rvec{X}$.
A limitation of QR is that it is only defined for scalar target variables, due to the formulation of its objective function, and since the notion of quantiles has no standard definition for multivariate distributions.
Recently, vector quantile regression (VQR) was proposed as an extension of QR for vector-valued target variables, thanks to a meaningful generalization of the notion of quantiles to multivariate distributions via optimal transport.
Despite its elegance, VQR is arguably not applicable in practice due to several limitations:
(i) it assumes a linear model for the quantiles of the target $\rvec{Y}$ given the features $\rvec{X}$;
(ii) its exact formulation is intractable even for modestly-sized problems in terms of target dimensions, number of regressed quantile levels, or number of features, and its relaxed dual formulation may violate the monotonicity of the estimated quantiles;
(iii) no fast or scalable solvers for VQR currently exist.

In this work we fully address these limitations, namely:
(i) We extend VQR to the non-linear case, showing substantial improvement over linear VQR;
(ii) We propose {vector monotone rearrangement}, a method which ensures the quantile functions estimated by VQR are monotone functions;
(iii) We provide fast, GPU-accelerated solvers for linear and nonlinear VQR which maintain a fixed memory footprint, and demonstrate that they scale to millions of samples and thousands of quantile levels;
(iv) We release an optimized python package of our solvers as to widespread the use of VQR in real-world applications.
****

Multi Task Learning of Different Class Label Representations for Stronger Models
Judah A Goldfeder,Boyuan Chen,Hod Lipson
We find that the way in which class labels are represented can have a powerful effect on how well models trained on them learn. In classification, the standard way of representing class labels is as one-hot vectors. We present a new way of representing class labels called Binary Labels, where each class label is a large binary vector. We further introduce a new paradigm, multi task learning on different label representations. We train a network on two tasks. The main task is to classify images based on their one-hot label, and the auxiliary task is to classify images based on their Binary Label. We show that networks trained on both tasks have many advantages, including higher accuracy across a wide variety of datasets and architectures, both when trained from scratch and when using transfer learning. Networks trained on both tasks are also much more effective when training data is limited, and seem to do especially well on more challenging problems.

On the Existence of a Trojaned Twin Model
Songzhu Zheng,Yikai Zhang,Weimin Lyu,Mayank Goswami,Anderson Schneider,Yuriy Nevmyvaka,Haibin Ling,Chao Chen
We study the Trojan Attack problem, where malicious attackers sabotage deep neural network models with poisoned training data. In most existing works, the effectiveness of the attack is largely overlooked; many attacks can be ineffective or inefficient for certain training schemes, e.g., adversarial training. In this paper, we adopt a novel perspective and look into the quantitative relationship between a clean model and its Trojaned counterpart. We formulate a successful attack using classic machine learning language. Under mild assumptions, we show theoretically that there exists a Trojaned model, named Trojaned Twin, that is very close to the

clean model. This attack can be achieved by simply using a universal Trojan trigger intrinsic to the data distribution. This has powerful implications in practice; the Trojaned twin model has enhanced attack efficacy and strong resiliency against detection. Empirically, we show that our method achieves consistent attack efficacy across different training schemes, including the challenging adversarial training scheme. Furthermore, this Trojaned twin model is robust against SoTA detection methods

On Information Maximisation in Multi-View Self-Supervised Learning

Borja Rodríguez Gálvez,Arno Blaas,Xavier Suau,Jason Ramapuram,Dan Busbridge,Luca Zappella

The strong performance of multi-view self-supervised learning (SSL) prompted the development of many different approaches (e.g. SimCLR, BYOL, and DINO). A unified understanding of how each of these methods achieves its performance has been limited by apparent differences across objectives and algorithmic details. Through the lens of information theory, we show that many of these approaches are maximising an approximate lower bound on the mutual information between the representations of multiple views of the same datum. Further, we show that this bound decomposes into a ``reconstruction" term, treated identically by all SSL methods, and an ``entropy" term, where existing SSL methods differ in their treatment. We prove that an exact optimisation of both terms of this lower bound encompasses and unifies current theoretical properties such as recovering the true latent variables of the underlying generative process (Zimmermann et al., 2021) or or isolating content from style in such true latent variables (Von Kügelgen et al., 2021). This theoretical analysis motivates a naive but principled objective (EntRec), that exactly optimises both the reconstruction and entropy terms, thus benefiting from said theoretical properties unlike other SSL frameworks. Finally, we show EntRec achieves a downstream performance on-par with existing SSL methods on ImageNet (69.7% after 400 epochs) and on an array of transfer tasks when pre-trained on ImageNet. Furthermore, EntRec is more robust to modifying the batch size, a sensitive hyperparameter in other SSL methods.

Leveraging Large Language Models for Multiple Choice Question Answering

Joshua Robinson,David Wingate

While large language models (LLMs) like GPT-3 have achieved impressive results on multiple choice question answering (MCQA) tasks in the zero, one, and few-shot settings, they generally lag behind the MCQA state of the art (SOTA). MCQA tasks have traditionally been presented to LLMs like cloze tasks. An LLM is conditioned on a question (without the associated answer options) and its chosen option is the one assigned the highest probability after normalization (for length, etc.). A more natural prompting approach is to present the question and answer options to the LLM jointly and have it output the symbol (e.g., “A”) associated with its chosen answer option. This approach allows the model to explicitly compare answer options, reduces computational costs, and mitigates the effects of tokenization scheme and answer option representations on answer selection. For the natural approach to be effective, the LLM it is used with must be able to associate answer options with the symbols that represent them. The LLM needs what we term multiple choice symbol binding (MCSB) ability. This ability varies greatly by model. We show that a model with high MCSB ability performs much better with the natural approach than with the traditional approach across 20 diverse datasets and largely closes the gap with the SOTA, suggesting that the MCQA ability of LLMs has been previously underestimated.

Learning with Logical Constraints but without Shortcut Satisfaction

Zenan Li,Zehua Liu,Yuan Yao,Jingwei Xu,Taolue Chen,Xiaoxing Ma,Jian L\"{u}

Recent studies have started to explore the integration of logical knowledge into deep learning via encoding logical constraints as an additional loss function. However, existing approaches tend to vacuously satisfy logical constraints through shortcuts, failing to fully exploit the knowledge. In this paper, we present a new framework for learning with logical constraints. Specifically, we address the shortcut satisfaction issue by introducing dual variables for logical connectives, encoding how the constraint is satisfied. We further propose a variational framework where the encoded logical constraint is expressed as a distributional loss that is compatible with the model's original training loss. The theoretical analysis shows that the proposed approach bears some nice properties, and the experimental evaluations demonstrate its superior performance in both model generalizability and constraint satisfaction.

****

Certified Training: Small Boxes are All You Need

Mark Niklas Mueller,Franziska Eckert,Marc Fischer,Martin Vechev

To obtain, deterministic guarantees of adversarial robustness, specialized training methods are used. We propose, SABR, a novel such certified training method, based on the key insight that propagating interval bounds for a small but carefully selected subset of the adversarial input region is sufficient to approximate the worst-case loss over the whole region while significantly reducing approximation errors. We show in an extensive empirical evaluation that SABR outperforms existing certified defenses in terms of both standard and certifiable accuracies across perturbation magnitudes and datasets, pointing to a new class of certified training methods promising to alleviate the robustness-accuracy trade-off.

****

Counterfactual Generation Under Confounding

Abbavaram Gowtham Reddy,Saloni Dash,Amit Sharma,Vineeth N. Balasubramanian

A machine learning model, under the influence of observed or unobserved confounders in the training data, can learn spurious correlations and fail to generalize when deployed. For image classifiers, augmenting a training dataset using counterfactual examples has been empirically shown to break spurious correlations. However, the counterfactual generation task itself becomes more difficult as the level of confounding increases. Existing methods for counterfactual generation under confounding consider a fixed set of interventions (e.g., texture, rotation) and are not flexible enough to capture diverse data-generating processes. Given a causal generative process, we formally characterize the adverse effects of confounding on any downstream tasks and show that the correlation between generative factors (attributes) can be used to quantitatively measure confounding between generative factors. To minimize such correlation, we propose a counterfactual generation method that learns to modify the value of any attribute in an image and generate new images given a set of observed attributes, even when the dataset is highly confounded. These counterfactual images are then used to regularize the downstream classifier such that the learned representations are the same across various generative factors conditioned on the class label. Our method is computationally efficient, simple to implement, and works well for any number of generative factors and confounding variables. Our experimental results on both synthetic (MNIST variants) and real-world (CelebA) datasets show the usefulness of our approach.

****

Regression with Label Differential Privacy

Badih Ghazi,Pritish Kamath,Ravi Kumar,Ethan Leeman,Pasin Manurangsi,Avinash Varadarajan,Chiyuan Zhang

We study the task of training regression models with the guarantee of _label_ differential privacy (DP). Based on a global prior distribution of label values, which could be obtained privately, we derive a label DP randomization mechanism that is optimal under a given regression loss function. We prove that the optimal mechanism takes the form of a "randomized response on bins", and propose an efficient algorithm for finding the optimal bin values. We carry out a thorough experimental evaluation on several datasets demonstrating the efficacy of our algorithm.

Hierarchical Abstraction for Combinatorial Generalization in Object Rearrangement

Michael Chang,Alyssa Li Dayan,Franziska Meier,Thomas L. Griffiths,Sergey Levine,Amy Zhang

Object rearrangement is a challenge for embodied agents because solving these tasks requires generalizing across a combinatorially large set of configurations of entities and their locations. Worse, the representations of these entities are unknown and must be inferred from sensory percepts. We present a hierarchical abstraction approach to uncover these underlying entities and achieve combinatorial generalization from unstructured visual inputs. By constructing a factorized transition graph over clusters of entity representations inferred from pixels, we show how to learn a correspondence between intervening on states of entities in the agent's model and acting on objects in the environment. We use this correspondence to develop a method for control that generalizes to different numbers and configurations of objects, which outperforms current offline deep RL methods when evaluated on simulated rearrangement tasks.

****

SRBGCN: Tangent space-Free Lorentz Transformations for Graph Feature Learning

Abdelrahman Mostafa,Wei Peng,Guoying Zhao

Hyperbolic graph convolutional networks have been successfully applied to represent complex graph data structures. However, optimization on Riemannian manifolds is nontrivial thus most of the existing hyperbolic networks build the network operations on the tangent space of the manifold, which is a Euclidean local approximation. This distorts the learnt features, limits the representation capacity of the network and makes it hard to optimize the network. In this work, we introduce a fully hyperbolic graph convolutional network (GCN), referred to as SRBGCN, which performs neural computations such as feature transformation and aggregation directly on the manifold, using manifold-preserving Lorentz transformations that include spatial rotation (SR) and boost (B) operations. Experiments conducted on static graph datasets for node classification and link prediction tasks validate the performance of the proposed method.

****

Transfer NAS with Meta-learned Bayesian Surrogates

Gresa Shala,Thomas Elsken,Frank Hutter,Josif Grabocka

While neural architecture search (NAS) is an intensely-researched area, approaches typically still suffer from either (i) high computational costs or (ii) lack of robustness across datasets and experiments. Furthermore, most methods start searching for an optimal architecture from scratch, ignoring prior knowledge. This is in contrast to the manual design process by researchers and engineers that leverage previous deep learning experiences by, e.g., transferring architectures from previously solved, related problems.

We propose to adopt this human design strategy and introduce a novel surrogate for NAS, that is meta-learned across prior architecture evaluations across different datasets. We utilizes Bayesian Optimization (BO) with deep-kernel Gaussian Processes, graph neural networks for the architecture embeddings and a transformer-based set encoder of datasets. As a result, our method consistently achieves state-of-the-art results on six computer vision datasets, while being as fast as one-shot NAS methods.

****

Mitigating the Limitations of Multimodal VAEs with Coordination-Based Approach

Masahiro Suzuki,Yutaka Matsuo

One of the key challenges in multimodal variational autoencoders (VAEs) is inferring a joint representation from arbitrary subsets of modalities. The state-of-the-art approach to achieving this is to sub-sample the modality subsets and learn to generate all modalities from them. However, this sub-sampling in the mixture-based approach has been shown to degrade other important features of multimodal VAEs, such as quality of generation, and furthermore, this degradation is theoretically unavoidable. In this study, we focus on another approach to learning the joint representation by bringing unimodal inferences closer to joint inference from all modalities, which does not have the above limitation. Although there have been models that can be categorized under this approach, they were derived from different backgrounds; therefore, the relation and superiority between them were not clear. To take a unified view, we first categorize them as coordination-based multimodal VAEs and show that these can be derived from the same multimodal evidence lower bound (ELBO) and that the difference in their performance is related to whether they are more tightly lower bounded. Next, we point out that these existing coordination-based models perform poorly on cross-modal generation (or cross-coherence) because they do not learn to reconstruct modalities from unimodal inferences. Therefore, we propose a novel coordination-based model that incorporates these unimodal reconstructions, which avoids the limitations of both mixture and coordination-based models. Experiments with diverse and challenging datasets show that the proposed model mitigates the limitations in multimodal VAEs and performs well in both cross-coherence and generation quality.

Incompatibility between Deterministic Policy and Generative Adversarial Imitation Learning

Wanying Wang,Yirui Zhou,Chaomin Shen,Yangchun Zhang,Jian Tang,Zhiyuan Xu,Yaxin Peng

Deterministic policies are widely applied in generative adversarial imitation learning (GAIL). When adopting these policies, some GAIL variants modify the reward function to avoid training instability. However, the mechanism behind this instability is still largely unknown. In this paper, we capture the instability through the underlying exploding gradients theoretically in the updating process. Our novelties lie in the following aspects: 1) By employing multivariate Gaussian policy with small covariance to approximate deterministic policy, we establish and prove the probabilistic lower bound for the exploding gradients, which can describe the degree of instability universally, while the stochastic policy will never suffer from such pathology subsequently. 2) We also prove that the modified reward function of adversarial inverse reinforcement learning (AIRL) can relieve exploding gradients, but at the expense of ``non-confidence''. Experiments and a toy demo support our analysis.

FiD-Light: Efficient and Effective Retrieval-Augmented Text Generation

Sebastian Hofstätter,Jiecao Chen,Karthik Raman,Hamed Zamani

Retrieval-augmented generation models offer many benefits over standalone language models: besides a textual answer to a given query they provide provenance items retrieved from an updateable knowledge base. However, they are also more complex systems and need to handle long inputs. In this work, we introduce FiD-Light to strongly increase the efficiency of the state-of-the-art retrieval-augmented FiD model, while maintaining the same level of effectiveness. Our FiD-Light model constrains the information flow from the encoder (which encodes passages separately) to the decoder (using concatenated encoded representations). Furthermore, we adapt FiD-Light with re-ranking capabilities through textual source pointers, to improve the top-ranked provenance precision. Our experiments on a diverse set of seven knowledge intensive tasks (KILT) show FiD-Light consistently improves the Pareto frontier between query latency and effectiveness. FiD-Light with source pointing sets substantial new state-of-the-art results on six KILT tasks for combined text generation and provenance retrieval evaluation, while maintaining reasonable efficiency.

Contrastive Learning of Molecular Representation with Fragmented Views

Seojin Kim,Jaehyun Nam,Junsu Kim,Hankook Lee,Sungsoo Ahn,Jinwoo Shin

Molecular representation learning is a fundamental task for AI-based drug design and discovery. Contrastive learning is an attractive framework for this task, as also evidenced in various domains of representation learning, e.g., image, language, and speech. However, molecule-specific ways of constructing good positive or negative views in contrastive training under consideration of their chemical semantics have been relatively under-explored. In this paper, we consider a molecule as a bag of meaningful fragments, e.g., functional groups, by disconnecting a non-ring single bond as the semantic-preserving transformation. Then, we sug

gest to construct a complete (or incomplete) bag of fragments as the positive (or negative) views of a molecule: each fragment loses chemical substructures from the original molecule, while the union of the fragments does not. Namely, this provides easy positive and hard negative views simultaneously for contrastive representation learning so that it can selectively learn useful features and ignore nuisance features. Furthermore, we additionally suggest to optimize the torsional angle reconstruction loss around the fragmented bond to incorporate with 3D geometric structure in the pre-training dataset. Our experiments demonstrate that our scheme outperforms prior state-of-the-art molecular representation learning methods across various downstream molecule property prediction tasks.

Sharp Convergence Analysis of Gradient Descent for Deep Linear Neural Networks
Hongru Zhao,Jinchao Xu

This paper provides sharp rates of convergence of the gradient descent (GD) method for deep linear neural networks with different random initialization. This study touches upon one major open theoretical problem in machine learning: why deep neural networks trained with GD methods are efficient in many practical applications. While the solution of this problem is still beyond reach for general nonlinear deep neural networks, there have been extensive efforts in the literature in studying relevant questions for deep linear neural networks and there are many interesting results in this research direction. For example, recent results on the loss landscape show that even though the loss function of deep linear neural networks is non-convex, every local minimizer is also a global minimizer. When the GD method is applied to train the deep linear networks, it has been shown in the literature that the convergence behavior of the GD method depends on the initialization. In this paper, we obtain the sharp rate of convergence of GD for deep linear networks, and we show that this rate does not depend on the types of random initialization. Furthermore, we show that the depth of the network does not affect the optimal rate of convergence, provided that the width of each hidden layer is appropriately large.

Selective Frequency Network for Image Restoration
Yuning Cui,Yi Tao,Zhenshan Bing,Wenqi Ren,Xinwei Gao,Xiaochun Cao,Kai Huang,Alois Knoll

Image restoration aims to reconstruct the latent sharp image from its corrupted counterpart. Besides dealing with this long-standing task in the spatial domain, a few approaches seek solutions in the frequency domain in consideration of the large discrepancy between spectra of sharp/degraded image pairs. However, these works commonly utilize transformation tools, e.g., wavelet transform, to split features into several frequency parts, which is not flexible enough to select the most informative frequency component to recover. In this paper, we exploit a multi-branch and content-aware module to decompose features into separate frequency subbands dynamically and locally, and then accentuate the useful ones via channel-wise attention weights. In addition, to handle large-scale degradation blurs, we propose an extremely simple decoupling and modulation module to enlarge the receptive field via global and window-based average pooling. Integrating two developed modules into a U-Net backbone, the proposed Selective Frequency Network (SFNet) performs favorably against state-of-the-art algorithms on five image restoration tasks, including single-image defocus deblurring, image dehazing, image motion deblurring, image desnowing, and image deraining.

Contextualized Generative Retrieval
Hyunji Lee,JaeYoung Kim,Hoyeon Chang,Hanseok Oh,Sohee Yang,vladimir karpukhin,Yi Lu,Minjoon Seo

The text retrieval task is mainly performed in two ways: the bi-encoder approach and the generative approach. The bi-encoder approach maps the document and query embeddings to common vector space and performs a nearest neighbor search. It stably shows high performance and efficiency across different domains but has an embedding space bottleneck as it interacts in L2 or inner product space. The generative retrieval model retrieves by generating a target sequence and overcomes

the embedding space bottleneck by interacting in the parametric space. However, it fails to retrieve the information it has not seen during the training process as it depends solely on the information encoded in its own model parameters. To leverage the advantages of both approaches, we propose Contextualized Generative Retrieval model, which uses contextualized embeddings (output embeddings of a language model encoder) as vocab embeddings at the decoding step of generative retrieval. The model uses information encoded in both the non-parametric space of contextualized token embeddings and the parametric space of the generative retrieval model. Our approach of generative retrieval with contextualized vocab embeddings shows higher performance than generative retrieval with only vanilla vocab embeddings in the document retrieval task, an average of 6% higher performance in KILT (NQ, TQA) and 2X higher in NQ-320k, suggesting the benefits of using contextualized embedding in generative retrieval models.
****

Mirror Training for Input Convex Neural Network

Jiaqi Wu,Yang Weng

The input convex neural network (ICNN) aims to learn a convex function from the input to the output by using non-decreasing convex activation functions and non-negativity constraints on the weight parameters of some layers. However, in practice, it loses some representation power because of these non-negativity parameters of the hidden units, even though the design of the ``passthrough'' layer can partially address this problem. To solve issues caused by these non-negativity constraints, we use a duplication input pair trick, i.e., the negation of the original input as part of the new input in our structure. This new method will preserve the convexity of the function from the original input to the output and tackle the representation problem in training. Additionally, we design a mirror unit to address this problem further, making the network Mirror ICNN. Moreover, we propose a recurrent input convex neural network (RICNN) structure to deal with the time-series problems. The recurrent unit of the structure can be ICNN or any other convex variant of ICNN. This structure can maintain convexity by constraining the mapping from the hidden output at time step t to the input of the next time step $t+1$. The experiments can support our design, including the simple numerical curve fitting, power system hosting capacity dataset regression, and the MNIST dataset classification.
****

Scaling Up Probabilistic Circuits by Latent Variable Distillation

Anji Liu,Honghua Zhang,Guy Van den Broeck

Probabilistic Circuits (PCs) are a unified framework for tractable probabilistic models that support efficient computation of various probabilistic queries (e.g., marginal probabilities). One key challenge is to scale PCs to model large and high-dimensional real-world datasets: we observe that as the number of parameters in PCs increases, their performance immediately plateaus. This phenomenon suggests that the existing optimizers fail to exploit the full expressive power of large PCs. We propose to overcome such bottleneck by latent variable distillation: we leverage the less tractable but more expressive deep generative models to provide extra supervision over the latent variables of PCs. Specifically, we extract information from Transformer-based generative models to assign values to latent variables of PCs, providing guidance to PC optimizers. Experiments on both image and language modeling benchmarks (e.g., ImageNet and WikiText-2) show that latent variable distillation substantially boosts the performance of large PCs compared to their counterparts without latent variable distillation. In particular, on the image modeling benchmarks, PCs achieve competitive performance against some of the widely-used deep generative models, including variational autoencoders and flow-based models, opening up new avenues for tractable generative modeling. Our code can be found at https://github.com/UCLA-StarAI/LVD.

Oscillation Neural Ordinary Differential Equations

Muhao Guo,Yang Weng

Neural ordinary differential equations (NODEs) have received a lot of attention in recent years due to their memory efficiency. Different from traditional deep learning, it defines a continuous deep learning architecture based on the theory of ordinary differential equations (ODEs), which also improves the interpretability of deep learning. However, it has several obvious limitations, such as a NODE is not a universal approximator, it requires a large number of function evaluations (NFEs), and it has a slow convergence rate. We address these drawbacks by modeling and adding an oscillator to the framework of the NODEs. The oscillator enables the trajectories of our model to cross each other. We prove that our model is a universal approximator, even in the original input space. Due to the presence of oscillators, the flows learned by the model will be simpler, thus our model needs fewer NFEs and has a faster convergence speed. We apply our model to various tasks including classification and time series extrapolation, then compare several metrics including accuracy, NFEs, and convergence speed. The experiments show that our model can achieve better results compared to the existing baselines.

Improving Differentiable Neural Architecture Search by Encouraging Transferability

Parth Sheth,Pengtao Xie

Differentiable neural architecture search methods are increasingly popular due to their computational efficiency. However, these methods have unsatisfactory generalizability and stability. Their searched architectures are often degenerate with a dominant number of skip connections and perform unsatisfactorily on test data. Existing methods for solving this problem have a variety of limitations, such as cannot prevent the happening of architecture degeneration, being excessively restrictive in setting the number of skip connections, etc. To address these limitations, we propose a new approach for improving the generalizability and stability of differentiable NAS, by developing a transferability-encouraging tri-level optimization framework which improves the architecture of a main model by encouraging good transferability to an auxiliary model. Our framework involves three stages performed end-to-end: 1) train network weights of a main model; 2) transfer knowledge from the main model to an auxiliary model; 3) optimize the architecture of the main model by maximizing its transferability to the auxiliary model. We propose a new knowledge transfer approach based on matching quadruple relative similarities. Experiments on several datasets demonstrate the effectiveness of our method.

MA-BERT: Towards Matrix Arithmetic-only BERT Inference by Eliminating Complex Non-Linear Functions

Neo Wei Ming,Zhehui Wang,Cheng Liu,Rick Siow Mong Goh,Tao Luo

Due to their superior results, Transformer-based models such as BERT have become de facto standards in many Natural Language Processing (NLP) applications. However, the intensive use of complex non-linear functions within the Transformer architecture impairs its computing efficiency and complicates corresponding accelerator designs, because non-linear functions are generally computation-intensive and require special hardware support. In light of this, we propose MA-BERT, which allows matrix arithmetic-only operations in Transformer-based NLP models and achieves efficient inference with negligible accuracy loss. Specifically, we propose four correlated techniques that include approximating softmax with a two-layer neural network, replacing GELU with ReLU, fusing normalization layers with adjacent linear layers, and leveraging knowledge transfer from baseline models. Through these techniques, we are able to eliminate the major non-linear functions in Transformer-based models and obtain MA-BERT with only matrix arithmetic and trivial ReLU operations without compromising on accuracy. With mainly regular matrix arithmetic operations, MA-BERT enables hardware-friendly processing on various computing engines, including CPUs and GPUs. Our experimental results show that MA-BERT achieves up to 27% and 41% reduction in inference time on CPU and GPU, respectively, with comparable accuracy on many downstream tasks compared to the baseline BERT models.

Automatically Answering and Generating Machine Learning Final Exams

Sarah Zhang,Reece S Shuttleworth,Zad Chin,Pedro Lantigua,Saisamrit Surbehera,Gregory Hunter,Derek Austin,Yann Hicke,Leonard Tang,Sathwik Karnik,Darnell Granberry,Iddo Drori

Can a machine learn machine learning? We propose to answer this question using the same criteria we use to answer a similar question: can a human learn machine learning? We automatically answer final exams in MIT's recent large machine learning course and generate new questions at a human level. Recently, program synthesis and few-shot learning solved university-level problem set questions in mathematics and STEM courses at a human level. In this work, we solve questions from final exams that differ from problem sets in several ways: the questions are longer, have multiple parts, are more complicated, and span a broader set of topics. We provide a new dataset and benchmark of questions from machine learning final exams and code for automatically answering these questions and generating new questions. To make our dataset a reproducible benchmark, we use automatic checkers for multiple choice questions, questions with numeric answers, and questions with expression answers, and evaluate a large free language model, Meta’s OPT, and compare the results with Open AI’s GPT-3 and Codex. A student survey comparing the quality, appropriateness, and difficulty of machine-generated questions with human-written questions shows that across multiple aspects, machine-generated questions are indistinguishable from human-generated questions and are suitable for final exams. We perform ablation studies comparing zero-shot learning with few-shot learning, chain-of-thought prompting, GPT-3 and OPT pre-trained on text and Codex fine-tuned on code on a range of machine learning topics and find that few-shot learning methods perform best. We make our data and code publicly available for the machine learning community.

CAT: Collaborative Adversarial Training

xingbin liu,Huafeng Kuang,Xianming Lin,GUANNAN JIANG,YONGJIAN WU,Xi Wang,Rongrong Ji

Adversarial training can improve the robustness of neural networks. Previous adversarial training methods focus on a single training strategy and do not consider the collaboration between different training strategies. In this paper, we find different adversarial training methods have distinct robustness for sample instances. For example, an instance can be correctly classified by a model trained using standard adversarial training (AT) but not by a model trained using TRADES, and vice versa. Based on this phenomenon, we propose a collaborative adversarial training framework to improve the robustness of neural networks. Specifically, we simultaneously use different adversarial training methods to train two robust models from scratch. We input the adversarial examples generated by each network to the peer network and use the logit of the peer network to guide the training of its network. Collaborative Adversarial Training (CAT) can improve both robustness and accuracy. Finally, Extensive experiments on CIFAR-10 and CIFAR-100 validated the effectiveness of our method.

CAT achieved new state-of-the-art robustness without using any additional data on CIFAR-10 under the Auto-Attack benchmark.

Efficient Certified Training and Robustness Verification of Neural ODEs

Mustafa Zeqiri,Mark Niklas Mueller,Marc Fischer,Martin Vechev

Neural Ordinary Differential Equations (NODEs) are a novel neural architecture, built around initial value problems with learned dynamics which are solved during inference. Thought to be inherently more robust against adversarial perturbations, they were recently shown to be vulnerable to strong adversarial attacks, highlighting the need for formal guarantees. However, despite significant progress in robustness verification for standard feed-forward architectures, the verification of high dimensional NODEs remains an open problem. In this work we address this challenge and propose GAINS, an analysis framework for NODEs combining three key ideas: (i) a novel class of ODE solvers, based on variable but discrete time steps, (ii) an efficient graph representation of solver trajectories, and (iii) a novel abstraction algorithm operating on this graph representation. Together, these advances enable the efficient analysis and certified training of high

-dimensional NODEs, by reducing the runtime from an intractable $\mathcal{O}(\exp(d)+\exp(T))$ to $\mathcal{O}(d+T^2\log^2T)$ in the dimensionality d and integration time T. In an extensive evaluation on computer vision (MNIST and Fashion-MNIST) and time-series forecasting (Physio-Net) problems, we demonstrate the effectiveness of both our certified training and verification methods.

Arbitrary Virtual Try-on Network: Characteristics Representation and Trade-off between Body and Clothing

Yu Liu,Mingbo Zhao,Zhao Zhang,Jicong Fan,Yang Lou,Shuicheng Yan

Deep learning based virtual try-on system has achieved some encouraging progress recently, but there still remain several big challenges that need to be solved, such as trying on arbitrary clothes of all types, trying on the clothes from one category to another and generating image-realistic results with few artifacts. To handle this issue, we propose the Arbitrary Virtual Try-On Network (AVTON) that is utilized for all-type clothes, which can synthesize realistic try-on images by preserving and trading off characteristics of the target clothes and the reference person. Our approach includes three modules: 1) Limbs Prediction Module, which is utilized for predicting the human body parts by preserving the characteristics of the reference person. This is especially good for handling cross-category try-on task (e.g., long sleeves \(\leftrightarrow\) short sleeves or long pants \(\leftrightarrow\) skirts, etc.), where the exposed arms or legs with the skin colors and details can be reasonably predicted; 2) Improved Geometric Matching Module, which is designed to warp clothes according to the geometry of the target person. We improve the TPS-based warping method with a compactly supported radial function (Wendland's \(\Psi\)-function); 3) Trade-Off Fusion Module, which is to trade off the characteristics of the warped clothes and the reference person. This module is to make the generated try-on images look more natural and realistic based on a fine-tuning symmetry of the network structure. Extensive simulations are conducted and our approach can achieve better performance compared with the state-of-the-art virtual try-on methods.

A Benchmark Dataset for Learning from Label Proportions

Anand Paresh Brahmbhatt,Mohith Pokala,Rishi Saket,Aravindan Raghuveer

Learning from label proportions (LLP) has recently emerged as an important technique of weakly supervised learning on aggregated labels. In LLP, a model is trained on groups (a.k.a bags) of feature-vectors and their corresponding label proportions to predict labels for individual feature-vectors. While previous works have developed a variety of techniques for LLP, including novel loss functions, model architectures and their optimization, they typically evaluated their methods on pseudo-synthetically generated LLP training data using common small scale supervised learning datasets by randomly sampling or partitioning their instances into bags. Despite growing interest in this important task there are no large scale open source LLP benchmarks to compare various approaches. Construction of such a benchmark is hurdled by two challenges a) lack of natural large scale LLP like data, b) large number of mostly artificial methods of forming bags from instance level datasets.

In this paper we propose LLP-Bench: a large scale LLP benchmark constructed from the Criteo Kaggle CTR dataset. We do an in-depth, systematic study of the Criteo dataset and propose a methodology to create a benchmark as a collection of diverse and large scale LLP datasets. We choose the Criteo dataset since it admits multiple natural collections of bags formed by grouping subsets of its 26 categorical features. We analyze all bag collections obtained through grouping by one or two categorical features, in terms of their bag-level statistics as well as embedding based distance metrics quantifying the geometric separation of bags. We then propose to include in LLP-Bench a few groupings to fairly represent real world bag distributions.

We also measure the performance of state of the art models, loss functions (adapted to LLP) and optimizers on LLP-Bench. We perform a series of ablations and explain the performance of various techniques on LLP-Bench. To the best of our knowledge LLP-Bench is the first open source benchmark for the LLP task. We hope t

hat the proposed benchmark and the evaluation methodology will be used by ML researchers and practitioners to better understand and hence devise state of art LLP algorithms.

UL2: Unifying Language Learning Paradigms

Yi Tay,Mostafa Dehghani,Vinh Q. Tran,Xavier Garcia,Jason Wei,Xuezhi Wang,Hyung Won Chung,Dara Bahri,Tal Schuster,Steven Zheng,Denny Zhou,Neil Houlsby,Donald Metzler

Existing pre-trained models are generally geared towards a particular class of problems. To date, there seems to be still no consensus on what the right architecture and pre-training setup should be. This paper presents a unified framework for pre-training models that are universally effective across datasets and setups. We begin by disentangling architectural archetypes with pre-training objectives -- two concepts that are commonly conflated. Next, we present a generalized and unified perspective for self-supervision in NLP and show how different pre-training objectives can be cast as one another and how interpolating between different objectives can be effective. We then propose Mixture-of-Denoisers (MoD), a pre-training objective that combines diverse pre-training paradigms together. We furthermore introduce a notion of mode switching, wherein downstream fine-tuning is associated with specific pre-training schemes. We conduct extensive ablative experiments to compare multiple pre-training objectives and find that our method pushes the Pareto-frontier by outperforming T5 and/or GPT-like models across multiple diverse setups. Finally, by scaling our model up to 20B parameters, we achieve SOTA performance on 50 well-established supervised NLP tasks ranging from language generation (with automated and human evaluation), language understanding, text classification, question answering, commonsense reasoning, long text reasoning, structured knowledge grounding and information retrieval. Our model also achieve strong results at in-context learning, outperforming 175B GPT-3 on zero-shot SuperGLUE and tripling the performance of T5-XXL on one-shot summarization. Finally, we show that UL2 20B works well with chain-of-thought prompting and reasoning, making it an appealing choice for research into reasoning at a small to medium scale of 20B parameters. We release Flax-based T5X model checkpoints for the 20B model publicly.

Emergence of Exploration in Policy Gradient Reinforcement Learning via Resetting

Sotetsu Koyamada,Paavo Parmas,Tadashi Kozuno,Shin Ishii

In reinforcement learning (RL), many exploration methods explicitly promote stochastic policies, e.g., by adding an entropy bonus. We argue that exploration only matters in RL because the agent repeatedly encounters the same or similar states, so that it is beneficial to gradually improve the performance over the encounters; otherwise, the greedy policy would be optimal. Based on this intuition, we propose ReMax, an objective for RL whereby stochastic exploration arises as an emergent property, without adding any explicit exploration bonus. In ReMax, an episode is modified so that the agent can reset to previous states in the trajectory, and the agent’s goal is to maximize the best return in the trajectory tree. We show that this ReMax objective can be directly optimized with an unbiased policy gradient method. Experiments confirm that ReMax leads to the emergence of a stochastic exploration policy, and improves the performance compared to RL with no exploration bonus.

CASR: Generating Complex Sequences with Autoregressive Self-Boost Refinement

Hongwei Han,Mengyu Zhou,Shi Han,Xiu Li,Dongmei Zhang

There are sequence generation tasks where the best order to generate the target sequence is not left-to-right. For example, an answer to the Sudoku game, a structured code like s-expression, and even a logical natural language answer where the analysis may be generated after the decision. We define the target sequences of those tasks as complex sequences. Obviously, a complex sequence should be constructed with multiple logical steps, and has dependencies among each part of itself (e.g. decisions depend on analyses). It's a great challenge for the classi c left-to-right autoregressive generation system to generate complex sequences. Current approaches improve one-pass left-to-right generation on NLG tasks by generating different heuristic intermediate sequences in multiple stages. However, for complex sequences, the heuristic rules to break down them may hurt performance, and increase additional exposure bias. To tackle these challenges, we propose a PLM-friendly autoregressive self-boost refinement framework, CASR. When training, CASR inputs the predictions generated by the model itself at the previous refinement step (instead of those produced by heuristic rules). To find an optimal design, we also discuss model architecture, parameter efficiency and initialization strategy. By evaluating CASR on Sudoku, WebQSP, MTOP and KVRET through controlled experiments and empirical studies, we find that CASR produces high-quality outputs. CASR also improves Accuracy on Sudoku (70.93% --> 97.28%) and achieves state-of-the-art performance on KVRET with Micro F1 score (67.88% --> 70.00%).

SciRepEval: A Multi-Format Benchmark for Scientific Document Representations
Amanpreet Singh,Mike D'Arcy,Arman Cohan,Doug Downey,Sergey Feldman

Learned representations of scientific documents can serve as valuable input features for downstream tasks, without the need for further fine-tuning. However, existing benchmarks for evaluating these representations fail to capture the diversity of relevant tasks. In response, we introduce SciRepEval, the first comprehensive benchmark for training and evaluating scientific document representations. It includes 25 challenging and realistic tasks across four formats: classification, regression, ranking and search. We then use the benchmark to study and improve the generalization ability of scientific document representation models. We show how state-of-the-art models struggle to generalize across task formats, and that simple multi-task training fails to improve them. However, a new approach that learns multiple embeddings per document, each tailored to a different task format, can improve performance.

We experiment with task-format-specific control codes and adapters in a multi-task setting and find that they outperform the existing single-embedding state-of-the-art by up to 1.5 points absolute.

On the convergence of SGD under the over-parameter setting
ruinan Jin,Yiwei Wang,Wei Liu,Baoxiang Wang

With the improvement of computing power, over-parameterized models get increasingly popular in machine learning. This type of model is usually with a complicated, non-smooth, and non-convex loss function landscape. However, when we train the model, simply using the first-order optimization algorithm like stochastic gradient descent (SGD) could acquire some good results, in both training and testing, albeit that SGD is known to not guarantee convergence for non-smooth and non-convex cases. Theoretically, it was previously proved that in training, SGD converges to the global optimum with probability $1 - \epsilon$, but only for certain models and ϵ depends on the model complexity. It was also observed that SGD tends to choose a flat minimum, which preserves its training performance in testing. In this paper, we first prove that SGD could iterate to the global optimum almost surely under arbitrary initial value and some mild assumptions on the loss function. Then, we prove that if the learning rate is larger than a value depending on the structure of a global minimum, the probability of converging to this global optimum is zero. Finally, we acquire the asymptotic convergence rate based on the local structure of the global optimum.

MASTER: Multi-task Pre-trained Bottlenecked Masked Autoencoders are Better Dense Retrievers
Kun Zhou,Xiao Liu,Yeyun Gong,Xin Zhao,Daxin Jiang,Nan Duan,Ji-Rong Wen

Dense retrieval aims to map queries and passages into low-dimensional vector space for efficient similarity measuring, showing promising effectiveness in various large-scale retrieval tasks. Since most existing methods commonly adopt pre-trained Transformers (\eg BERT) for parameter initialization, some work focuses on proposing new pre-training tasks for compressing the useful semantic informatio n from passages into dense vectors, achieving remarkable performances. However, it is still challenging to effectively capture the rich semantic information and relations about passages into the dense vectors via one single particular pre-training task. In this work, we propose a multi-task pre-trained model, MASTER, that unifies and integrates multiple pre-training tasks with different learning objectives under the bottlenecked masked autoencoder architecture. Concretely, MASTER utilizes a multi-decoder architecture to integrate three types of pre-training tasks: corrupted passages recovering, related passage recovering and PLMs outputs recovering. By incorporating a shared deep encoder, we construct a representation bottleneck in our architecture, compressing the abundant semantic information across tasks into dense vectors. The first two types of tasks concentrate on the semantic information of passages and capturing relationships among them within the pre-training corpus. The third can capture the knowledge beyond the corpus from external PLMs (\eg GPT-2). Extensive experiments on several large-scale passage retrieval datasets have shown that our approach outperforms the previous state-of-the-art dense retrieval methods.

Bitrate-Constrained DRO: Beyond Worst Case Robustness To Unknown Group Shifts

Amrith Setlur,Don Dennis,Benjamin Eysenbach,Aditi Raghunathan,Chelsea Finn,Virginia Smith,Sergey Levine

Training machine learning models robust to distribution shifts is critical for real-world applications. Some robust training algorithms (e.g., Group DRO) specialize to group shifts and require group information on all training points. Other methods (e.g., CVaR DRO) that do not need group annotations can be overly conservative, since they naively upweight high loss points which may form a contrived set that does not correspond to any meaningful group in the real world (e.g., when the high loss points are randomly mislabeled training points). In this work, we address limitations in prior approaches by assuming a more nuanced form of group shift: conditioned on the label, we assume that the true group function (indicator over group) is simple. For example, we may expect that group shifts occur along low bitrate features (e.g., image background, lighting). Thus, we aim to learn a model that maintains high accuracy on simple group functions realized by these low bitrate features, that need not spend valuable model capacity achieving high accuracy on contrived groups of examples. Based on this, we consider the two-player game formulation of DRO where the adversary's capacity is bitrate-constrained. Our resulting practical algorithm, Bitrate-Constrained DRO (\bdro), does not require group information on training samples yet matches the performance of Group DRO on datasets that have training group annotations and that of CVaR DRO on long-tailed distributions. Our theoretical analysis reveals that in some settings \bdro objective can provably yield statistically efficient and less conservative solutions than unconstrained CVaR DRO.

Some Practical Concerns and Solutions for Using Pretrained Representation in Industrial Systems

Da Xu

Deep learning has dramatically changed the way data scientists and engineers craft features -- the once tedious process of measuring and constructing can now be achieved by training learnable representations. Recent work shows pretraining can endow representations with relevant signals, and in practice they are often used as feature vectors in downstream models. In real-world production, however, we have encountered key problems that cannot be justified by existing knowledge. They raise concerns that the naive use of pretrained representation as feature vector could lead to unwarranted and suboptimal solution.

Our investigation reveals critical insights into the gap of uniform convergence for analyzing pretrained representations, their stochastic nature under gradient descent optimization, what does model convergence means to them, and how they might interact with downstream tasks. Inspired by our analysis, we explore a simple yet powerful approach that can refine pretrained representation in multiple ways, which we call "Featurizing Pretrained Representations". Our work balances practicality and rigor, and contributes to both applied and theoretical research of representation learning.

Exphormer: Scaling Graph Transformers with Expander Graphs

Hamed Shirzad,Ameya Velingker,Balaji Venkatachalam,Danica J. Sutherland,Ali Kemal Sinop

Graph transformers have emerged as a promising architecture for a variety of graph learning and representation tasks. Despite their successes, it remains challenging to scale graph transformers to large graphs while maintaining accuracy competitive with message-passing networks. In this paper, we introduce Exphormer, a framework for building powerful and scalable graph transformers. Exphormer consists of a sparse attention mechanism based on expander graphs, whose mathematical characteristics, such as spectral expansion, and sparsity, yield graph transformers with complexity only linear in the size of the graph, while allowing us to prove desirable theoretical properties of the resulting transformer models. We show that incorporating Exphormer into the recently-proposed GraphGPS framework produces models with competitive empirical results on a wide variety of graph datasets, including state-of-the-art results on three datasets. We also show that Exphormer can scale to datasets on larger graphs than shown in previous graph transformer architectures.

****

Feature selection and low test error in shallow low-rotation ReLU networks

Matus Telgarsky

This work establishes low test error of gradient flow (GF) and stochastic gradient descent (SGD) on two-layer ReLU networks with standard initialization scale, in three regimes where key sets of weights rotate little (either naturally due to GF and SGD, or due to an artificial constraint), and making use of margins as the core analysis technique. The first regime is near initialization, specifically until the weights have moved by $\mathcal{O}(\sqrt m)$, where m denotes the network width, which is in sharp contrast to the $\mathcal{O}(1)$ weight motion allowed by the Neural Tangent Kernel (NTK); here it is shown that GF and SGD only need a network width and number of samples inversely proportional to the NTK margin, and moreover that GF attains at least the NTK margin itself and in particular escapes bad KKT points of the margin objective, whereas prior work could only establish nondecreasing but arbitrarily small margins. The second regime is the Neural Collapse (NC) setting, where data lies in well-separated groups, and the sample complexity scales with the number of groups; here the contribution over prior work is an analysis of the entire GF trajectory from initialization. Lastly, if the inner layer weights are constrained to change in norm only and cannot rotate, then GF with large widths achieves globally maximal margins, and its sample complexity scales with their inverse; this is in contrast to prior work, which required infinite width and a tricky dual convergence assumption.

Backpropagation through Combinatorial Algorithms: Identity with Projection Works

Subham Sekhar Sahoo,Anselm Paulus,Marin Vlastelica,Vít Musil,Volodymyr Kuleshov,Georg Martius

Embedding discrete solvers as differentiable layers has given modern deep learning architectures combinatorial expressivity and discrete reasoning capabilities. The derivative of these solvers is zero or undefined, therefore a meaningful replacement is crucial for effective gradient-based learning. Prior works rely on smoothing the solver with input perturbations, relaxing the solver to continuous problems, or interpolating the loss landscape with techniques that typically require additional solver calls, introduce extra hyper-parameters, or compromise performance. We propose a principled approach to exploit the geometry of the discrete solution space to treat the solver as a negative identity on the backward pass and further provide a theoretical justification. Our experiments demonstrate that such a straightforward hyper-parameter-free approach is able to compete with previous more complex methods on numerous experiments such as backpropagation through discrete samplers, deep graph matching, and image retrieval. Furthermore, we substitute the previously proposed problem-specific and label-dependent ma rgin with a generic regularization procedure that prevents cost collapse and increases robustness.

Coupled Multiwavelet Operator Learning for Coupled Differential Equations

Xiongye Xiao,Defu Cao,Ruochen Yang,Gaurav Gupta,Gengshuo Liu,Chenzhong Yin,Radu Balan,Paul Bogdan

Coupled partial differential equations (PDEs) are key tasks in modeling the complex dynamics of many physical processes. Recently, neural operators have shown the ability to solve PDEs by learning the integral kernel directly in Fourier/Wavelet space, so the difficulty of solving the coupled PDEs depends on dealing with the coupled mappings between the functions. Towards this end, we propose a \textit{coupled multiwavelets neural operator} (CMWNO) learning scheme by decoupling the coupled integral kernels during the multiwavelet decomposition and reconstruction procedures in the Wavelet space. The proposed model achieves significantly higher accuracy compared to previous learning-based solvers in solving the coupled PDEs including Gray-Scott (GS) equations and the non-local mean field game (MFG) problem. According to our experimental results, the proposed model exhibits a $2X-4X$ improvement relative $L$2 error compared to the best results from the state-of-the-art models.

Mid-Vision Feedback

Michael Maynord,Eadom T Dessalene,Cornelia Fermuller,Yiannis Aloimonos

Feedback plays a prominent role in biological vision, where perception is modulated based on agents' evolving expectations and world model. We introduce a novel mechanism which modulates perception based on high level categorical expectations: Mid-Vision Feedback (MVF). MVF associates high level contexts with linear transformations. When a context is "expected" its associated linear transformation is applied over feature vectors in a mid level of a network. The result is that mid-level network representations are biased towards conformance with high level expectations, improving overall accuracy and contextual consistency. Additionally, during training mid-level feature vectors are biased through introduction of a loss term which increases the distance between feature vectors associated with different contexts. MVF is agnostic as to the source of contextual expectations, and can serve as a mechanism for top down integration of symbolic systems with deep vision architectures. We show the superior performance of MVF to post-hoc filtering for incorporation of contextual knowledge, and show superior performance of configurations using predicted context (when no context is known a priori) over configurations with no context awareness.

Cross-Window Self-Training via Context Variations from Sparsely-Labeled Time Series

Yooju Shin,Susik Yoon,Hwanjun Song,Jae-Gil Lee,Byung Suk Lee

A real-world time series is often sparsely labeled due to the expensive annotation cost. Recently, self-training methods have been applied to a dataset with few labels to infer the labels of unlabeled augmented instances. Accelerating this trend for time-series data, fully taking advantage of its sequential nature, we propose a novel data augmentation approach called context-additive augmentation, which allows a target instance to be augmented easily by adding preceding and succeeding instances to form an augmented instance. Unlike the existing augmentation techniques which may alter the target instance by directly perturbing its features, it preserves a target instance as is but still gives various augmented instances with varying contexts. Additionally, we propose a cross-window self-training framework based on the context-additive augmentation. The framework first augments target instances by applying context-varying windows over a given time series. Then, the framework derives reliability-based cross-window labels and uses them to maintain consistency among augmented instances across the windows. Extensive experiments using real datasets show that the framework outperforms the existing state-of-the-art self-training methods.

Safe Reinforcement Learning From Pixels Using a Stochastic Latent Representation

Yannick Hogewind,Thiago D. Simão,Tal Kachman,Nils Jansen

We address the problem of safe reinforcement learning from pixel observations. Inherent challenges in such settings are (1) a trade-off between reward optimization and adhering to safety constraints, (2) partial observability, and (3) high-dimensional observations. We formalize the problem in a constrained, partially observable Markov decision process framework, where an agent obtains distinct reward and safety signals. To address the curse of dimensionality, we employ a novel safety critic using the stochastic latent actor-critic (SLAC) approach. The latent variable model predicts rewards and safety violations, and we use the safety critic to train safe policies. Using well-known benchmark environments, we demonstrate competitive performance over existing approaches regarding computational requirements, final reward return, and satisfying the safety constraints.

TrojText: Test-time Invisible Textual Trojan Insertion

Yepeng Liu,Bo Feng,Qian Lou

In Natural Language Processing (NLP), intelligent neuron models can be susceptible to textual Trojan attacks. Such attacks occur when Trojan models behave normally for standard inputs but generate malicious output for inputs that contain a specific trigger. Syntactic-structure triggers, which are invisible, are becoming more popular for Trojan attacks because they are difficult to detect and defend against. However, these types of attacks require a large corpus of training data to generate poisoned samples with the necessary syntactic structures for Trojan insertion. Obtaining such data can be difficult for attackers, and the process of generating syntactic poisoned triggers and inserting Trojans can be time-consuming. This paper proposes a solution called TrojText, which aims to determine whether invisible textual Trojan attacks can be performed more efficiently and cost-effectively without training data. The proposed approach, called the Representation-Logit Trojan Insertion (RLI) algorithm, uses smaller sampled test data instead of large training data to achieve the desired attack. The paper also introduces two additional techniques, namely the accumulated gradient ranking (AGR) and Trojan Weights Pruning (TWP), to reduce the number of tuned parameters and the attack overhead. The TrojText approach was evaluated on three datasets (AG’s News, SST-2, and OLID) using three NLP models (BERT, XLNet, and DeBERTa). The experiments demonstrated that the TrojText approach achieved a 98.35% classification accuracy for test sentences in the target class on the BERT model for the AG’s News dataset. The source code for TrojText is available at https://github.com/UCF-ML-Research/TrojText.

An Experiment Design Paradigm using Joint Feature Selection and Task Optimization

Stefano B Blumberg,Hongxiang Lin,Yukun Zhou,Paddy John Slator,Daniel C. Alexander

This paper presents a subsampling-task paradigm for data-driven task-specific experiment design (ED) and a novel method in populationwide supervised feature selection (FS). Optimal ED, the choice of sampling points under constraints of limited acquisition-time, arises in a wide variety of scientific and engineering contexts. However the continuous optimization used in classical approaches depend on a-priori parameter choices and challenging non-convex optimization landscapes. This paper proposes to replace this strategy with a subsampling-task paradigm, analogous to populationwide supervised FS. In particular, we introduce JOFSTO, which performs JOint Feature Selection and Task Optimization. JOFSTO jointly optimizes two coupled networks: one for feature scoring, which provides the ED, the other for execution of a downstream task or process. Unlike most FS problems, e.g. selecting protein expressions for classification, ED problems typically select from highly correlated globally informative candidates rather than seeking a small number of highly informative features among many uninformative features. JOFSTO's construction efficiently identifies potentially correlated, but effective subsets and returns a trained task network. We demonstrate the approach using parameter estimation and mapping problems in quantitative MRI, where economical ED is crucial for clinical application. Results from simulations and empi rical data show the subsampling-task paradigm strongly outperforms classical ED, and within our paradigm, JOFSTO outperforms state-of-the-art supervised FS techniques. JOFSTO extends immediately to wider image-based ED problems and other scenarios where the design must be specified globally across large numbers of acquisitions. Our code is available for reviewers https://www.dropbox.com/scl/fo/qe6vb1w6fuf869hx4ht0k/h?dl=0&rlkey=og8czcorurl57jbiixio7hcjt

Multi-Objective Online Learning

Jiyan Jiang,Wenpeng Zhang,Shiji Zhou,Lihong Gu,Xiaodong Zeng,Wenwu Zhu

This paper presents a systematic study of multi-objective online learning. We first formulate the framework of Multi-Objective Online Convex Optimization, which encompasses a novel multi-objective regret. This regret is built upon a sequence-wise extension of the commonly used discrepancy metric Pareto suboptimality gap in zero-order multi-objective bandits. We then derive an equivalent form of the regret, making it amenable to be optimized via first-order iterative methods. To motivate the algorithm design, we give an explicit example in which equipping OMD with the vanilla min-norm solver for gradient composition will incur a linear regret, which shows that merely regularizing the iterates, as in single-objective online learning, is not enough to guarantee sublinear regrets in the multi-objective setting. To resolve this issue, we propose a novel min-regularized-norm solver that regularizes the composite weights. Combining min-regularized-norm with OMD results in the Doubly Regularized Online Mirror Multiple Descent algorithm. We further derive the multi-objective regret bound for the proposed algorithm, which matches the optimal bound in the single-objective setting. Extensive experiments on real-world datasets verify the effectiveness of the proposed algorithm.

Improved Training of Physics-Informed Neural Networks Using Energy-Based Priors: a Study on Electrical Impedance Tomography

Akarsh Pokkunuru,Pedram Rooshenas,Thilo Strauss,Anuj Abhishek,Taufiquar Khan

Physics-informed neural networks (PINNs) are attracting significant attention for solving partial differential equation (PDE) based inverse problems, including electrical impedance tomography (EIT). EIT is non-linear and especially its inverse problem is highly ill-posed. Therefore, successful training of PINN is extremely sensitive to interplay between different loss terms and hyper-parameters, including the learning rate. In this work, we propose a Bayesian approach through data-driven energy-based model (EBM) as a prior, to improve the overall accuracy and quality of tomographic reconstruction. In particular, the EBM is trained over the possible solutions of the PDEs with different boundary conditions. By imparting such prior onto physics-based training, PINN convergence is expedited by more than ten times faster to the PDE’s solution. Evaluation outcome shows that our proposed method is more robust for solving the EIT problem. Our code is available at: https://rooshenasgroup.github.io/eit_ebprior.

Efficient Bayesian Optimization with Deep Kernel Learning and Transformer Pre-trained on Muliple Heterogeneous Datasets

Wenlong Lyu,Shoubo Hu,Jie Chuai,Zhitang Chen

Bayesian optimization (BO) is widely adopted in black-box optimization problems and it relies on a surrogate model to approximate the black-box response function. With the increasing number of black-box optimization tasks solved and even more to solve, the ability to learn from multiple prior tasks to jointly pre-train a surrogate model is long-awaited to further boost optimization efficiency. In this paper, we propose a simple approach to pre-train a surrogate, which is a Gaussian process (GP) with a kernel defined on deep features learned from a Transformer-based encoder, using datasets from prior tasks with possibly heterogeneous input spaces. In addition, we provide a simple yet effective mix-up initialization strategy for input tokens corresponding to unseen input variables and therefore accelerate new tasks' convergence. Experiments on both synthetic and real benchmark problems demonstrate the effectiveness of our proposed pre-training and transfer BO strategy over existing methods.

Robustness Guarantees for Adversarially Trained Neural Networks

Poorya Mianjy,Raman Arora

We study robust adversarial training of two-layer neural networks with Leaky ReLU activation function as a bi-level optimization problem. In particular, for the inner-loop that implements the PGD attack, we propose maximizing a lower bound on the 0/1-loss by reflecting a surrogate loss about the origin. This allows us to give a convergence guarantee for the inner-loop PGD attack and precise iteration complexity results for end-to-end adversarial training, which hold for any width and initialization in a realizable setting.

****

Fast-PINN for Complex Geometry: Solving PDEs with Boundary Connectivity Loss

Jian Cheng Wong,Pao-Hsiung Chiu,Chin Chun Ooi,My Ha Dao,Yew-Soon Ong

We present a novel loss formulation for efficient learning of complex dynamics from governing physics, typically described by partial differential equations (PDEs), using physics-informed neural networks (PINNs). In our experiments, existing versions of PINNs are seen to learn poorly in many problems, especially for complex geometries, as it becomes increasingly difficult to establish appropriate sampling strategy at the near boundary region. Overly dense sampling can adversely impede training convergence if the local gradient behaviors are too complex to be adequately modelled by PINNs. On the other hand, if the samples are too sparse, PINNs may over-fit the near boundary region, leading to incorrect solution. To prevent such issues, we propose a new Boundary Connectivity (BCXN) loss function which provides local structure approximation at the boundary. Our BCXN-loss can implicitly or explicitly impose such approximations during training, thus facilitating fast physics-informed learning across entire problem domains with order of magnitude fewer training samples. This method shows a few orders of magnitude smaller errors than existing methods in terms of the standard L2-norm metric, while using dramatically fewer training samples and iterations. Our proposed Fast-PINN method does not pose any requirement on the differentiable property of the networks, and we demonstrate its benefits and ease of implementation on both multi-layer perceptron and convolutional neural network versions as commonly used in current physics-informed neural network literature.

****

Noise Transforms Feed-Forward Networks into Sparse Coding Networks

Trenton Bricken,Bruno Olshausen,Gabriel Kreiman

A hallmark of biological neural networks, which distinguishes them from their artificial counterparts, is the high degree of sparsity in their activations. Here, we show that by simply injecting symmetric, random, noise during training in reconstruction or classification tasks, artificial neural networks with ReLU activation functions eliminate this difference; the neurons converge to a sparse coding solution where only a small fraction are active for any input. The resulting network learns receptive fields like those of primary visual cortex and remains sparse even when noise is removed in later stages of learning.

****

DEFENDING BACKDOOR ATTACKS VIA ROBUSTNESS AGAINST NOISY LABEL

Boyang Liu,Zhuangdi Zhu,Yijiang Pang,Pang-Ning Tan,Jiayu Zhou

Many deep neural networks are vulnerable to backdoor poisoning attacks, in which an adversary strategically injects a backdoor trigger into a small fraction of the training data. The trigger can later be applied during inference to manipulate prediction labels. While the data label could be changed to arbitrary values by an adversary, the extent of corruption injected into the feature values is strictly limited to keep the backdoor attack in disguise, which leads to a resemblance between the backdoor attack and a milder attack that involves only noisy labels.

This paper investigates an intriguing question: \textit{Can we leverage algorithms that defend against noisy label corruptions to defend against general backdoor attacks?} We first discuss the limitations of directly using current noisy-label defense algorithms to defend against backdoor attacks. We then propose a meta-algorithm for both supervised and semi-supervised settings that transforms an e xisting noisy label defense algorithm into one that protects against backdoor attacks. Extensive experiments on different settings show that, by introducing a lightweight alteration for minimax optimization to the existing noisy-label defense algorithms, the robustness against backdoor attacks can be substantially improved, while the initial form of those algorithms would fail in the presence of a backdoor attack.

****

A Kernel Perspective of Skip Connections in Convolutional Networks

Daniel Barzilai,Amnon Geifman,Meirav Galun,Ronen Basri

Over-parameterized residual networks (ResNets) are amongst the most successful convolutional neural architectures for image processing. Here we study their properties through their Gaussian Process and Neural Tangent kernels. We derive explicit formulas for these kernels, analyze their spectra, and provide bounds on their implied condition numbers. Our results indicate that (1) with ReLU activation, the eigenvalues of these residual kernels decay polynomially at a similar rate compared to the same kernels when skip connections are not used, thus maintaining a similar frequency bias; (2) however, residual kernels are more locally biased. Our analysis further shows that the matrices obtained by these residual kernels yield favorable condition numbers at finite depths than those obtained without the skip connections, enabling therefore faster convergence of training with gradient descent.

****

Ordered GNN: Ordering Message Passing to Deal with Heterophily and Over-smoothing

Yunchong Song,Chenghu Zhou,Xinbing Wang,Zhouhan Lin

Most graph neural networks follow the message passing mechanism. However, it faces the over-smoothing problem when multiple times of message passing is applied to a graph, causing indistinguishable node representations and prevents the model to effectively learn dependencies between farther-away nodes. On the other hand, features of neighboring nodes with different labels are likely to be falsely mixed, resulting in the heterophily problem. In this work, we propose to order the messages passing into the node representation, with specific blocks of neurons targeted for message passing within specific hops. This is achieved by aligning the hierarchy of the rooted-tree of a central node with the ordered neurons in its node representation. Experimental results on an extensive set of datasets show that our model can simultaneously achieve the state-of-the-art in both homophily and heterophily settings, without any targeted design. Moreover, its performance maintains pretty well while the model becomes really deep, effectively preventing the over-smoothing problem. Finally, visualizing the gating vectors shows that our model learns to behave differently between homophily and heterophily settings, providing an explainable graph neural model.

Sparse Distributed Memory is a Continual Learner

Trenton Bricken,Xander Davies,Deepak Singh,Dmitry Krotov,Gabriel Kreiman

Continual learning is a problem for artificial neural networks that their biological counterparts are adept at solving. Building on work using Sparse Distributed Memory (SDM) to connect a core neural circuit with the powerful Transformer model, we create a modified Multi-Layered Perceptron (MLP) that is a strong continual learner. We find that every component of our MLP variant translated from biology is necessary for continual learning. Our solution is also free from any memory replay or task information, and introduces novel methods to train sparse networks that may be broadly applicable.

****

Optimistic Exploration in Reinforcement Learning Using Symbolic Model Estimates

Sarath Sreedharan,Michael Katz

There has been increasing interest in using symbolic models along with reinforcement learning (RL) problems, where these coarser abstract models are used as a way to provide higher level guidance to the RL agent. However, most of these works are limited by their assumption that they have access to a symbolic approximation of the underlying problem. To address this problem, we introduce a new metho d for learning optimistic symbolic approximations of the underlying world model. We will see how these representations, coupled with fast diverse planners developed from the automated planning community, provides us with a new paradigm for optimistic exploration in sparse reward settings. We also investigate how we could speed up the learning process by generalizing learned model dynamics across similar actions with minimal human input. We will evaluate the method, by testing it on multiple benchmark domains and compare it with other RL strategies for sparse reward settings, including hierarchical RL and intrinsic reward based exploration.

FLIP: A Provable Defense Framework for Backdoor Mitigation in Federated Learning

Kaiyuan Zhang,Guanhong Tao,Qiuling Xu,Siyuan Cheng,Shengwei An,Yingqi Liu,Shiwei Feng,Guangyu Shen,Pin-Yu Chen,Shiqing Ma,Xiangyu Zhang

Federated Learning (FL) is a distributed learning paradigm that enables different parties to train a model together for high quality and strong privacy protection. In this scenario, individual participants may get compromised and perform backdoor attacks by poisoning the data (or gradients). Existing work on robust aggregation and certified FL robustness does not study how hardening benign clients can affect the global model (and the malicious clients). In this work, we theoretically analyze the connection among cross-entropy loss, attack success rate, and clean accuracy in this setting. Moreover, we propose a trigger reverse engineering based defense and show that our method can achieve robustness improvement with guarantee (i.e., reducing the attack success rate) without affecting benign accuracy. We conduct comprehensive experiments across different datasets and attack settings. Our results on nine competing SOTA defense methods show the empirical superiority of our method on both single-shot and continuous FL backdoor attacks. Code is available at https://github.com/KaiyuanZh/FLIP.

Robust attributions require rethinking robustness metrics

Sandesh Kamath,Amit Deshpande,Vineeth N. Balasubramanian

For machine learning models to be reliable and trustworthy, their decisions must be interpretable. As these models find increasing use in safety-critical applications, it is important that not just the model predictions but also their explanations (as feature attributions) be robust to small human-imperceptible input perturbations. Recent works have shown that many attribution methods are fragile and have proposed improvements in either the attribution methods or the model training. Existing works measure attributional robustness by metrics such as top-k intersection, Spearman's rank-order correlation (or Spearman's ρ) or Kendall's rank-order correlation (or Kendall's τ) to quantify the change in feature attributions under input perturbation. However, we show that these metrics are fragile. That is, under such metrics, a simple random perturbation attack can seem to be as significant as more principled attributional attacks. We instead propose Locality-sENSitive (LENS) improvements of the above metrics, namely, LENS-top-k, LENS-Spearman and LENS-Kendall, that incorporate the locality of attributions along with their rank order. Our locality-sensitive metrics provide tighter bounds on attributional robustness and do not disproportionately penalize attribution methods for reasonable local changes. We show that the robust attribution methods proposed in recent works also reflect this premise of locality, thus highlighting the need for a locality-sensitive metric for progress in the field. Our empirical results on well-known benchmark datasets using well-known models and attribution methods support our observations and conclusions in this work.

GradientMix: A Simple yet Effective Regularization for Large Batch Training

Jihun Yun,Jung Hyun Lee,Eunho Yang

Stochastic gradient descent (SGD) is the core tool for training deep neural networks. As modern deep learning tasks become more complex and state-of-the-art architectures grow as well, network training with SGD takes a huge amount of time; for example, training ResNet on the ImageNet dataset or BERT pre-training can take days to dozens of days. To reduce the network training time, distributed lear ning using a large batch size for SGD has been one of the main active research areas in recent years, but this approach entails a significant degradation in generalization. To address this issue, in this paper, we propose a simple yet effective regularization technique, GradientMix, for large-scale distributed learning. GradientMix can enhance the generalization in large batch regimes by giving appropriate noise through a mixup of local gradients computed at multiple devices, which is contrary to the conventions that simply average local gradients. Furthermore, GradientMix is optimizer-agnostic, hence can be applied to any popular optimization algorithm as long as the overall loss is expressed as the sum of the subgroup losses. Our extensive experiments show the effectiveness in both small and large-scale problems, and especially we consistently achieve state-of-the-art performance for various optimizers on training ResNet-50 on the ImageNet dataset with 32K batch size.

UniMax: Fairer and More Effective Language Sampling for Large-Scale Multilingual Pretraining

Hyung Won Chung,Xavier Garcia,Adam Roberts,Yi Tay,Orhan Firat,Sharan Narang,Noah Constant

Pretrained multilingual large language models have typically used heuristic temperature-based sampling to balance between different languages. However previous work has not systematically evaluated the efficacy of different pretraining language distributions across model scales. In this paper, we propose a new sampling method, UniMax, that delivers more uniform coverage of head languages while mitigating overfitting on tail languages by explicitly capping the number of repeats over each language's corpus. We perform an extensive series of ablations testing a range of sampling strategies on a suite of multilingual benchmarks, while varying model scale. We find that UniMax outperforms standard temperature-based sampling, and the benefits persist as scale increases. As part of our contribution, we release: (i) an improved and refreshed mC4 multilingual corpus consisting of 29 trillion characters across 107 languages, and (ii) a suite of pretrained umT5 model checkpoints trained with UniMax sampling.

Discrete State-Action Abstraction via the Successor Representation

Amnon Attali,Pedro Cisneros,Marco Morales,Nancy Amato

While the difficulty of reinforcement learning problems is typically related to the complexity of their state spaces, Abstraction proposes that solutions often lie in simpler underlying latent spaces. Prior works have focused on learning either a continuous or dense abstraction, or require a human to provide one. Information-dense representations capture features irrelevant for solving tasks, and continuous spaces can struggle to represent discrete objects. In this work we automatically learn a sparse discrete abstraction of the underlying environment. We do so using a simple end-to-end trainable model based on the successor representation and max-entropy regularization. We describe an algorithm to apply our model, named Discrete State-Action Abstraction (DSAA), which computes an action abstraction in the form of temporally extended actions, i.e., Options, to transition between discrete abstract states. Empirically, we demonstrate the effects of different exploration schemes on our resulting abstraction, and show that it is efficient for solving downstream tasks.

Hyper-parameter Tuning for Fair Classification without Sensitive Attribute Access

Akshaj Kumar Veldanda,Ivan Brugere,Sanghamitra Dutta,Alan Mishler,Siddharth Garg

Fair machine learning methods seek to train models that balance model performance across demographic subgroups defined over sensitive attributes like race and gender. Although sensitive attributes are typically assumed to be known during training, they may not be available in practice due to privacy and other logistical concerns. Recent work has sought to train fair models without sensitive attributes on training data. However, these methods need extensive hyper-parameter tuning to achieve good results, and hence assume that sensitive attributes are known on validation data. However, this assumption too might not be practical. Here, we propose a framework to train fair classifiers without access to sensitive attributes on either training or validation data. Instead, we generate pseudo sensitive attributes on the validation data by training a biased classifier and using the classifier’s incorrectly (correctly) labeled examples as proxies for minority (majority) groups. Since fairness metrics like demographic parity, equal opportunity and subgroup accuracy can be estimated to within a proportionality constant even with noisy sensitive attribute information, we show theoretically and empirically that these proxy labels can be used to maximize fairness under average accuracy constraints. Key to our results is a principled approach to select the hyper-parameters of the biased classifier in a completely unsupervised fashion (meaning without access to ground truth sensitive attributes) that minimizes the gap between fairness estimated using noisy versus ground-truth sensitive labels.

Towards Learning Implicit Symbolic Representation for Visual Reasoning

Chen Sun,Calvin Luo,Xingyi Zhou,Anurag Arnab,Cordelia Schmid

Visual reasoning tasks are designed to test a learning algorithm's capability to infer causal relationships, discover object interactions, and understand temporal dynamics, all from visual cues. It is commonly believed that to achieve compositional generalization on visual reasoning, an explicit abstraction of the visual scene must be constructed; for example, object detection can be applied to the visual input to produce representations that are then processed by a neural network or a neuro-symbolic framework. We demonstrate that a simple and general self-supervised approach is able to learn implicit symbolic representations with general-purpose neural networks, enabling the end-to-end learning of visual reasoning directly from raw visual inputs. Our proposed approach ``compresses'' each frame of a video into a small set of tokens with a transformer network. The self-supervised learning objective is to reconstruct each image based on the compressed temporal context. To minimize the reconstruction loss, the network must learn a compact representation for each image, as well as capture temporal dynamics and object permanence from temporal context. We evaluate the proposed approach on two visual reasoning benchmarks, CATER and ACRE. We observe that self-supervised pretraining is essential to achieve compositional generalization for our end-to-end trained neural network, and our proposed method achieves on par or better performance compared to recent neuro-symbolic approaches that often require additional object-level supervision.

GNNInterpreter: A Probabilistic Generative Model-Level Explanation for Graph Neural Networks

Xiaoqi Wang,Han Wei Shen

Recently, Graph Neural Networks (GNNs) have significantly advanced the performance of machine learning tasks on graphs. However, this technological breakthrough makes people wonder: how does a GNN make such decisions, and can we trust its prediction with high confidence? When it comes to some critical fields, such as biomedicine, where making wrong decisions can have severe consequences, it is crucial to interpret the inner working mechanisms of GNNs before applying them. In this paper, we propose a model-agnostic model-level explanation method for different GNNs that follow the message passing scheme, GNNInterpreter, to explain the high-level decision-making process of the GNN model. More specifically, GNNInterpreter learns a probabilistic generative graph distribution that produces the most discriminative graph pattern the GNN tries to detect when making a certain prediction by optimizing a novel objective function specifically designed for the model-level explanation for GNNs. Compared to existing works, GNNInterpreter is more flexible and computationally efficient in generating explanation graphs with different types of node and edge features, without introducing another blackbox or requiring manually specified domain-specific rules. In addition, the experimental studies conducted on four different datasets demonstrate that the explanation graphs generated by GNNInterpreter match the desired graph pattern if the model is ideal; otherwise, potential model pitfalls can be revealed by the explanation.

Rethinking Symbolic Regression: Morphology and Adaptability in the Context of Evolutionary Algorithms

Kei Sen Fong,Shelvia Wongso,Mehul Motani

Symbolic Regression (SR) is the well-studied problem of finding closed-form analytical expressions that describe the relationship between variables in a measurement dataset. In this paper, we rethink SR from two perspectives: morphology and adaptability. Morphology: Current SR algorithms typically use several man-made heuristics to influence the morphology (or structure) of the expressions in the search space. These man-made heuristics may introduce unintentional bias and data leakage, especially with the relatively few equation-recovery benchmark problems available for evaluating SR approaches. To address this, we formulate a novel minimalistic approach, based on constructing a depth-aware mathematical language model trained on terminal walks of expression trees, as a replacement to these heuristics. Adaptability: Current SR algorithms tend to select expressions based on only a single fitness function (e.g., MSE on the training set). We promote the use of an adaptability framework in evolutionary SR which uses fitness functions that alternate across generations. This leads to robust expressions that perform well on the training set and are close to the true functional form. We demonstrate this by alternating fitness functions that quantify faithfulness to values (via MSE) and empirical derivatives (via a novel theoretically justified fitness metric coined MSEDI). Proof-of-concept: We combine these ideas into a minimalistic evolutionary SR algorithm that outperforms all benchmark and state of-the-art SR algorithms in problems with unknown constants added, which we claim are more reflective of SR performance for real-world applications. Our claim is then strengthened by reproducing the superior performance on real-world regression datasets from SRBench. For researchers interested in equation-recovery problems, we also propose a set of conventions that can be used to promote fairness in comparison across SR methods and to reduce unintentional bias.

On Pre-training Language Model for Antibody

Danqing Wang,Fei YE,Hao Zhou

Antibodies are vital proteins offering robust protection for the human body from pathogens. The development of general protein and antibody-specific pre-trained language models both facilitate antibody prediction tasks. However, there have been limited studies that comprehensively explore the representation capability of distinct pre-trained language models on different antibody tasks. To investigate the problem, we aim to answer several key questions in this paper, such as how pre-trained language models perform in antibody tasks with different specificity and how introducing specific biological mechanisms to the pre-training process can benefit the model. Additionally, we evaluate if the learned antibody pre-trained representations can be applied to real-world antibody problems, like drug discovery and immune process understanding. Previously, no benchmark available largely hindered the study to answer these questions. To aid in our investigation, we provide an AnTibody Understanding Evaluation (ATUE) benchmark. We comprehensively evaluate the performance of protein pre-trained language models by empirical study along with conclusions and new insights. Our ATUE and code are released at https://github.com/dqwang122/EATLM.

Challenging Common Assumptions about Catastrophic Forgetting

Timothee LESORT,Oleksiy Ostapenko,Pau Rodriguez,Md Rifat Arefin,Diganta Misra,Laurent Charlin,Irina Rish

Standard gradient descent algorithms applied to sequences of tasks are known to induce catastrophic forgetting in deep neural networks. When trained on a new task, the model's parameters are updated in a way that degrades performance on past tasks.

This article explores continual learning (CL) on long sequences of tasks sampled from a finite environment.

\textbf{We show that in this setting, learning with stochastic gradient descent (SGD) results in knowledge retention and accumulation without specific memorizat ion mechanisms.} This is in contrast to the current notion of forgetting from the CL literature, which shows that training on new tasks with such an approach results in forgetting previous tasks, especially in class-incremental settings.

To study this phenomenon, we propose an experimental framework, \Scole{} (Scaling Continual Learning), which allows to generate arbitrarily long task sequences. Our experiments show that the previous results obtained on relatively short task sequences may not reveal certain phenomena that emerge in longer ones.

Learning to reason over visual objects

Shanka Subhra Mondal,Taylor Whittington Webb,Jonathan Cohen

A core component of human intelligence is the ability to identify abstract patterns inherent in complex, high-dimensional perceptual data, as exemplified by visual reasoning tasks such as Raven’s Progressive Matrices (RPM). Motivated by the goal of designing AI systems with this capacity, recent work has focused on evaluating whether neural networks can learn to solve RPM-like problems. Previous work has generally found that strong performance on these problems requires the incorporation of inductive biases that are specific to the RPM problem format, raising the question of whether such models might be more broadly useful. Here, we investigated the extent to which a general-purpose mechanism for processing visual scenes in terms of objects might help promote abstract visual reasoning. We found that a simple model, consisting only of an object-centric encoder and a transformer reasoning module, achieved state-of-the-art results on both of two challenging RPM-like benchmarks (PGM and I-RAVEN), as well as a novel benchmark with greater visual complexity (CLEVR-Matrices). These results suggest that an inductive bias for object-centric processing may be a key component of abstract visual reasoning, obviating the need for problem-specific inductive biases.

Imitating Graph-Based Planning with Goal-Conditioned Policies

Junsu Kim,Younggyo Seo,Sungsoo Ahn,Kyunghwan Son,Jinwoo Shin

Recently, graph-based planning algorithms have gained much attention to solve goal-conditioned reinforcement learning (RL) tasks: they provide a sequence of subgoals to reach the target-goal, and the agents learn to execute subgoal-conditioned policies. However, the sample-efficiency of such RL schemes still remains a challenge, particularly for long-horizon tasks. To address this issue, we present a simple yet effective self-imitation scheme which distills a subgoal-conditioned policy into the target-goal-conditioned policy. Our intuition here is that to reach a target-goal, an agent should pass through a subgoal, so target-goal- and subgoal- conditioned policies should be similar to each other. We also propose a novel scheme of stochastically skipping executed subgoals in a planned path, which further improves performance. Unlike prior methods that only utilize graph-based planning in an execution phase, our method transfers knowledge from a planner along with a graph into policy learning. We empirically show that our method can significantly boost the sample-efficiency of the existing goal-conditioned RL methods under various long-horizon control tasks.

Prefer to Classify: Improving Text Classifier via Pair-wise Preference Learning

Jaehyung Kim,Jinwoo Shin,Dongyeop Kang

The development of largely human-annotated benchmarks has driven the success of deep neural networks in various NLP tasks. These benchmarks are collected by aggregating decisions made by different annotators on the target task. Aggregating the annotated decisions via majority is still used as a common practice, despite its inevitable limitation from simple aggregation. In this paper, we establish a novel classification framework, based on task-specific human preference between a pair of samples, which provides an informative training signal to capture fine-grained and complementary task information through pair-wise comparison. Hence, it improves the existing instance-wise annotation system by enabling better task modeling from learning the relation between samples. Specifically, we propose a new multi-task learning framework, called prefer-to-classify (P2C), to effectively learn human preferences in addition to the given classification task.

We collect human preference signals in two ways: (1) extracting relative prefere nces implicitly from annotation records (for free) or (2) collecting subjective preferences explicitly from (paid) crowd workers. In various text classification tasks, we demonstrate that both extractive and subjective preferences are effective in improving the classifier with our preference learning framework. Interestingly, we found that subjective preference shows more significant improvements than extractive preference, revealing the effectiveness of explicit modeling of human preferences. Our code and preference dataset will be publicly available upon acceptance.

Seeing Differently, Acting Similarly: Heterogeneously Observable Imitation Learning

Xin-Qiang Cai,Yao-Xiang Ding,Zixuan Chen,Yuan Jiang,Masashi Sugiyama,Zhi-Hua Zhou

In many real-world imitation learning tasks, the demonstrator and the learner have to act under different observation spaces. This situation brings significant obstacles to existing imitation learning approaches, since most of them learn policies under homogeneous observation spaces. On the other hand, previous studies under different observation spaces have strong assumptions that these two observation spaces coexist during the entire learning process. However, in reality, the observation coexistence will be limited due to the high cost of acquiring expert observations. In this work, we study this challenging problem with limited observation coexistence under heterogeneous observations: Heterogeneously Observable Imitation Learning (HOIL). We identify two underlying issues in HOIL: the dynamics mismatch and the support mismatch, and further propose the Importance Weighting with REjection (IWRE) algorithm based on importance weighting and learning with rejection to solve HOIL problems. Experimental results show that IWRE can solve various HOIL tasks, including the challenging tasks of transforming the vision-based demonstrations to random access memory (RAM)-based policies in the Atari domain, even with limited visual observations.

A theoretical study of inductive biases in contrastive learning

Jeff Z. HaoChen,Tengyu Ma

Understanding self-supervised learning is important but challenging. Previous theoretical works study the role of pretraining losses, and view neural networks as general black boxes. However, the recent work of [Saunshi et al.] argues that the model architecture --- a component largely ignored by previous works --- also has significant influences on the downstream performance of self-supervised learning. In this work, we provide the first theoretical analysis of self-supervised learning that incorporates the effect of inductive biases originating from the model class. In particular, we focus on contrastive learning --- a popular self-supervised learning method that is widely used in the vision domain. We show that when the model has limited capacity, contrastive representations would recover certain special clustering structures that are compatible with the model architecture, but ignore many other clustering structures in the data distribution. As a result, our theory can capture the more realistic setting where contrastive representations have much lower dimensionality than the number of clusters in the data distribution. We instantiate our theory on several synthetic data distributions, and provide empirical evidence to support the theory.

Combinatorial Pure Exploration of Causal Bandits

Nuoya Xiong,Wei Chen

The combinatorial pure exploration of causal bandits is the following online learning task: given a causal graph with unknown causal inference distributions, in each round we choose a subset of variables to intervene or do no intervention, and observe the random outcomes of all random variables, with the goal that using as few rounds as possible, we can output an intervention that gives the best (or almost best) expected outcome on the reward variable Y with probability at least $1-\delta$, where δ is a given confidence level. We provide the first gap-dependent and fully adaptive pure exploration algorithms on two types of causal models --- the binary generalized linear model (BGLM) and general graphs.

For BGLM, our algorithm is the first to be designed specifically for this setting and achieves polynomial sample complexity, while all existing algorithms for general graphs have either sample complexity exponential to the graph size or some unreasonable assumptions. For general graphs, our algorithm provides a significant improvement on sample complexity, and it nearly matches the lower bound we prove. Our algorithms achieve such improvement by a novel integration of prior causal bandit algorithms and prior adaptive pure exploration algorithms, the former of which utilize the rich observational feedback in causal bandits but are not adaptive to reward gaps, while the latter of which have the issue in reverse.

How to fine-tune vision models with SGD
Ananya Kumar,Ruoqi Shen,Sebastien Bubeck,Suriya Gunasekar
SGD (with momentum) and AdamW are the two most commonly used optimizers for fine-tuning large neural networks in computer vision. When the two methods perform the same, SGD is preferable because it uses less memory and is more efficient than AdamW. However, when evaluating on downstream tasks that differ significantly from pretraining, we find that across five popular benchmarks SGD fine-tuning gets substantially lower accuracies than AdamW on many modern vision models such as Vision Transformers and ConvNeXts---especially out-of-distribution (OOD). We find that such large gaps arise in instances where the fine-tuning gradients in the first (``embedding'') layer are much larger than the rest of the model. Our analysis suggests an easy fix: if we simply freeze the embedding layer (0.7\% of the parameters), SGD performs competitively with AdamW while using less memory across a suite of benchmarks. Our insights lead to state-of-the-art accuracies on popular distribution shift benchmarks: WILDS-FMoW, WILDS-Camelyon, BREEDS-Living-17, Waterbirds, and DomainNet.

Computational Language Acquisition with Theory of Mind
Andy Liu,Hao Zhu,Emmy Liu,Yonatan Bisk,Graham Neubig
Unlike current state-of-the-art language models, young children actively acquire language through interactions with their surrounding environment and caretakers. One mechanism that has been argued to be critical to language learning is the ability to infer the mental states of other agents in social environments, coined Theory of Mind (ToM) by Premack & Woodruff (1978). Drawing inspiration from the modern operationalized versions of ToM implemented in Rabinowitz et al. (2018) and Zhu et al. (2021), we build language-learning agents equipped with ToM, and measure its effects on the learning process. We model ToM by giving the speaker agent an internal listener model that is trained alongside the speaker and used to rerank potential utterances. We experiment with varying task difficulty, hypothesizing that models will acquire more complex language to adapt to stronger environmental pressures. We find that training speakers with a highly weighted ToM listener component leads to performance gains in our image referential game setting. We also find some evidence that increasing task difficulty in the training process results in more fluent and precise utterances in evaluation. This suggests the potential utility of further incorporating ToM, as well as other insights from child language acquisition, into computational models of language acquisition.

MiDAS: Multi-integrated Domain Adaptive Supervision for Fake News Detection
Abhijit Suprem,Calton Pu
COVID-19 related misinformation and fake news, coined an 'infodemic', has dramatically increased over the past few years. This misinformation exhibits concept drift, where the distribution of fake news changes over time, reducing effectiveness of previously trained models for fake news detection. Given a set of fake news models trained on multiple domains, we propose an adaptive decision module to select the best-fit model for a new sample. We propose MiDAS, a multi-domain adaptative approach for fake news detection that ranks relevancy of existing models to new samples. MiDAS contains 2 components: a doman-invariant encoder, and an adaptive model selector. MiDAS integrates multiple pre-trained and fine-tuned models with their training data to create a domain-invariant representation. Then

, MiDAS uses local Lipschitz smoothness of the invariant embedding space to estimate each model's relevance to a new sample. Higher ranked models provide predictions, and lower ranked models abstain. We evaluate MiDAS on generalization to drifted data with 9 fake news datasets, each obtained from different domains and modalities. MiDAS achieves new state-of-the-art performance on multi-domain adaptation for out-of-distribution fake news classification.

Walking the Tightrope: An Investigation of the Convolutional Autoencoder Bottleneck

Ilja Manakov,Markus Rohm,Volker Tresp

In this paper, we present an in-depth investigation of the convolutional autoencoder (CAE) bottleneck.

Autoencoders (AE), and especially their convolutional variants, play a vital role in the current deep learning toolbox.

Researchers and practitioners employ CAEs for various tasks, ranging from outlier detection and compression to transfer and representation learning.

Despite their widespread adoption, we have limited insight into how the bottleneck shape impacts the CAE's emergent properties.

We demonstrate that increased bottleneck area (i.e., height $\times$ width) drastically improves generalization in terms of reconstruction error while also speeding up training.

The number of channels in the bottleneck, on the other hand, is of secondary importance.

Furthermore, we show empirically that CAEs do not learn to copy their input, even when all layers have the same number of neurons as there are pixels in the input (i.e. there is no bottleneck).

Besides raising important questions for further research, our findings are directly applicable to two of the most common use-cases for CAEs:

In image compression, it is advantageous to increase the feature map size in the bottleneck as this greatly improves reconstruction quality.

For reconstruction-based outlier detection, we recommend decreasing the feature map size so that out-of-distribution samples will yield a higher reconstruction error.

A Closer Look at Model Adaptation using Feature Distortion and Simplicity Bias

Puja Trivedi,Danai Koutra,Jayaraman J. Thiagarajan

Advances in the expressivity of pretrained models have increased interest in the design of adaptation protocols which enable safe and effective transfer learning. Going beyond conventional linear probing (LP) and fine tuning (FT) strategies, protocols that can effectively control feature distortion, i.e., the failure to update features orthogonal to the in-distribution, have been found to achieve improved out-of-distribution generalization (OOD). In order to limit this distortion, the LP+FT protocol, which first learns a linear probe and then uses this initialization for subsequent FT, was proposed. However, in this paper, we find when adaptation protocols (LP, FT, LP+FT) are also evaluated on a variety of safety objectives (e.g., calibration, robustness, etc.), a complementary perspective to feature distortion is helpful to explain protocol behavior. To this end, we study the susceptibility of protocols to simplicity bias (SB), i.e. the well-known propensity of deep neural networks to rely upon simple features, as SB has recently been shown to underlie several problems in robust generalization. Using a synthetic dataset, we demonstrate the susceptibility of existing protocols to SB. Given the strong effectiveness of LP+FT, we then propose modified linear probes that help mitigate SB, and lead to better initializations for subsequent FT. We verify the effectiveness of the proposed LP+FT variants for decreasing SB in a controlled setting, and their ability to improve OOD generalization and safety on three adaptation datasets.

Pareto Invariant Risk Minimization: Towards Mitigating the Optimization Dilemma in Out-of-Distribution Generalization

Yongqiang Chen,Kaiwen Zhou,Yatao Bian,Binghui Xie,Bingzhe Wu,Yonggang Zhang,MA K

AILI,Han Yang,Peilin Zhao,Bo Han,James Cheng

Recently, there has been a growing surge of interest in enabling machine learning systems to generalize well to Out-of-Distribution (OOD) data. Most efforts are devoted to advancing optimization objectives that regularize models to capture the underlying invariance; however, there often are compromises in the optimization process of these OOD objectives: i) Many OOD objectives have to be relaxed as penalty terms of Empirical Risk Minimization (ERM) for the ease of optimization, while the relaxed forms can weaken the robustness of the original objective; ii) The penalty terms also require careful tuning of the penalty weights due to the intrinsic conflicts between ERM and OOD objectives. Consequently, these compromises could easily lead to suboptimal performance of either the ERM or OOD objective. To address these issues, we introduce a multi-objective optimization (MOO) perspective to understand the OOD optimization process, and propose a new optimization scheme called PAreto Invariant Risk Minimization (PAIR). PAIR improves the robustness of OOD objectives by cooperatively optimizing with other OOD objectives, thereby bridging the gaps caused by the relaxations. Then PAIR approaches a Pareto optimal solution that trades off the ERM and OOD objectives properly. Extensive experiments on challenging benchmarks, WILDS, show that PAIR alleviates the compromises and yields top OOD performances.

Understanding and Adopting Rational Behavior by Bellman Score Estimation

Kuno Kim,Stefano Ermon

We are interested in solving a class of problems that seek to understand and adopt rational behavior from demonstrations. We may broadly classify these problems into four categories of reward identification, counterfactual analysis, behavior imitation, and behavior transfer. In this work, we make a key observation that knowing how changes in the underlying rewards affect the optimal behavior allows one to solve a variety of aforementioned problems. To a local approximation, this quantity is precisely captured by what we term the Bellman score, i.e gradient of log probabilities of the optimal policy with respect to the reward. We introduce the Bellman score operator which provably converges to the gradient of the infinite-horizon optimal Q-values with respect to the reward which can then be used to directly estimate the score. Guided by our theory, we derive a practical score-learning algorithm which can be used for score estimation in high-dimensional state-actions spaces. We show that score-learning can be used to reliably identify rewards, perform counterfactual predictions, achieve state-of-the-art behavior imitation, and transfer policies across environments.

L2B: Learning to Bootstrap for Combating Label Noise

Yuyin Zhou,Xianhang Li,Fengze Liu,Xuxi Chen,Lequan Yu,Cihang Xie,Matthew P. Lungren,Lei Xing

Deep neural networks are powerful tools for representation learning, but can easily overfit to noisy labels which are prevalent in many real-world scenarios. Generally, noisy supervision could stem from variation among labelers, label corruption by adversaries, etc. To combat such label noises, one popular line of approach is to apply customized weights to the training instances, so that the corrupted examples contribute less to the model learning. However, such learning mechanisms potentially erase important information about the data distribution and therefore yield suboptimal results. To leverage useful information from the corrupted instances, an alternative is the bootstrapping loss, which reconstructs new training targets on-the-fly by reweighting the real labels and the network's own predictions (i.e., pseudo labels).

In this paper, we propose a more generic learnable loss objective which enables a joint reweighting of instances and labels at once. Specifically, our method dynamically adjusts the $\textit{per-sample importance weight}$ between the real observed labels and pseudo-labels, where the weights are efficiently determined in a meta process. Compared to the previous instance reweighting methods, our approach concurrently conducts implicit relabeling, and thereby yields substantial improvements with almost no extra cost. Extensive experimental results demonstrated the strengths of our approach over existing methods on multiple natural and medical image benchmark datasets, including CIFAR-10, CIFAR-100, ISIC2019 and Clothing 1M. Code will be made publicly available.

What Makes Convolutional Models Great on Long Sequence Modeling?
Yuhong Li,Tianle Cai,Yi Zhang,Deming Chen,Debadeepta Dey

Convolutional models have been widely used in multiple domains. However, most existing models only use local convolution, making the model unable to handle long-range dependencies efficiently. Attention overcomes this problem by aggregating global information based on the pair-wise attention score but also makes the computational complexity quadratic to the sequence length. Recently, Gu et al. proposed a model called S4 inspired by the state space model. S4 can be efficiently implemented as a global convolutional model whose kernel size equals the input sequence length. With Fast Fourier Transform, S4 can model much longer sequences than Transformers and achieve significant gains over SoTA on several long-range tasks. Despite its empirical success, S4 is involved. It requires sophisticated parameterization and initialization schemes that combine the wisdom from several prior works. As a result, S4 is less intuitive and hard to use for researchers with limited prior knowledge. Here we aim to demystify S4 and extract basic principles that contribute to the success of S4 as a global convolutional model. We focus on the structure of the convolution kernel and identify two critical but intuitive principles enjoyed by S4 that are sufficient to make up an effective global convolutional model: 1) The parameterization of the convolutional kernel needs to be efficient in the sense that the number of parameters should scale sub-linearly with sequence length. 2) The kernel needs to satisfy a decaying structure that the weights for convolving with closer neighbors are larger than the more distant ones. Based on the two principles, we propose a simple yet effective convolutional model called Structured Global Convolution (SGConv). SGConv exhibits strong empirical performance over several tasks: 1) With faster speed, SGConv surpasses the previous SoTA on Long Range Arena and Speech Command datasets. 2) When plugging SGConv into standard language and vision models, it shows the potential to improve both efficiency and performance.

Progressive Mixup Augmented Teacher-Student Learning for Unsupervised Domain Adaptation
Aotian Zheng,Jie Mei,Farron Wallace,Craig Rose,Rania Hussein,Jenq-Neng Hwang

Unsupervised Domain Adaptation (UDA) aims to transfer knowledge learned from a labeled source domain to an unlabeled target domain, mostly through learning a domain invariant feature representation. Currently, the best performing UDA methods use category level domain alignment to capture fine-grained information, resulting in significantly improved performance over global alignment. While successful, category level UDA methods suffer from the unreliable pseudo-labels for target data. Additionally, most UDA methods directly adapt from source to target domain without regard for the large domain discrepancy. In this paper, we propose an UDA approach with teacher-student learning where the teacher network is used to provide more reliable target pseudo-labels for the student network to train with. Furthermore, we use a progressive mixup augmentation strategy which generates intermediate samples that become increasingly target-dominant as training progresses. Aligning the source and intermediate domains allows the model to gradually transfer fine-grained domain knowledge from the source to the target domain while minimizing the negative impact of noisy target pseudo-labels. This progressive mixup augmented teacher-student (PMATS) training strategy along with class subset sampling and clustering based pseudo-label refinement achieves state-of-the-art performance on two public UDA benchmark datasets: Office-31, and Office-Home.

M^{3}SAT: A Sparsely Activated Transformer for Efficient Multi-Task Learning from Multiple Modalities
Jie Peng,Tianlong Chen,Ruida Zhou,Jianmin Ji,Yanyong Zhang,Zhangyang Wang

Multi-modal multi-task learning (M^{2}TL) aims to discover the implicit correspondences among heterogeneous modalities and tasks, which is common in real-world applications like autonomous driving and robotics control. Current single-model solutions for M^{2}TL usually fall short in several aspects. The shared backbone between the modalities is prone to overfitting the simpler modality, while jointly optimizing the tasks suffers from unstable training due to the gradient conflicts across tasks. On the other hand, designing a separate model for each task and modality can avoid the above problems but leads to prohibitively expensive computation and memory consumption, rendering this approach unrealistic.

In this work, we propose M^{3}SAT, a sparsely activated transformer for efficient M^{2}TL. The proposed framework tailors the mixture-of-experts (MoEs) into both the self-attention and the feed-forward networks (FFN) of a transformer backbone. It adopts the routing policy to assign attention-heads and FFN experts during training, which effectively disentangles the parameter space to prevent training conflicts among diverse modalities and tasks. Meanwhile, disentangled parameter space also restrains the problem of simple modal prone to overfitting. Sparsely activating the transformer also enables efficient computation for each input sample. Through comprehensive evaluation, we demonstrate the effectiveness of our M^{3}SAT: a remarkable performance margin (\textit{e.g.}, $\ge 1.37\%$) is achieved over the dense models with the same computation cost. More importantly, M^{3}SAT can achieve the above performance improvements with a fraction of the computation cost -- our computation is only $1.38\% \sim 53.51\%$ of that of the SOTA methods. Our code will be released upon acceptance.

Editing models with task arithmetic
Gabriel Ilharco,Marco Tulio Ribeiro,Mitchell Wortsman,Ludwig Schmidt,Hannaneh Hajishirzi,Ali Farhadi
Changing how pre-trained models behave---e.g., improving their performance on a downstream task or mitigating biases learned during pre-training---is a common practice when developing machine learning systems. In this work, we propose a new paradigm for steering the behavior of neural networks, centered around task vectors. A task vector specifies a direction in the weight space of a pre-trained model, such that movement in that direction improves performance on the task. We build task vectors by subtracting the weights of a pre-trained model from the weights of the same model after fine-tuning on a task. We show that these task vectors can be modified and combined together through arithmetic operations such as negation and addition, and the behavior of the resulting model is steered accordingly. Moreover, task vectors can be added together to improve performance on multiple tasks at once. Finally, when tasks are linked by an analogy relationship of the form ``A is to B as C is to D", combining task vectors from three of the tasks can improve performance on the fourth, even when no data from the fourth task is used for training.

Neural Systematic Binder
Gautam Singh,Yeongbin Kim,Sungjin Ahn
The key to high-level cognition is believed to be the ability to systematically manipulate and compose knowledge pieces. While token-like structured knowledge representations are naturally provided in text, it is elusive how to obtain them for unstructured modalities such as scene images. In this paper, we propose a neural mechanism called Neural Systematic Binder or SysBinder for constructing a novel structured representation called Block-Slot Representation. In Block-Slot Representation, object-centric representations known as slots are constructed by composing a set of independent factor representations called blocks, to facilitate systematic generalization. SysBinder obtains this structure in an unsupervised way by alternatingly applying two different binding principles: spatial binding for spatial modularity across the full scene and factor binding for factor modularity within an object. SysBinder is a simple, deterministic, and general-purpose layer that can be applied as a drop-in module in any arbitrary neural network and on any modality. In experiments, we find that SysBinder provides significantly better factor disentanglement within the slots than the conventional object-centric methods, including, for the first time, in visually complex scene imag

es such as CLEVR-Tex. Furthermore, we demonstrate factor-level systematicity in controlled scene generation by decoding unseen factor combinations.

Training-Free Structured Diffusion Guidance for Compositional Text-to-Image Synthesis

Weixi Feng,Xuehai He,Tsu-Jui Fu,Varun Jampani,Arjun Reddy Akula,Pradyumna Narayana,Sugato Basu,Xin Eric Wang,William Yang Wang

Large-scale diffusion models have achieved state-of-the-art results on text-to-image synthesis (T2I) tasks. Despite their ability to generate high-quality yet creative images, we observe that attribution-binding and compositional capabilities are still considered major challenging issues, especially when involving multiple objects. Attribute-binding requires the model to associate objects with the correct attribute descriptions, and compositional skills require the model to combine and generate multiple concepts into a single image. In this work, we improve these two aspects of T2I models to achieve more accurate image compositions. To do this, we incorporate linguistic structures with the diffusion guidance process based on the controllable properties of manipulating cross-attention layers in diffusion-based T2I models. We observe that keys and values in cross-attention layers have strong semantic meanings associated with object layouts and content. Therefore, by manipulating the cross-attention representations based on linguistic insights, we can better preserve the compositional semantics in the generated image. Built upon Stable Diffusion, a SOTA T2I model, our structured cross-attention design is efficient that requires no additional training samples. We achieve better compositional skills in qualitative and quantitative results, leading to a significant 5-8\% advantage in head-to-head user comparison studies. Lastly, we conduct an in-depth analysis to reveal potential causes of incorrect image compositions and justify the properties of cross-attention layers in the generation process.

Atomized Deep Learning Models

Yi-Lin Tuan,Zih-Yun Chiu,William Yang Wang

Deep learning models often tackle the intra-sample structure, such as the order of words in a sentence and pixels in an image, but have not pay much attention to the inter-sample relationship. In this paper, we show that explicitly modeling the inter-sample structure to be more discretized can potentially help model's expressivity. We propose a novel method, Atom Modeling, that can discretize a continuous latent space by drawing an analogy between a data point and an {\it atom}, which is naturally spaced away from other atoms with distances depending on their intra structures. Specifically, we model each data point as an atom composed of electrons, protons, and neutrons and minimize the potential energy caused by the interatomic force among data points. Through experiments with qualitative analysis in our proposed Atom Modeling on synthetic and real datasets, we find that Atom Modeling can improve the performance by maintaining the inter-sample relation and can capture an interpretable intra-sample relation by mapping each component in a data point to electron/proton/neutron.

Topology Matters in Fair Graph Learning: a Theoretical Pilot Study

Zhimeng Jiang,Xiaotian Han,Chao Fan,Zirui Liu,Xiao Huang,Na Zou,Ali Mostafavi,Xia Hu

Recent advances in fair graph learning observe that graph neural networks (GNNs) further amplify prediction bias compared with multilayer perception (MLP), while the reason behind this is unknown. In this paper, we conduct a theoretical analysis of the bias amplification mechanism in GNNs. This is a challenging task since GNNs are difficult to be interpreted, and real-world networks are complex. To bridge the gap, we theoretically and experimentally demonstrate that aggregation operation in representative GNNs accumulates bias in node representation due to topology bias induced by graph topology. We provide a sufficient condition identifying the statistical information of graph data, so that graph aggregation enhances prediction bias in GNNs.

Motivated by this data-centric finding, we propose a fair graph refinement algo rithm, named \textit{FairGR}, to rewire graph topology to reduce sensitive homophily coefficient while preserving useful graph topology. Experiments on node classification tasks demonstrate that \textit{FairGR} can mitigate the prediction bias with comparable performance on three real-world datasets. Additionally, \textit{FairGR} is compatible with many state-of-the-art methods, such as adding regularization, adversarial debiasing, and Fair mixup via refining graph topology. Therefore, \textit{FairGR} is a plug-in fairness method and can be adapted to improve existing fair graph learning strategies.

Context-Aware Image Completion

Jinoh Cho,Minguk Kang,Vibhav Vineet,Jaesik Park

Image completion is a task that aims to fill in the missing region of a masked image with plausible contents. However, existing image completion methods tend to fill in the missing region with the surrounding texture instead of hallucinating a visual instance that is suitable in accordance with the context of the scene. In this work, we propose a novel image completion model, dubbed Refill, that hallucinates the missing instance that harmonizes well with - and thus preserves - the original context. Refill first adopts a transformer architecture that considers the types, locations of the visible instances, and the location of the missing region. Then, Refill completes the missing foreground and background semantic segmentation masks within the missing region, providing pixel-level semantic and structural guidance to generate missing contents with seamless boundaries. Finally, we condition the image synthesis blocks by using the completed segmentation mask to generate photo-realistic contents to fill out the missing region. Experimental results show the superiority of Refill over state-of-the-art image completion approaches on various natural images.

Can Agents Run Relay Race with Strangers? Generalization of RL to Out-of-Distribution Trajectories

Li-Cheng Lan,Huan Zhang,Cho-Jui Hsieh

In this paper, we evaluate and improve the generalization performance for reinforcement learning (RL) agents on the set of ``controllable'' states, where good policies exist on these states to achieve the goal. An RL agent that generally masters a task should reach its goal starting from any controllable state of the environment instead of memorizing a small set of trajectories. To practically evaluate this type of generalization, we propose relay evaluation, which starts the test agent from the middle of other independently well-trained stranger agents' trajectories. With extensive experimental evaluation, we show the prevalence of generalization failure on controllable states from stranger agents. For example, in the Humanoid environment, we observed that a well-trained Proximal Policy Optimization (PPO) agent, with only 3.9\% failure rate during regular testing, failed on 81.6\% of the states generated by well-trained stranger PPO agents. To improve "relay generalization," we propose a novel method called Self-Trajectory Augmentation (STA), which will reset the environment to the agent's old states according to the Q function during training. After applying STA to the Soft Actor Critic's (SAC) training procedure, we reduced the failure rate of SAC under relay-evaluation by more than three times in most settings without impacting agent performance and increasing the needed number of environment interactions. Our code is available at https://github.com/lan-lc/STA.

DYNAMIC BATCH NORM STATISTICS UPDATE FOR NATURAL ROBUSTNESS

Shahbaz Rezaei,Mohammad Sadegh Norouzzadeh

DNNs trained on natural clean samples have been shown to perform poorly on corrupted samples,
such as noisy or blurry images. Various data augmentation methods have been recently proposed
to improve DNN’s robustness against common corruptions. Despite their success, they require
computationally expensive training and cannot be applied to off-the-shelf trained models. Recently,

updating only BatchNorm(BN) statistics of a model on a single corruption has been shown to improve its accuracy on that corruption significantly. However, adopting the idea at inference time when the type of corruption changes decreases the effectiveness of this method. In this paper, we harness the Fourier domain to detect the corruption type, a challenging task in the image domain. We propose a unified framework consisting of a corruption-detection model and BN statistics update that can improve the corruption accuracy of any off-the-shelf trained model. We benchmark our framework on different models and datasets. Our results demonstrate about 8% and 4% accuracy improvement on CIFAR10-C and ImageNet-C, respectively. Furthermore, our framework can further improve the accuracy of state-of-the-art robust models, such as AugMix and DeepAug.

SKTformer: A Skeleton Transformer for Long Sequence Data
xue wang,Tian Zhou,Jianqing Zhu,Jialin Liu,Kun Yuan,Tao Yao,Wotao Yin,Rong Jin,HanQin Cai

Transformers have become a preferred tool for modeling sequential data. Many studies of using Transformers for long sequence modeling focus on reducing computational complexity. They usually exploit the low-rank structure of data and approximate a long sequence by a sub-sequence. One challenge with such approaches is how to make an appropriate tradeoff between information preserving and noise reduction: the longer the sub-sequence used to approximate the long sequence, the better the information is preserved but at a price of introducing more noise into the model and of course more computational costs. We propose skeleton transformer, SKTformer for short, an efficient transformer architecture that effectively addresses the tradeoff. It introduces two mechanisms to effectively reduce the impact of noise while still keeping the computation linear to the sequence length: a smoothing block to mix information over long sequences and a matrix sketch method that simultaneously selects columns and rows from the input matrix. We verify the effectiveness of SKTformer both theoretically and empirically. Extensive studies over both Long Range Arena (LRA) datasets and six time-series forecasting show that SKTformer significantly outperforms both villain Transformer and other state-of-the-art variants of Transformer. Code is available at
https://anonymous.4open.science/r/SKTFormer-B33B/

CktGNN: Circuit Graph Neural Network for Electronic Design Automation
Zehao Dong,Weidong Cao,Muhan Zhang,Dacheng Tao,Yixin Chen,Xuan Zhang

The electronic design automation of analog circuits has been a longstanding challenge in the integrated circuit field due to the huge design space and complex design trade-offs among circuit specifications. In the past decades, intensive research efforts have only been paid to automate the transistor sizing with a given circuit topology. By recognizing the graph nature of circuits, this paper presents a Circuit Graph Neural Network (CktGNN) that simultaneously automates the circuit topology generation and device sizing based on the encoder-dependent optimization subroutines. Particularly, CktGNN encodes circuit graphs using a two-level GNN framework (of nested GNN) where circuits are represented as combinations of subgraphs in a known subgraph basis. In this way, it significantly improves efficiency by reducing the number of subgraphs to perform message passing.

Nonetheless, another critical roadblock to advancing learning-assisted circuit design automation is a lack of public benchmarks to perform canonical assessment and reproducible research. To tackle the challenge, we introduce Open Circuit Benchmark (OCB), an open-sourced dataset that contains 10K distinct operational amplifiers with carefully-extracted circuit specifications from physical implementations. OCB also equips with communicative circuit generation and evaluation c apabilities such that it can be used to generalize the applicability of CktGNN to design various analog circuits by efficiently producing corresponding datasets. Experiments on OCB show the extraordinary advantages of CktGNN through representation-based optimization frameworks over other recent powerful GNN baselines and manual design from human experts. Our work paves the way toward a learning-based open-sourced design automation flow for analog circuits.

Substructure-Atom Cross Attention for Molecular Representation Learning
Jiye Kim,Seungbeom Lee,Dongwoo Kim,Sungsoo Ahn,Jaesik Park

Designing a neural network architecture for molecular representation is crucial for AI-driven drug discovery and molecule design. In this work, we propose a new framework for molecular representation learning. Our contribution is threefold: (a) demonstrating the usefulness of incorporating substructures to node-wise features from molecules, (b) designing two branch networks consisting of a transformer and a graph neural network so that the networks fused with asymmetric attention, and (c) not requiring heuristic features and computationally-expensive information from molecules. Using 1.8 million molecules collected from ChEMBL and PubChem database, we pretrain our network to learn a general representation of molecules with minimal supervision. The experimental results show that our pretrained network achieves competitive performance on 11 downstream tasks for molecular property prediction.

****

Differentially Private Algorithms for Smooth Nonconvex ERM
Changyu Gao,Stephen Wright

We develop simple differentially private optimization algorithms that move along directions of (expected) descent to find approximate second-order necessary solution for non-convex ERM problems. We use line search, mini-batching, and a two-phase strategy to improve the speed and practicality of the algorithm. Numerical experiments demonstrate the effectiveness of these approaches.

****

Untangling Effect and Side Effect: Consistent Causal Inference in Non-Targeted Trials
Georgios Mavroudeas,Malik Magdon-Ismail,Kristin Bennett,Jason Kuruzovich

A treatment is usually appropriate for some group (the ``sick" group) on whom it has an effect, but it can also have a side-effect when given to subjects from another group (the ``healthy" group). In a non-targeted trial both sick and healthy subjects may be treated, producing
heterogeneous effects within the treated group. Inferring the correct treatment effect on the sick population is then
difficult, because the effect and side-effect are tangled. We propose an efficient nonparametric approach to untangling the effect and side-effect, called PCM (pre-cluster and merge). We prove its asymptotic consistency in a general setting and
show, on synthetic data,
more than a 10x improvement in accuracy over existing state-of-the-art.

STUNT: Few-shot Tabular Learning with Self-generated Tasks from Unlabeled Tables
Jaehyun Nam,Jihoon Tack,Kyungmin Lee,Hankook Lee,Jinwoo Shin

Learning with few labeled tabular samples is often an essential requirement for industrial machine learning applications as varieties of tabular data suffer from high annotation costs or have difficulties in collecting new samples for novel tasks. Despite the utter importance, such a problem is quite under-explored in the field of tabular learning, and existing few-shot learning schemes from other domains are not straightforward to apply, mainly due to the heterogeneous characteristics of tabular data. In this paper, we propose a simple yet effective framework for few-shot semi-supervised tabular learning, coined Self-generated Tasks from UNlabeled Tables (STUNT). Our key idea is to self-generate diverse few-shot tasks by treating randomly chosen columns as a target label. We then employ a meta-learning scheme to learn generalizable knowledge with the constructed task

s. Moreover, we introduce an unsupervised validation scheme for hyperparameter search (and early stopping) by generating a pseudo-validation set using STUNT from unlabeled data. Our experimental results demonstrate that our simple framework brings significant performance gain under various tabular few-shot learning benchmarks, compared to prior semi- and self-supervised baselines. Code is available at https://github.com/jaehyun513/STUNT.

The Role of Pre-training Data in Transfer Learning

Rahim Entezari,Mitchell Wortsman,Olga Saukh,M. Moein Shariatnia,Hanie Sedghi,Ludwig Schmidt

The transfer learning paradigm of model pre-training and subsequent fine-tuning produces high accuracy models. However, a question remains: what data and method should be used for pre-training? We study the effect of the pre-training distribution on transfer learning in the context of image classification. Through controlled experiments, we find that the pre-training dataset is initially important for low-shot transfer. However, the differences between distributions is diminished as more data is made available for fine-tuning. Still, fine-tuning outperforms training from scratch. We also investigate dataset size and observe that larger pre-training datasets lead to better accuracy, however, the absolute accuracy difference is largest in the few-shot regime. Beyond data, we study the effect of the pre-training method, language-image contrastive vs. image-image contrastive, finding that the latter usually leads to better transfer accuracy

Compressed Predictive Information Coding

Rui Meng,Tianyi Luo,Kristofer Bouchard

Unsupervised learning plays an important role in many fields, such as machine learning, data compression, and neuroscience. Compared to static data, methods for extracting low-dimensional structure for dynamic data are lagging. We developed a novel information-theoretic framework, Compressed Predictive Information Coding (CPIC), to extract predictive latent representations from dynamic data. Predictive information quantifies the ability to predict the future of a time series from its past. CPIC selectively projects the past (input) into a low dimensional space that is predictive about the compressed data projected from the future (output). The key insight of our framework is to learn representations by balancing the minimization of compression complexity with maximization of the predictive information in the latent space. We derive tractable variational bounds of the CPIC loss by leveraging bounds on mutual information. The CPIC loss induces the latent space to capture information that is maximally predictive of the future of the data from the past. We demonstrate that introducing stochasticity in the encoder and maximizing the predictive information in latent space contributes to learning more robust latent representations. Furthermore, our variational approaches perform better in mutual information estimation compared with estimates under the Gaussian assumption commonly used. We show numerically in synthetic data that CPIC can recover dynamical systems embedded in noisy observation data with low signal-to-noise ratio. Finally, we demonstrate that CPIC extracts features more predictive of forecasting exogenous variables as well as auto-forecasting in various real datasets compared with other state-of-the-art representation learning models. Together, these results indicate that CPIC will be broadly useful for extracting low-dimensional dynamic structure from high-dimensional, noisy time-series data.

Importance of Class Selectivity in Early Epochs of Training

Omkar Ranadive,Nikhil Thakurdesai,Matthew L Leavitt,Stephane Deny

Deep networks trained for classification exhibit class-selective neurons in intermediate layers. Intriguingly, recent studies have shown that class-selective neurons are not strictly necessary for network function. But if class-selective neurons are not necessary, why do they exist? We attempt to answer this question in a series of experiments on ResNet-50 trained on ImageNet. We begin by showing that class-selective neurons emerge in the first few epochs of training before receding rapidly. Single-neuron ablation experiments show that class-selective ne

urons are important for network function during this early phase of training. The network is close to a linear regime during this early training phase, which may explain the emergence of these class-selective neurons in intermediate layers. Finally, by regularizing against class selectivity at different points in training, we show that the emergence of these class-selective neurons during the first few epochs of training is essential to the successful training of the network. Altogether, our results indicate that class-selective neurons in intermediate layers are vestigial remains of early epochs of training, during which they appear as quasi-linear shortcut solutions to the classification task which are essential to the successful training of the network.

Mechanistic Mode Connectivity
Ekdeep Singh Lubana,Eric J Bigelow,Robert Dick,David Krueger,Hidenori Tanaka
With the rise of pretrained models, fine-tuning has become of central importance in deep learning. However, unlike retraining from scratch, fine-tuning can fail to qualitatively change the behavior of a pre-trained network. For instance, we find in practice that naive fine-tuning does not eliminate a model’s sensitivity to spurious features. To understand and address this limitation, we study the geometry of neural network loss landscapes through the lens of mode-connectivity. Our work addresses two questions about mode-connectivity: 1) Are models trained on different data distributions mode-connected? 2) Can we fine tune a pre-trained model to switch modes? We define a notion of mechanistic mode-connectivity, and find that only models that already share the same invariances (which we call “mechanistically similar”) are mechanistically mode-connected. We hypothesize this property explains inability of naive fine-tuning methods to induce invariance to spurious features. Based on our analysis, we propose and validate a method of “mechanistic fine-tuning” called connectivity-based fine-tuning (CBFT)
****

WebBrain: Learning to Generate Factually Correct Articles for Queries by Grounding on Large Web Corpus
Hongjin Qian,Yutao Zhu,Zhicheng Dou,Haoqi Gu,Xinyu Zhang,Zheng Liu,Ruofei Lai,Zhao Cao,Jian-Yun Nie,Ji-Rong Wen
In this paper, we introduce a new NLP task – generating short factual articles for queries by mining supporting evidence from the Web. In this task, called WebBrain, the ultimate goal is to generate a fluent, informative, and factually-correct short article (e.g., Wiki article) for a factual query unseen in Wikipedia. To enable experiments on WebBrain, we construct a large-scale dataset WebBrain-Raw by extracting English Wikipedia articles and their crawlable Wiki references. WebBrain-Raw is ten times larger than the previous biggest peer dataset, which can greatly benefit the research community. Besides, we empirically analyze the performances of the current state-of-the-art NLP techniques on WebBrain and introduce a new framework ReGen, which enhances the generation factualness by improved evidence retrieval and task-specific pre-training for generation. Experiment results show that ReGen outperforms all baselines in both automatic and human evaluations.
****

HloEnv: A Graph Rewrite Environment for Deep Learning Compiler Optimization Research
Chin Yang Oh,Kunhao Zheng,Bingyi Kang,Xinyi Wan,Zhongwen Xu,Shuicheng YAN,Min Lin,Yangzihao Wang
We introduce HloEnv, an environment based on Accelerated Linear Algebra (XLA) for deep learning (DL) compiler optimization research. HloEnv transforms all graph rewrites into a common representation, providing a flexible interface to control and modify existing graph optimization passes. In this representation, an XLA pass is converted into a set of sequential rewrite decisions, which control when and if the rewrites are applied. Along with HloEnv, we present a dataset with broad coverage of computation graphs drawn from modern real-world machine learning models. We select two XLA passes with the largest impact on the runtime of the compiled program, and explore the potential for further improvement over XLA in this decision space. We show that using simple heuristics for decision-making c

an achieve on-par or better performance than XLA. Using search algorithms further boosts performance. We intend for HloEnv and our dataset to be an open-source, community-driven effort that helps spur advances in DL compiler optimization research.

Deep Latent State Space Models for Time-Series Generation

Linqi Zhou,Michael Poli,Winnie Xu,Stefano Massaroli,Stefano Ermon

Methods based on ordinary differential equations (ODEs) are widely used to build generative models of time-series. In addition to high computational overhead due to explicitly computing hidden states recurrence, existing ODE-based models fall short in learning sequence data with sharp transitions - common in many real-world systems - due to numerical challenges during optimization. In this work, we propose LS4, a generative model for sequences with latent variables evolving according to a state space ODE to increase modeling capacity. Inspired by recent deep state space models (S4), we achieve speedups by leveraging a convolutional representation of LS4 which bypasses the explicit evaluation of hidden states. We show that LS4 significantly outperforms previous continuous-time generative models in terms of marginal distribution, classification, and prediction scores on real-world datasets in the Monash Forecasting Repository, and is capable of modeling highly stochastic data with sharp temporal transitions. LS4 sets state-of-the-art for continuous-time latent generative models, with significant improvement of mean squared error and tighter variational lower bounds on irregularly-sampled datasets, while also being x100 faster than other baselines on long sequences.

****

Specformer: Spectral Graph Neural Networks Meet Transformers

Deyu Bo,Chuan Shi,Lele Wang,Renjie Liao

Spectral graph neural networks (GNNs) learn graph representations via spectral-domain graph convolutions. However, most existing spectral graph filters are scalar-to-scalar functions, i.e., mapping a single eigenvalue to a single filtered value, thus ignoring the global pattern of the spectrum. Furthermore, these filters are often constructed based on some fixed-order polynomials, which have limited expressiveness and flexibility. To tackle these issues, we introduce Specformer, which effectively encodes the set of all eigenvalues and performs self-attention in the spectral domain, leading to a learnable set-to-set spectral filter. We also design a decoder with learnable bases to enable non-local graph convolution. Importantly, Specformer is equivariant to permutation. By stacking multiple Specformer layers, one can build a powerful spectral GNN. On synthetic datasets, we show that our Specformer can better recover ground-truth spectral filters than other spectral GNNs. Extensive experiments of both node-level and graph-level tasks on real-world graph datasets show that our Specformer outperforms state-of-the-art GNNs and learns meaningful spectrum patterns. Code and data are available at https://github.com/bdy9527/Specformer.

MetaP: How to Transfer Your Knowledge on Learning Hidden Physics

Lu Zhang,Huaiqian You,Tian Gao,Mo Yu,Chung-Hao Lee,Yue Yu

Gradient-based meta-learning methods have primarily focused on classical machine learning tasks such as image classification and function regression, where they were found to perform well by recovering the underlying common representation among a set of given tasks. Recently, PDE-solving deep learning methods, such as neural operators, are starting to make an important impact on learning and predicting the response of a complex physical system directly from observational data. Since the data acquisition in this context is commonly challenging and costly, the call of utilization and transfer of existing knowledge to new and unseen physical systems is even more acute.

Herein, we propose a novel meta-learnt approach for transfer-learning knowledge between neural operators, which can be seen as transferring the knowledge of solution operators between governing (unknown) PDEs with varying parameter fields. With the key theoretical observation that the underlying parameter field can be captured in the first layer of the neural operator model, in contrast to typical final-layer transfer in existing meta-learning methods, our approach is a provably universal solution operator for multiple PDE solving tasks. As applications, we demonstrate the efficacy of our proposed approach on heterogeneous material modeling tasks, which shows that our method can handle complex and nonlinear physical response learning tasks while greatly improving the sampling efficiency in new and unseen materials.

CommsVAE: Learning the brain's macroscale communication dynamics using coupled sequential VAEs

Eloy Geenjaar,Noah Lewis,Amrit Kashyap,Robyn Miller,Vince Calhoun

Communication within or between complex systems is commonplace in the natural sciences and fields such as graph neural networks. The brain is a perfect example of such a complex system, where communication between brain regions is constantly being orchestrated. To analyze communication, the brain is often split up into anatomical regions that each perform certain computations. These regions must interact and communicate with each other to perform tasks and support higher-level cognition. On a macroscale, these regions communicate through signal propagation along the cortex and along white matter tracts over longer distances. When and what types of signals are communicated over time is an unsolved problem and is often studied using either functional or structural data. In this paper, we propose a non-linear generative approach to communication from functional data. We address three issues with common connectivity approaches by explicitly modeling the directionality of communication, finding communication at each timestep, and encouraging sparsity. To evaluate our model, we simulate temporal data that has sparse communication between nodes embedded in it and show that our model can uncover the expected communication dynamics. Subsequently, we apply our model to temporal neural data from multiple tasks and show that our approach models communication that is more specific to each task. The specificity of our method means it can have an impact on the understanding of psychiatric disorders, which are believed to be related to highly specific communication between brain regions compared to controls. In sum, we propose a general model for dynamic communication learning on graphs, and show its applicability to a subfield of the natural sciences, with potential widespread scientific impact.

Answer Me if You Can: Debiasing Video Question Answering via Answering Unanswerable Questions

Dohwan Ko,Heeji Won,Jongha Kim,Miso CHOI,Byungseok Roh,Hyunwoo J. Kim

Video Question Answering (VideoQA) is a task to predict a correct answer given a question-video pair. Recent studies have shown that most VideoQA models rely on spurious correlations induced by various biases when predicting an answer. For instance, VideoQA models tend to predict `two’ as an answer without considering the video if a question starts with ``How many’' since the majority of answers to such type of questions are `two’. In causal inference, such bias ($\textit{question type}$), which simultaneously affects the input X ($\textit{How many...}$) and the answer Y ($\textit{two}$), is referred to as a confounder Z that hinders a model from learning the true relationship between the input and the answer. The effect of the confounders Z can be removed with a causal intervention $P(Y|do(X))$ when Z is observed. However, there exist many unobserved confounders affecting questions and videos, $\textit{e.g.}$, dataset bias induced by annotators who mainly focus on human activities and salient objects resulting in a spurious correlation between videos and questions. To address this problem, we propose a novel framework that learns unobserved confounders by capturing the bias using $\textit{unanswerable}$ questions, which refers to an artificially constructed VQA sample with a video and a question from two different samples, and leverages the confounders for debiasing a VQA model through causal intervention. We demonstrate that our confounders successfully capture the dataset bias by investigating which part in a video or question that confounders pay attention to. Our experiments on multiple VideoQA benchmark datasets show the effectiveness of the proposed debiasing framework, resulting in an even larger performance gap compared to biased models under the distribution shift.

Language Models Are Greedy Reasoners: A Systematic Formal Analysis of Chain-of-Thought

Abulhair Saparov,He He

Large language models (LLMs) have shown remarkable reasoning capabilities given chain-of-thought prompts (examples with intermediate reasoning steps). Existing benchmarks measure reasoning ability indirectly, by evaluating accuracy on downstream tasks such as mathematical reasoning. However, it is unclear how these models obtain the answers and whether they rely on simple heuristics rather than the generated chain-of-thought. To enable systematic exploration of the reasoning ability of LLMs, we present a new synthetic question-answering dataset called PrOntoQA, where each example is generated from a synthetic world model represented in first-order logic. This allows us to parse the generated chain-of-thought into symbolic proofs for formal analysis. Our analysis on InstructGPT and GPT-3 shows that LLMs are quite capable of making correct individual deduction steps, and so are generally capable of reasoning, even in fictional contexts. However, they have difficulty with proof planning: When multiple valid deduction steps are available, they are not able to systematically explore the different options.

Approximation ability of Transformer networks for functions with various smoothness of Besov spaces: error analysis and token extraction

Yuki Wada,Shokichi Takakura,Taiji Suzuki

Although Transformer networks outperform various natural language processing tasks, many aspects of their theoretical nature are still unclear. On the other hand, fully connected neural networks have been extensively studied in terms of their approximation and estimation capability where the target function is included in such function classes as H\"older class and Besov class. In this paper, we study the approximation and estimation error of Transformer networks in a setting where the target function takes a fixed-length sentence as an input and belongs to two variants of Besov spaces known as anisotropic Besov and mixed smooth Besov spaces, in which it is shown that Transformer networks can avoid curse of dimensionality. By overcoming the difficulties in limited interactions among tokens, we prove that Transformer networks can accomplish minimax optimal rate. Our result also shows that token-wise parameter sharing in Transformer networks decreases dependence of the network width on the input length. Moreover, we prove that, under suitable situations, Transformer networks dynamically select tokens to pay careful attention to. This phenomenon matches attention mechanism, on which Transformer networks are based. Our analyses strongly support the reason why Transformer networks have outperformed various natural language processing tasks from a theoretical perspective.

****

Clustering Embedding Tables, Without First Learning Them

Henry Ling-Hei Tsang,Thomas Dybdahl Ahle

Machine learning systems use embedding tables to work with categorical features. These tables may get extremely large in modern recommendation systems, and various methods have been suggested to fit them in memory.

Product- and Residual Vector Quantization are some of the most successful methods for table compression. They function by substituting table rows with references to ``codewords'' picked by k-means clustering. Unfortunately, this means that they must first know the table before compressing it, thus they can only save memory at inference time, not training time. Recent work has employed hashing-based approaches to minimize memory usage during training, however the compression obtained is poorer than that achieved by ``post-training'' quantization.

We demonstrate that combining hashing and clustering based algorithms provides the best of both worlds. By first training a hashing-based ``sketch'', then clustering it, and then training the clustered quantization, our method may achieve compression ratios close to those of post-training quantization with the training time memory reductions of hashing-based methods. We prove that this technique works rigorously in the least-square setting.

Architecture Matters in Continual Learning

Seyed Iman Mirzadeh,Arslan Chaudhry,Dong Yin,Timothy Nguyen,Razvan Pascanu,Dilan Gorur,Mehrdad Farajtabar

A large body of research in continual learning is devoted to overcoming the catastrophic forgetting of neural networks by designing new algorithms that are robust to the distribution shifts. However, the majority of these works are strictly focused on the "algorithmic" part of continual learning for a "fixed neural network architecture", and the implications of using different architectures are not clearly understood. The few existing continual learning methods that expand the model also assume a fixed architecture and develop algorithms that can efficiently use the model throughout the learning experience. In contrast, in this work, we build on existing works that study continual learning from a neural network's architecture perspective and provide new insights into how the architecture choice, for the same learning algorithm, can impact stability-plasticity trade-off resulting in markedly different continual learning performance. We empirically analyze the impact of various architectural components providing best practices and recommendations that can improve the continual learning performance irrespective of the learning algorithm.

Machine Learning Force Fields with Data Cost Aware Training

Alexander Bukharin,Tianyi Liu,Shengjie Wang,Simiao Zuo,Weihao Gao,Wen Yan,Tuo Zhao

Machine learning force fields (MLFF) have been proposed to accelerate molecular dynamics (MD) simulation, which finds widespread applications in chemistry and biomedical research. Even for the most data-efficient MLFF models, reaching chemical accuracy can require hundreds of frames of force and energy labels generated by expensive quantum mechanical algorithms, which may scale as $O(n^3)$ to $O(n^7)$, with n being the number of basis functions used and typically proportional to the number of atoms.

To address this issue, we propose a multi-stage computational framework -- ASTEROID, which enjoys low training data generation cost without significantly sacrificing MLFFs' accuracy. Specifically, ASTEROID leverages a combination of both large cheap inaccurate data and small expensive accurate data. The motivation behind ASTEROID is that inaccurate data, though incurring large bias, can help capture the sophisticated structures of the underlying force field. Therefore, we first train a MLFF model on a large amount of inaccurate training data, employing a bias-aware loss function to prevent the model from overfitting the potential bias of the inaccurate training data. We then fine-tune the obtained model using a small amount of accurate training data, which preserves the knowledge learned from the inaccurate training data while significantly improving the model's accuracy. Moreover, we propose a variant of ASTEROID based on score matching for the setting where the inaccurate training data are unlabelled. Extensive experiments on MD simulation datasets show that ASTEROID can significantly reduce data generation costs while improving the accuracy of MLFFs.

Covariance Matrix Adaptation MAP-Annealing

Matthew Christopher Fontaine,Stefanos Nikolaidis

Single-objective optimization algorithms search for the single highest-quality solution with respect to an objective. Quality diversity (QD) algorithms, such as Covariance Matrix Adaptation MAP-Elites (CMA-ME), search for a collection of solutions that are both high-quality with respect to an objective and diverse with respect to specified measure functions. However, CMA-ME suffers from three major limitations highlighted by the QD community: prematurely abandoning the objective in favor of exploration, struggling to explore flat objectives, and having poor performance for low-resolution archives. We propose a new quality diversity algorithm, Covariance Matrix Adaptation MAP-Annealing (CMA-MAE), that addresses all three limitations. We provide theoretical justifications for the new algorit hm with respect to each limitation. Our theory informs our experiments, which support the theory and show that CMA-MAE achieves state-of-the-art performance.

Learning Rewards and Skills to Follow Commands with a Data Efficient Visual-Audio Representation

Peixin Chang,Shuijing Liu,Tianchen Ji,Neeloy Chakraborty,D Livingston McPherson,Katherine Rose Driggs-Campbell

Based on the recent advancements in representation learning, we propose a novel framework for command-following robots with raw sensor inputs. Previous RL-based methods are either difficult to continuously improve after the deployment or require a large number of new labels during the fine-tuning. Motivated by (self-)supervised contrastive learning literature, we propose a novel representation, named VAR++, that generates an intrinsic reward function for command-following robot tasks by associating images with sound commands. After the robot is deployed in a new domain, the representation can be updated intuitively and data-efficiently by non-expert, and the robots are able to fulfill sound commands without any hand-crafted reward functions. We demonstrate our approach to various sound types and robotic tasks, including navigation and manipulation with raw sensor inputs. In the simulated experiments, we show that our system can continually self-improve in previously unseen scenarios given fewer new labeled data, yet achieves better performance, compared with previous methods.

Reinforcement Learning-Based Estimation for Partial Differential Equations

Saviz Mowlavi,Mouhacine Benosman,Saleh Nabi

In systems governed by nonlinear partial differential equations such as fluid flows, the design of state estimators such as Kalman filters relies on a reduced-order model (ROM) that projects the original high-dimensional dynamics onto a computationally tractable low-dimensional space. However, ROMs are prone to large errors, which negatively affects the performance of the estimator. Here, we introduce the reinforcement learning reduced-order estimator (RL-ROE), a ROM-based estimator in which the correction term that takes in the measurements is given by a nonlinear policy trained through reinforcement learning. The nonlinearity of the policy enables the RL-ROE to compensate efficiently for errors of the ROM, while still taking advantage of the imperfect knowledge of the dynamics. Using examples involving the Burgers and Navier-Stokes equations, we show that in the limit of very few sensors, the trained RL-ROE outperforms a Kalman filter designed using the same ROM. Moreover, it yields accurate high-dimensional state estimates for reference trajectories corresponding to various physical parameter values, without direct knowledge of the latter.

Heterogeneous-Agent Mirror Learning

Jakub Grudzien Kuba,Xidong Feng,Shiyao Ding,Hao Dong,Yaodong Yang

The necessity for cooperation among intelligent machines has popularised cooperative multi-agent reinforcement learning (MARL) in the artificial intelligence (AI) research community. However, many research endeavours have been focused on developing practical MARL algorithms whose effectiveness has been studied only empirically, thereby lacking theoretical guarantees. As recent studies have revealed, MARL methods often achieve performance that is unstable in terms of reward monotonicity or suboptimal at convergence. To resolve these issues, in this paper, we introduce a novel framework named Heterogeneous-Agent Mirror Learning (HAML) that provides a general template for MARL algorithmic designs. We prove that algorithms derived from the HAML template satisfy the desired properties of the monotonic improvement of the joint reward and the convergence to Nash equilibrium. We verify the practicality of HAML by proving that the current state-of-the-art cooperative MARL algorithms, HATRPO and HAPPO, are in fact HAML instances. Next, as a natural outcome of our theory, we propose HAML extensions of two well-known RL algorithms, HAA2C (for A2C) and HADDPG (for DDPG), and demonstrate their effectiveness against strong baselines on StarCraftII and Multi-Agent MuJoCo task

Recursive Time Series Data Augmentation

Amine Mohamed Aboussalah,Minjae Kwon,Raj G Patel,Cheng Chi,Chi-Guhn Lee

Time series observations can be seen as realizations of an underlying dynamical system governed by rules that we typically do not know. For time series learning tasks we create our model using available data. Training on available realizations, where data is limited, often induces severe over-fitting thereby preventing generalization. To address this issue, we introduce a general recursive framework for time series augmentation, which we call the Recursive Interpolation Method (RIM). New augmented time series are generated using a recursive interpolation function from the original time series for use in training. We perform theoretical analysis to characterize the proposed RIM and to guarantee its performance under certain conditions. We apply RIM to diverse synthetic and real-world time series cases to achieve strong performance over non-augmented data on a variety of learning tasks. Our method is also computationally more efficient and leads to better performance when compared to state of the art time series data augmentation.

Auto-Encoding Goodness of Fit

Aaron Palmer,Zhiyi Chi,Derek Aguiar,Jinbo Bi

For generative autoencoders to learn a meaningful latent representation for data generation, a careful balance must be achieved between reconstruction error and how close the distribution in the latent space is to the prior. However, this balance is challenging to achieve due to a lack of criteria that work both at the mini-batch (local) and aggregated posterior (global) level. In this work, we develop the Goodness of Fit Autoencoder (GoFAE), which incorporates hypothesis tests at two levels. At the mini-batch level, it uses GoF test statistics as regularization objectives. At a more global level, it selects a regularization coefficient based on higher criticism, i.e., a test on the uniformity of the local GoF p-values. We justify the use of GoF tests by providing a relaxed L_2-Wasserstein bound on the distance between the latent distribution and target prior. We propose to use GoF tests and prove that optimization based on these tests can be done with stochastic gradient (SGD) descent on a compact Riemannian manifold. Empirically, we show that our higher criticism parameter selection procedure balances reconstruction and generation using mutual information and uniformity of p-values respectively. Finally, we show that GoFAE achieves comparable FID scores and mean squared errors with competing deep generative models while retaining statistical indistinguishability from Gaussian in the latent space based on a variety of hypothesis tests.

VER: Learning Natural Language Representations for Verbalizing Entities and Relations

Jie Huang,Kevin Chang

Entities and relationships between entities are vital in the real world. Essentially, we understand the world by understanding entities and relations. For instance, to understand a field, e.g., computer science, we need to understand the relevant concepts, e.g., machine learning, and the relationships between concepts, e.g., machine learning and artificial intelligence. To understand a person, we should first know who he/she is and how he/she is related to others. To understand entities and relations, humans may refer to natural language descriptions. For instance, when learning a new scientific term, people usually start by reading its definition in dictionaries or encyclopedias. To know the relationship between two entities, humans tend to create a sentence to connect them. In this paper, we propose VER: A Unified Model for Verbalizing Entities and Relations. Specifically, we attempt to build a system that takes any entity or entity set as input and generates a sentence to represent entities and relations, named ``natural language representation''. Extensive experiments demonstrate that our model can generate high-quality sentences describing entities and entity relationships and facilitate various tasks on entities and relations, including definition modeling, relation modeling, and generative commonsense reasoning.

Adaptive IMLE for Few-shot Image Synthesis

Mehran Aghabozorgi,Shichong Peng,Ke Li

Despite their success on large datasets, GANs have been difficult to apply in the few-shot setting, where only a limited number of training examples are provided. Due to mode collapse, GANs tend to ignore some training examples, causing overfitting to a subset of the training dataset, which is small to begin with. A recent method called Implicit Maximum Likelihood Estimation (IMLE) is an alternative to GAN that tries to address this issue. It uses the same kind of generators as GANs but trains it with a different objective that encourages mode coverage. However, the theoretical guarantees of IMLE hold under restrictive conditions, such as the requirement for the optimal likelihood at all data points to be the same. In this paper, we present a more generalized formulation of IMLE which includes the original formulation as a special case, and we prove that the theoretical guarantees hold under weaker conditions. Using this generalized formulation, we further derive a new algorithm, which we dub Adaptive IMLE, which can adapt to the varying difficulty of different training examples. We demonstrate on multiple few-shot image synthesis datasets that our method significantly outperforms existing methods.

Understanding the Covariance Structure of Convolutional Filters

Asher Trockman,Devin Willmott,J Zico Kolter

Neural network weights are typically initialized at random from univariate distributions, controlling just the variance of individual weights even in highly-structured operations like convolutions. Recent ViT-inspired convolutional networks such as ConvMixer and ConvNeXt use large-kernel depthwise convolutions whose learned filters have notable structure; this presents an opportunity to study their empirical covariances. In this work, we first observe that such learned filters have highly-structured covariance matrices, and moreover, we find that covariances calculated from small networks may be used to effectively initialize a variety of larger networks of different depths, widths, patch sizes, and kernel sizes, indicating a degree of model-independence to the covariance structure. Motivated by these findings, we then propose a learning-free multivariate initialization scheme for convolutional filters using a simple, closed-form construction of their covariance. Models using our initialization outperform those using traditional univariate initializations, and typically meet or exceed the performance of those initialized from the covariances of learned filters; in some cases, this improvement can be achieved without training the depthwise convolutional filters at all. Our code is available at https://github.com/locuslab/convcov.

Reinforcement Logic Rule Learning for Temporal Point Processes

Chao Yang,Lu Wang,Kun Gao,Shuang Li

We aim to learn a set of temporal logic rules to explain the occurrence of temporal events. Leveraging the temporal point process modeling and learning framework, the rule content and rule weights are jointly learned by maximizing the likelihood of the observed noisy event sequences. The proposed algorithm alternates between a master problem, where the rule weights are updated, and a subproblem, where a new rule is searched and included. The formulated master problem is convex and relatively easy to solve, whereas the subproblem requires searching the huge combinatorial rule predicate and relationship space. To tackle this challenge, we propose a neural search policy to learn to generate the new rule content as a sequence of actions. The policy parameters will be trained end-to-end using the reinforcement learning framework, where the reward signals can be efficiently queried by evaluating the subproblem objective. The trained policy can be used to generate new rules, and moreover, the well-trained policies can be directly transferred to other tasks to speed up the rule searching procedure in the new task. We evaluate our methods on both synthetic and real-world datasets, obtaining promising results.

Masked Distillation with Receptive Tokens

Tao Huang,Yuan Zhang,Shan You,Fei Wang,Chen Qian,Jian Cao,Chang Xu

Distilling from the feature maps can be fairly effective for dense prediction tasks since both the feature discriminability and localization information can be well transferred. However, not every pixel contributes equally to the performance, and a good student should learn from what really matters to the teacher. In this paper, we introduce a learnable embedding dubbed receptive token to locate the pixels of interests (PoIs) in the feature map, with a distillation mask generated via pixel-wise attention. Then the masked distillation will be performed via the pixel-wise reconstruction. In this way, a distillation mask refers to a pattern of pixel dependencies. We thus adopt multiple receptive tokens to investigate more sophisticated and informative pixel dependencies within feature maps to enhance the distillation. To obtain a group of masks, the receptive tokens are learned via the regular task loss but with teacher fixed, and we also leverage a Dice loss to enrich the diversity of obtained masks. Our method dubbed MasKD is simple and practical, and needs no priors of ground-truth labels, which can apply to various dense prediction tasks. Experiments show that our MasKD can achieve state-of-the-art performance consistently on object detection and semantic segmentation benchmarks.

Robust Multivariate Time-Series Forecasting: Adversarial Attacks and Defense Mechanisms

Linbo Liu,Youngsuk Park,Trong Nghia Hoang,Hilaf Hasson,Luke Huan

This work studies the threats of adversarial attack on multivariate probabilistic forecasting models and viable defense mechanisms. Our studies discover a new attack pattern that negatively impact the forecasting of a target time series via making strategic, sparse (imperceptible) modifications to the past observations of a small number of other time series. To mitigate the impact of such attack, we have developed two defense strategies. First, we extend a previously developed randomized smoothing technique in classification to multivariate forecasting scenarios. Second, we develop an adversarial training algorithm that learns to create adversarial examples and at the same time optimizes the forecasting model to improve its robustness against such adversarial simulation. Extensive experiments on real-world datasets confirm that our attack schemes are powerful and our defense algorithms are more effective compared with baseline defense mechanisms.

TextShield: Beyond Successfully Detecting Adversarial Sentences in text classification

Lingfeng Shen,Ze Zhang,Haiyun Jiang,Ying Chen

Adversarial attack serves as a major challenge for neural network models in NLP, which precludes the model's deployment in safety-critical applications. A recent line of work, detection-based defense, aims to distinguish adversarial sentences from benign ones. However, {the core limitation of previous detection methods is being incapable of giving correct predictions on adversarial sentences unlike defense methods from other paradigms.} To solve this issue, this paper proposes TextShield: (1) we discover a link between text attack and saliency information, and then we propose a saliency-based detector, which can effectively detect whether an input sentence is adversarial or not. (2) We design a saliency-based corrector, which converts the detected adversary sentences to benign ones. By combining the saliency-based detector and corrector, TextShield extends the detection-only paradigm to a detection-correction paradigm, thus filling the gap in the existing detection-based defense. Comprehensive experiments show that (a) TextShield consistently achieves higher or comparable performance than state-of-the-art defense methods across various attacks on different benchmarks. (b) our saliency-based detector outperforms existing detectors for detecting adversarial sentences.

Efficient Deep Reinforcement Learning Requires Regulating Overfitting

Qiyang Li,Aviral Kumar,Ilya Kostrikov,Sergey Levine

Deep reinforcement learning algorithms that learn policies by trial-and-error must learn from limited amounts of data collected by actively interacting with the environment. While many prior works have shown that proper regularization techniques are crucial for enabling data-efficient RL, a general understanding of the bottlenecks in data-efficient RL has remained unclear. Consequently, it has been difficult to devise a universal technique that works well across all domains. In this paper, we attempt to understand the primary bottleneck in sample-efficient deep RL by examining several potential hypotheses such as non-stationarity, excessive action distribution shift, and overfitting. We perform thorough empirical analysis on state-based DeepMind control suite (DMC) tasks in a controlled and systematic way to show that high temporal-difference (TD) error on the validation set of transitions is the main culprit that severely affects the performance of deep RL algorithms, and prior methods that lead to good performance do in fact, control the validation TD error to be low. This observation gives us a robust principle for making deep RL efficient: we can hill-climb on the validation TD error by utilizing any form of regularization techniques from supervised learning. We show that a simple online model selection method that targets the validation TD error is effective across state-based DMC and Gym tasks.

Nuisances via Negativa: Adjusting for Spurious Correlations via Data Augmentation

Aahlad Manas Puli,Nitish Joshi,He He,Rajesh Ranganath

There exist features that are related to the label in the same way across different settings for that task; these are semantic features or semantics. Features with varying relationships to the label are nuisances. For example, in detecting cows from natural images, the shape of the head is a semantic and because images of cows often have grass backgrounds but not always, the background is a nuisance. Relationships between a nuisance and the label are unstable across settings and, consequently, models that exploit nuisance-label relationships face performance degradation when these relationships change. Direct knowledge of a nuisance helps build models that are robust to such changes, but knowledge of a nuisance requires extra annotations beyond the label and the covariates. In this paper, we develop an alternative way to produces robust models by data augmentation. These data augmentations corrupt semantic information to produce models that identify and adjust for where nuisances drive predictions. We study semantic corruptions in powering different robust-modeling methods for multiple out-of distribution (OOD) tasks like classifying waterbirds, natural language inference, and detecting Cardiomegaly in chest X-rays.

GNN Domain Adaptation using Optimal Transport

Qi Zhu,Yizhu Jiao,Haonan Wang,Natalia Ponomareva,Bryan Perozzi

While Graph Convolutional Networks (GCNs) have recently grown in popularity due to their excellent performance on graph data, their performance under domain shift has not been studied extensively. In this work, we first explore the ability of GCNs to generalize to out-of-distribution data using contextual stochastic block models (CSBMs) on the node classification task. Our results in this area provide the first generalization criteria for GCNs on feature distribution and structure changes. Next we examine a popular Unsupervised Domain Adaptation (UDA) covariate shift assumption and demonstrate that it rarely holds for graph data. Motivated by these results, we propose addressing bias in graph models using domain adaptation with optimal transport - GDOT which features a transportation plan that minimizes the cost of the joint feature and estimated label distribution $P(X,\hat{Y})$ between source and target domains. Additionally, we demonstrate that such transportation cost metric serves as a good proxy for estimating transferability between source and target graphs, and is better as a transferability metric than other common metrics like maximum mean discrepancy (MMD). In our controlled CSBM experiments, GDOT demonstrates robustness towards distributional shift, resulting in 90\% ROC AUC (vs.\ the second-best algorithm achieving <80\% on feature shift). Comprehensive experiments on both semi-supervised and supervis ed real-world node classification problems show that our method is the only one that performs consistently better than baseline GNNs in the cross-domain adaptation setting.

Ask Me Anything: A simple strategy for prompting language models

Simran Arora,Avanika Narayan,Mayee F Chen,Laurel Orr,Neel Guha,Kush Bhatia,Ines Chami,Christopher Re

Large language models (LLMs) transfer well to new tasks out-of-the-box simply given a natural language prompt that demonstrates how to perform the task and no additional training. Prompting is a brittle process wherein small modifications to the prompt can cause large variations in the model predictions, and therefore significant effort is dedicated towards designing a painstakingly crafted "perfect prompt" for a task. To mitigate the high degree of effort, we instead ask whether collecting multiple decent, yet imperfect, prompts and aggregating them can lead to a high quality prompting strategy. Our observations motivate our proposed method, Ask Me Anything (AMA). We first develop an understanding of the effective prompt formats, finding question-answering (QA) prompts, which encourage open-ended generation ("Who went to the park?") tend to outperform those that restrict the model outputs ("John went to the park. True or False?"). AMA recursively uses the LLM to transform task inputs to the effective QA format. AM generates multiple questions per input and applies these prompts to collect several noisy "votes" for the input's true label. We find the prompts have varying accuracies and dependencies and thus propose to use weak supervision, a procedure for combining the noisy predictions, to produce the final predictions. We evaluate AMA across open-source model families (EleutherAI, BLOOM, OPT, and T0) and sizes (125M-175B parameters), demonstrating an average performance lift of 10.2\% over the few-shot baseline. This simple strategy enables the open-source GPT-J-6B model to match and exceed the performance of few-shot GPT3-175B on 15 of 20 popular benchmarks. Averaged across these tasks, the GPT-J-6B model outperforms few-shot GPT3-175B. We release our code here: https://github.com/HazyResearch/ama_prompting.

Limits of Algorithmic Stability for Distributional Generalization

Neha Hulkund,Vinith Menon Suriyakumar,Taylor W. Killian,Marzyeh Ghassemi

As machine learning models become widely considered in safety critical settings, it is important to understand when models may fail after deployment. One cause of model failure is distribution shift, where the training and test data distributions differ. In this paper we investigate the benefits of training models using methods which are algorithmically stable towards improving model robustness, motivated by recent theoretical developments which show a connection between the two. We use techniques from differentially private stochastic gradient descent (DP-SGD) to control the level of algorithmic stability during training. We compare the performance of algorithmically stable training procedures to stochastic gradient descent (SGD) across a variety of possible distribution shifts - specifically covariate, label, and subpopulation shifts. We find that models trained with algorithmically stable procedures result in models with consistently lower generalization gap across various types of shifts and shift severities. as well as a higher absolute test performance in label shift. Finally, we demonstrate that there is there is a tradeoff between distributional robustness, stability, and performance.

WikiWhy: Answering and Explaining Cause-and-Effect Questions

Matthew Ho,Aditya Sharma,Justin Chang,Michael Saxon,Sharon Levy,Yujie Lu,William Yang Wang

As large language models (LLMs) grow larger and more sophisticated, assessing their "reasoning" capabilities in natural language grows more challenging. Recent question answering (QA) benchmarks that attempt to assess reasoning are often limited by a narrow scope of covered situations and subject matters. We introduce WikiWhy, a QA dataset built around a novel auxiliary task: explaining why an answer is true in natural language. WikiWhy contains over 9,000 "why" question-answ er-rationale triples, grounded on Wikipedia facts across a diverse set of topics. Each rationale is a set of supporting statements connecting the question to the answer. WikiWhy serves as a benchmark for the reasoning capabilities of LLMs because it demands rigorous explicit rationales for each answer to demonstrate the acquisition of implicit commonsense knowledge, which is unlikely to be easily memorized. GPT-3 baselines achieve only 38.7% human-evaluated correctness in the end-to-end answer & explain condition, leaving significant room for future improvements.

****

Offline Reinforcement Learning with Differentiable Function Approximation is Provably Efficient

Ming Yin,Mengdi Wang,Yu-Xiang Wang

Offline reinforcement learning, which aims at optimizing sequential decision-making strategies with historical data, has been extensively applied in real-life applications. State-Of-The-Art algorithms usually leverage powerful function approximators (e.g. neural networks) to alleviate the sample complexity hurdle for better empirical performances. Despite the successes, a more systematic under- standing of the statistical complexity for function approximation remains lacking. Towards bridging the gap, we take a step by considering offline reinforcement learning with differentiable function class approximation (DFA). This function class naturally incorporates a wide range of models with nonlinear/nonconvex structures. We show offline RL with differentiable function approximation is provably efficient by analyzing the pessimistic fitted Q-learning (PFQL) algorithm, and our results provide the theoretical basis for understanding a variety of practical heuristics that rely on Fitted Q-Iteration style design. In addition, we further im- prove our guarantee with a tighter instance-dependent characterization. We hope our work could draw interest in studying reinforcement learning with differentiable function approximation beyond the scope of current research.

Proto-Value Networks: Scaling Representation Learning with Auxiliary Tasks

Jesse Farebrother,Joshua Greaves,Rishabh Agarwal,Charline Le Lan,Ross Goroshin,Pablo Samuel Castro,Marc G Bellemare

Auxiliary tasks improve the representations learned by deep reinforcement learning agents. Analytically, their effect is reasonably well-understood; in practice, how-ever, their primary use remains in support of a main learning objective, rather than as a method for learning representations. This is perhaps surprising given that many auxiliary tasks are defined procedurally, and hence can be treated as an essentially infinite source of information about the environment. Based on this observation, we study the effectiveness of auxiliary tasks for learning rich representations, focusing on the setting where the number of tasks and the size of the agent’s network are simultaneously increased. For this purpose, we derive a new family of auxiliary tasks based on the successor measure. These tasks are easy to implement and have appealing theoretical properties. Combined with a suitable off-policy learning rule, the result is a representation learning algorithm that can be understood as extending Mahadevan & Maggioni (2007)’s proto-value functions to deep reinforcement learning – accordingly, we call the resulting object proto-value networks. Through a series of experiments on the Arcade Learning Environment, we demonstrate that proto-value networks produce rich features that may be used to obtain performance comparable to established algorithms, using only linear approximation and a small number (~4M) of interactions with the environment’s reward function.

****

Pseudometric guided online query and update for offline reinforcement learning

Haoran Li,Yang Weng

Offline Reinforcement Learning (RL) extracts effective policies from historical data without the need to interact with the environment. However, the learned policy often suffers large generalization errors in the online environment due to the distributional shift. While existing work mostly focuses on learning a generalizable policy, we propose to adapt the learned policy to fit the online environ ment with limited queries. The goals include querying reasonable actions with limited chances and efficiently modifying the policy. Our insight is to unify these two goals via a proper pseudometric. Intuitively, the metric can compare online and offline states to infer optimal query actions. Additionally, efficient policy updates require good knowledge of the similarity between query results and historical data. Therefore, we propose a unified framework, denoted Pseudometric Guided Offline-to-Online RL (PGO2). Specifically, in deep Q learning, PGO2 has a structural design between the Q-neural network and the Siamese network, which guarantees simultaneous Q-network updating and pseudometric learning, promoting Q-network fine-tuning. In the inference phase, PGO2 solves convex optimizations to identify optimal query actions. We also show that PGO2 training converges to the so-called bisimulation metric with strong theoretical guarantees. Finally, we demonstrate the superiority of PGO2 on diversified datasets.

Efficient Data Subset Selection to Generalize Training Across Models: Transductive and Inductive Networks

Eeshaan Jain,Tushar Nandy,Gaurav Aggarwal,Ashish V. Tendulkar,Rishabh K Iyer,Abir De

Subset selection, in recent times, has emerged as a successful approach toward efficient training of models by significantly reducing the amount of data and computational resources required. However, existing methods employ discrete combinatorial and model-specific approaches which lack generalizability--- for each new model, the algorithm has to be executed from the beginning. Therefore, for data subset selection for an unseen architecture, one cannot use the subset chosen for a different model. In this work, we propose SubSelNet, a non-adaptive subset selection framework, which tackles these problems with two main components. First, we introduce an attention-based neural gadget that leverages the graph structure of architectures and acts as a surrogate to trained deep neural networks for quick model prediction. Then, we use these predictions to build subset samplers. This leads us to develop two variants of SubSelNet. The first variant is transductive (called as Transductive-SubSelNet) which computes the subset separately for each model by solving a small optimization problem. Such an optimization is still super fast, thanks to the replacement of explicit model training by the model approximator. The second variant is inductive (called as Inductive-SubSelNet) which computes the subset using a trained subset selector, without any optimization. Most state-of-the-art data subset selection approaches are adaptive, in that the subset selection adapts as the training progresses, and as a result, they require access to the entire data at training time. Our approach, in contrast, is non-adaptive and does the subset selection only once in the beginning, thereby achieving resource and memory efficiency along with compute-efficiency at training time. Our experiments show that both transductive and inductive variants of our models outperform several methods on the quality of the subset chosen and further demonstrate that our method can be used for choosing the best architecture from a set of architectures.

Probe Into Multi-agent Adversarial Reinforcement Learning through Mean-Field Optimal Control

Ziming Wang,Fengxiang He,Bohan Wang,Die Gan,Dacheng Tao

Multi-agent adversarial reinforcement learning (MaARL) has shown promise in solving adversarial games. However, the theoretical tools for MaARL's analysis is still elusive. In this paper, we take the first step to theoretically understanding MaARL through mean-field optimal control. Specifically, we model MaARL as a mean-field quantitative differential game between two dynamical systems with implicit terminal constraints. Based on the game, we respectively study the optimal solution and the generalization of the fore-mentioned game. First of all, a two-sided extremism principle (TSEP) is then established as a necessary condition for the optimal solution of the game. We further show that TSEP is also sufficient given that the terminal time is sufficiently small. Secondly, based on the TSEP, a generalization bound for MaARL is proposed. The bound does not explicitly rel

y on the dimensions, norms, or other capacity measures of the model, which are usually prohibitively large in deep learning.
****

Robust Algorithms on Adaptive Inputs from Bounded Adversaries

Yeshwanth Cherapanamjeri,Sandeep Silwal,David Woodruff,Fred Zhang,Qiuyi Zhang,Samson Zhou

We study dynamic algorithms robust to adaptive input generated from sources with bounded capabilities, such as sparsity or limited interaction. For example, we consider robust linear algebraic algorithms when the updates to the input are sparse but given by an adversary with access to a query oracle. We also study robust algorithms in the standard centralized setting, where an adversary queries an algorithm in an adaptive manner, but the number of interactions between the adversary and the algorithm is bounded. We first recall a unified framework of (Hassidim et al., 2020; Beimel et al., 2022; Attias et al., 2023) for answering Q adaptive queries that incurs $\widetilde{\mathcal{O}}(\sqrt{Q})$ overhead in space, which is roughly a quadratic improvement over the na\"{i}ve implementation, and only incurs a logarithmic overhead in query time. Although the general framework has diverse applications in machine learning and data science, such as adaptive distance estimation, kernel density estimation, linear regression, range queries, point queries, and serves as a preliminary benchmark, we demonstrate even better algorithmic improvements for (1) reducing the pre-processing time for adaptive distance estimation and (2) permitting an unlimited number of adaptive queries for kernel density estimation. Finally, we complement our theoretical results with additional empirical evaluations.

Chasing All-Round Graph Representation Robustness: Model, Training, and Optimization

Chunhui Zhang,Yijun Tian,Mingxuan Ju,Zheyuan Liu,Yanfang Ye,Nitesh Chawla,Chuxu Zhang

Graph Neural Networks (GNNs) have achieved state-of-the-art results on a variety of graph learning tasks, however, it has been demonstrated that they are vulnerable to adversarial attacks, raising serious security concerns. A lot of studies have been developed to train GNNs in a noisy environment and increase their robustness against adversarial attacks. However, existing methods have not uncovered a principled difficulty: the convoluted mixture distribution between clean and attacked data samples, which leads to sub-optimal model design and limits their frameworks’ robustness. In this work, we first begin by identifying the root cause of mixture distribution, then, for tackling it, we propose a novel method GAME - Graph Adversarial Mixture of Experts to enlarge the model capacity and enrich the representation diversity of adversarial samples, from three perspectives of model, training, and optimization. Specifically, we first propose a plug-and-play GAME layer that can be easily incorporated into any GNNs and enhance their adversarial learning capabilities. Second, we design a decoupling-based graph adversarial training in which the component of the model used to generate adversarial graphs is separated from the component used to update weights. Third, we introduce a graph diversity regularization that enables the model to learn diverse representation and further improves model performance. Extensive experiments demonstrate the effectiveness and advantages of GAME over the state-of-the-art adversarial training methods across various datasets given different attacks.

Training Neural Networks with Low-Precision Model Memory

Bingrui Li,Ziteng Wang,Jianfei Chen,Jun Zhu

The demand for memory to store model-related statistics ("model memory") is a major bottleneck for training large neural networks. A promising solution is low-precision optimizers, which reduce the numerical precision of the model memory. However, existing work only compresses the momentum, resulting in suboptimal memory efficiency. This paper proposes Low-Precision Model Memory (LPMM), an optimization framework with the entire model memory kept in low precision. LPMM compresses not only the momentum but also model parameters and gradient accumulators. We identify arithmetic underflow as the main problem in building low-precision op timizers and propose a stochastic quantization method and a microbatching technique to overcome this problem. We analyze the convergence behavior of LPMM and theoretically show how the proposed techniques could affect underflowing, which in turn affects the convergence. We apply LPMM to the SGD optimizer with momentum (SGDM). On several realistic benchmarks, LPMM-SGDM can train neural networks with negligible loss of accuracy while reducing over 70% of the model memory compared to the full-precision SGDM.

Raisin: Residual Algorithms for Versatile Offline Reinforcement Learning

Braham Snyder,Yuke Zhu

The residual gradient algorithm (RG), gradient descent of the Mean Squared Bellman Error, brings robust convergence guarantees to bootstrapped value estimation. Meanwhile, the far more common semi-gradient algorithm (SG) suffers from well-known instabilities and divergence. Unfortunately, RG often converges slowly in practice. Baird (1995) proposed residual algorithms (RA), weighted averaging of RG and SG, to combine RG's robust convergence and SG's speed. RA works moderately well in the online setting. We find, however, that RA works disproportionately well in the offline setting. Concretely, we find that merely adding a variable residual component to SAC increases its score on D4RL gym tasks by a median factor of 54. We further show that using the minimum of ten critics lets our algorithm match SAC-N's state-of-the-art returns using 50$\times$ less compute and no additional hyperparameters. In contrast, TD3+BC with the same minimum-of-ten-critics trick does not match SAC-N's returns on a handful of environments.

VQR: Automated Software Vulnerability Repair Through Vulnerability Queries

Michael Fu,Van Nguyen,Chakkrit Tantithamthavorn,Trung Le,Dinh Phung

Recently, automated vulnerability repair (AVR) approaches have been widely adopted to combat the increasing number of software security issues. In particular, transformer-based models achieve competitive results. While existing models are learned to generate vulnerability repairs, existing AVR models lack a mechanism to provide their models with the precise location of vulnerable code (i.e., models may generate repairs for the non-vulnerable areas). To address this problem, we base our framework on the VIT-based approaches for object detection that learn to locate bounding boxes via the cross-matching between object queries and image patches. We cross-match vulnerability queries and their corresponding vulnerable code areas through the cross-attention mechanism to generate more accurate repairs. To strengthen our cross-matching, we propose to learn a novel vulnerability query mask that greatly focuses on vulnerable code areas and integrate it into the cross-attention. Moreover, we also incorporate the vulnerability query mask into the self-attention to learn embeddings that emphasize the vulnerable areas of a program. Through an extensive evaluation using the real-world 5,417 vulnerabilities, our approach outperforms all of the baseline methods by 3.39%-33.21%. The training code and pre-trained models are available at https://github.com/AVR-VQR/VQR.

Fully Online Meta Learning

Jathushan Rajasegaran,Chelsea Finn,Sergey Levine

While deep networks can learn complex functions such as classifiers, detectors, and trackers, many applications require models that continually adapt to changing input distributions, changing tasks, and changing environmental conditions. Indeed, this ability to continuously accrue knowledge and use past experience to learn new tasks quickly in continual settings is one of the key properties of an intelligent system. For complex and high-dimensional problems, simply updating the model continually with standard learning algorithms such as gradient descent may result in slow adaptation. Meta-learning can provide a powerful tool to accelerate adaptation yet is conventionally studied in batch settings. In this paper, we study how meta-learning can be applied to tackle online problems of this nature, simultaneously adapting to changing tasks and input distributions and meta-training the model in order to adapt more quickly in the future. Extending meta-learning into the online setting presents its own challenges, and although seve ral prior methods have studied related problems, they generally require a discrete notion of tasks, with known ground-truth task boundaries. Such methods typically adapt to each task in sequence, resetting the model between tasks, rather than adapting continuously across tasks. In many real-world settings, such discrete boundaries are unavailable, and may not even exist. To address these settings, we propose a Fully Online Meta-Learning (FOML) algorithm, which does not require any ground truth knowledge about the task boundaries and stays fully online without resetting back to pre-trained weights. Our experiments show that FOML was able to learn new tasks faster than the state-of-the-art online learning methods on Rainbow-MNIST, CIFAR100 and CELEBA datasets.

Learning Globally Smooth Functions on Manifolds

Juan Cervino,Luiz F. O. Chamon,Benjamin David Haeffele,Rene Vidal,Alejandro Ribeiro

Smoothness and low dimensional structures play central roles in improving generalization and stability in learning and statistics. The combination of these properties has led to many advances in semi-supervised learning, generative modeling, and control of dynamical systems. However, learning smooth functions is generally challenging, except in simple cases such as learning linear or kernel models. Typical methods are either too conservative, relying on crude upper bounds such as spectral normalization, too lax, penalizing smoothness on average, or too computationally intensive, requiring the solution of large-scale semi-definite programs. These issues are only exacerbated when trying to simultaneously exploit low dimensionality using, e.g., manifolds. This work proposes to overcome these obstacles by combining techniques from semi-infinite constrained learning and manifold regularization. To do so, it shows that, under typical conditions, the problem of learning a Lipschitz continuous function on a manifold is equivalent to a dynamically weighted manifold regularization problem. This observation leads to a practical algorithm based on a weighted Laplacian penalty whose weights are adapted using stochastic gradient techniques. We prove that, under mild conditions, this method estimates the Lipschitz constant of the solution, learning a globally smooth solution as a byproduct. Numerical examples illustrate the advantages of using this method to impose global smoothness on manifolds as opposed to imposing smoothness on average.

On Representing Mixed-Integer Linear Programs by Graph Neural Networks

Ziang Chen,Jialin Liu,Xinshang Wang,Wotao Yin

While Mixed-integer linear programming (MILP) is NP-hard in general, practical MILP has received roughly 100--fold speedup in the past twenty years. Still, many classes of MILPs quickly become unsolvable as their sizes increase, motivating researchers to seek new acceleration techniques for MILPs. With deep learning, they have obtained strong empirical results, and many results were obtained by applying graph neural networks (GNNs) to making decisions in various stages of MILP solution processes. This work discovers a fundamental limitation: there exist feasible and infeasible MILPs that all GNNs will, however, treat equally, indicating GNN's lacking power to express general MILPs. Then, we show that, by restricting the MILPs to unfoldable ones or by adding random features, there exist GNNs that can reliably predict MILP feasibility, optimal objective values, and optimal solutions up to prescribed precision. We conducted small-scale numerical experiments to validate our theoretical findings.

LEARNING DYNAMIC ABSTRACT REPRESENTATIONS FOR SAMPLE-EFFICIENT REINFORCEMENT LEARNING

Mehdi Dadvar,Rashmeet Kaur Nayyar,Siddharth Srivastava

In many real-world problems, the learning agent needs to learn a problem’s abstractions and solution simultaneously. However, most such abstractions need to be designed and refined by hand for different problems and domains of application. This paper presents a novel top-down approach for constructing state abstractions while carrying out reinforcement learning. Starting with state variables and a simulator, it presents a novel domain-independent approach for dynamically comp uting an abstraction based on the dispersion of Q-values in abstract states as the agent continues acting and learning. Extensive empirical evaluation on multiple domains and problems shows that this approach automatically learns abstractions that are finely-tuned to the problem, yield powerful sample efficiency, and result in the RL agent significantly outperforming existing approaches.

Fighting Fire with Fire: Contrastive Debiasing without Bias-free Data via Generative Bias-transformation

Yeonsung Jung,Hajin Shim,June Yong Yang,Eunho Yang

Despite their remarkable ability to generalize with over-capacity networks, deep neural networks often abuse bias instead of using the actual task-related information for discriminative tasks. Since such shortcuts are only effective within the collected dataset, the resulting biased model underperforms on real-world inputs. To counteract the influence of bias, existing methods either exploit auxiliary information which is rarely obtainable in practice, or sift bias-free samples to exploit them for debiasing. However, such presumptions about the availability of the auxiliary information or bias-free samples are not always guaranteed and the existing methods could break down due to the unmet presumptions. In this paper, we propose Contrastive Debiasing via Generative Bias-transformation (CDvG) which is capable of operating without exploiting bias labels and bias-free samples explicitly. Motivated by our observation that not only discriminative models but also image translation models tend to focus on the easy-to-learn bias, CDvG employs a image translation model to transform the bias to another mode of bias while preserving task-relevant information. Through contrastive learning, we set transformed biased views against another, learning bias-invariant representations. Especially, as the bias has a stronger correlation or is easier to perceive compared to the signal, the translation model is more likely to be a bias translation model, resulting in better debiasing effect. Experimental results demonstrate that CDvG outperforms the state-of-the-arts, especially when bias-free samples are extremely scarce.

On Representing Linear Programs by Graph Neural Networks

Ziang Chen,Jialin Liu,Xinshang Wang,Wotao Yin

Learning to optimize is a rapidly growing area that aims to solve optimization problems or improve existing optimization algorithms using machine learning (ML). In particular, the graph neural network (GNN) is considered a suitable ML model for optimization problems whose variables and constraints are permutation--invariant, for example, the linear program (LP). While the literature has reported encouraging numerical results, this paper establishes the theoretical foundation of applying GNNs to solving LPs. Given any size limit of LPs, we construct a GNN that maps different LPs to different outputs. We show that properly built GNNs can reliably predict feasibility, boundedness, and an optimal solution for each LP in a broad class. Our proofs are based upon the recently--discovered connections between the Weisfeiler--Lehman isomorphism test and the GNN. To validate our results, we train a simple GNN and present its accuracy in mapping LPs to their feasibilities and solutions.

On the Importance and Applicability of Pre-Training for Federated Learning

Hong-You Chen,Cheng-Hao Tu,Ziwei Li,Han Wei Shen,Wei-Lun Chao

Pre-training is prevalent in nowadays deep learning to improve the learned model's performance. However, in the literature on federated learning (FL), neural networks are mostly initialized with random weights. These attract our interest in conducting a systematic study to explore pre-training for FL. Across multiple visual recognition benchmarks, we found that pre-training can not only improve FL, but also close its accuracy gap to the counterpart centralized learning, especially in the challenging cases of non-IID clients' data. To make our findings applicable to situations where pre-trained models are not directly available, we explore pre-training with synthetic data or even with clients' data in a decentralized manner, and found that they can already improve FL notably. Interestingly, many of the techniques we explore are complementary to each other to further bo ost the performance, and we view this as a critical result toward scaling up deep FL for real-world applications. We conclude our paper with an attempt to understand the effect of pre-training on FL. We found that pre-training enables the learned global models under different clients' data conditions to converge to the same loss basin, and makes global aggregation in FL more stable. Nevertheless, pre-training seems to not alleviate local model drifting, a fundamental problem in FL under non-IID data.

Scale-invariant Bayesian Neural Networks with Connectivity Tangent Kernel

SungYub Kim,Sihwan Park,Kyung-Su Kim,Eunho Yang

Studying the loss landscapes of neural networks is critical to identifying generalizations and avoiding overconfident predictions. Flatness, which measures the perturbation resilience of pre-trained parameters for loss values, is widely acknowledged as an essential predictor of generalization. While the concept of flatness has been formalized as a PAC-Bayes bound, it has been observed that the generalization bounds can vary arbitrarily depending on the scale of the model parameters. Despite previous attempts to address this issue, generalization bounds remain vulnerable to function-preserving scaling transformations or are limited to impractical network structures. In this paper, we introduce new PAC-Bayes prior and posterior distributions invariant to scaling transformations, achieved through the \textit{decomposition of perturbations into scale and connectivity components}. In this way, this approach expands the range of networks to which the resulting generalization bound can be applied, including those with practical transformations such as weight decay with batch normalization. Moreover, we demonstrate that scale-dependency issues of flatness can adversely affect the uncertainty calibration of Laplace approximation, and we propose a solution using our invariant posterior. Our proposed invariant posterior allows for effective measurement of flatness and calibration with low complexity while remaining invariant to practical parameter transformations, also applying it as a reliable predictor of neural network generalization.

Autoregressive Graph Network for Learning Multi-step Physics

Sakthi Kumar Arul Prakash,Conrad Tucker

In this work, we propose an Autoregressive Graph Network~(AGN) that learns forward physics using a temporal inductive bias. Currently, temporal state space information is provided as additional input to a GN when generating roll-out physics simulations. While this relatively increases the network's predictive performance over multiple time steps, a temporal model enables the network to induce and learn temporal biases. In dynamical systems, the arrow of time simplifies possible interactions in the sense that we can assume current observations to be dependent on preceding states. The autoregressive property naturally induces the arrow of time and can further constrain physics-induced GNs to conserve symmetries over long time-steps. Our proposed GN encodes temporal state information using an autoregressive encoder that can parallelly compute latent temporal embeddings over multiple time steps during a single forward pass. We perform case studies that compare multi-step forward predictions against baseline data-driven GNs across diverse datasets that feature different particle interactions. Our approach outperforms the state of the art GN and physics-induced GNs in 9 out of 10 and in 7 out of 10 particle physics datasets when conditioned on optimal historical states.

Simple initialization and parametrization of sinusoidal networks via their kernel bandwidth

Filipe de Avila Belbute-Peres,J Zico Kolter

Neural networks with sinusoidal activations have been proposed as an alternative to networks with traditional activation functions. Despite their promise, particularly for learning implicit models, their training behavior is not yet fully understood, leading to a number of empirical design choices that are not well justified. In this work, we first propose a simplified version of such sinusoidal neural networks, which allows both for easier practical implementation and simple r theoretical analysis. We then analyze the behavior of these networks from the neural tangent kernel perspective and demonstrate that their kernel approximates a low-pass filter with an adjustable bandwidth. Finally, we utilize these insights to inform the sinusoidal network initialization, optimizing their performance for each of a series of tasks, including learning implicit models and solving differential equations.

Quasiconvex Shallow Neural Network

CHENHAN XIAO,Yang Weng

Deep neural networks generally have highly non-convex structures, resulting in multiple local optima of network weights. The non-convex network is likely to fail, i.e., being trapped in bad local optima with large errors, especially when the task involves convexity (e.g., linearly separable classification). While convexity is essential in training neural networks, designing a convex network structure without strong assumptions (e.g., linearity) of activation or loss function is challenging. To extract and utilize convexity, this paper presents the QuasiConvex shallow Neural Network (QCNN) architecture with mild assumptions. We first decompose the network into building blocks where quasiconvexity is thoroughly studied. Then, we design additional layers to preserve quasiconvexity where such building blocks are integrated into general networks. The proposed QCNN, interpreted as a quasiconvex optimization problem, allows for efficient training with theoretical guarantees. Specifically, we construct equivalent convex feasibility problems to solve the quasiconvex optimization problem. Our theoretical results are verified via extensive experiments on common machine learning tasks. The quasiconvex structure in QCNN demonstrates even better learning ability than non-convex deep networks in some tasks.

The Best of Both Worlds: Accurate Global and Personalized Models through Federated Learning with Data-Free Hyper-Knowledge Distillation

Huancheng Chen,Chaining Wang,Haris Vikalo

Heterogeneity of data distributed across clients limits the performance of global models trained through federated learning, especially in the settings with highly imbalanced class distributions of local datasets. In recent years, personalized federated learning (pFL) has emerged as a potential solution to the challenges presented by heterogeneous data. However, existing pFL methods typically enhance performance of local models at the expense of the global model's accuracy. We propose FedHKD (Federated Hyper-Knowledge Distillation), a novel FL algorithm in which clients rely on knowledge distillation (KD) to train local models. In particular, each client extracts and sends to the server the means of local data representations and the corresponding soft predictions -- information that we refer to as ``hyper-knowledge". The server aggregates this information and broadcasts it to the clients in support of local training. Notably, unlike other KD-based pFL methods, FedHKD does not rely on a public dataset nor it deploys a generative model at the server. We analyze convergence of FedHKD and conduct extensive experiments on visual datasets in a variety of scenarios, demonstrating that FedHKD provides significant improvement in both personalized as well as global model performance compared to state-of-the-art FL methods designed for heterogeneous data settings.

Minimalistic Unsupervised Representation Learning with the Sparse Manifold Transform

Yubei Chen,Zeyu Yun,Yi Ma,Bruno Olshausen,Yann LeCun

We describe a minimalistic and interpretable method for unsupervised representation learning that does not require data augmentation, hyperparameter tuning, or other engineering designs, but nonetheless achieves performance close to the state-of-the-art (SOTA) SSL methods. Our approach leverages the sparse manifold transform, which unifies sparse coding, manifold learning, and slow feature analysis. With a one-layer deterministic (one training epoch) sparse manifold transform, it is possible to achieve 99.3% KNN top-1 accuracy on MNIST, 81.1% KNN top-1 accuracy on CIFAR-10, and 53.2% on CIFAR-100. With simple gray-scale aug mentation, the model achieves 83.2% KNN top-1 accuracy on CIFAR-10 and 57% on CIFAR-100. These results significantly close the gap between simplistic ``white-box'' methods and SOTA methods. We also provide visualization to illustrate how an unsupervised representation transform is formed. The proposed method is closely connected to latent-embedding self-supervised methods and can be treated as the simplest form of VICReg. Though a small performance gap remains between our simple constructive model and SOTA methods, the evidence points to this as a promising direction for achieving a principled and white-box approach to unsupervised representation learning, which has potential to significantly improve learning efficiency.

Over-Training with Mixup May Hurt Generalization

Zixuan Liu,Ziqiao Wang,Hongyu Guo,Yongyi Mao

Mixup, which creates synthetic training instances by linearly interpolating random sample pairs, is a simple and yet effective regularization technique to boost the performance of deep models trained with SGD. In this work, we report a previously unobserved phenomenon in Mixup raining: on a number of standard datasets, the performance of Mixup-trained models starts to decay after training for a large number of epochs, giving rise to a U-shaped generalization curve. This behavior is further aggravated when the size of original dataset is reduced. To help understand such a behavior of Mixup, we show theoretically that Mixup training may introduce undesired data-dependent label noises to the synthesized data. Via analyzing a least-square regression problem with a random feature model, we explain why noisy labels may cause the U-shaped curve to occur: Mixup improves generalization through fitting the clean patterns at the early training stage, but as training progresses, Mixup becomes over-fitting to the noise in the synthetic data. Extensive experiments are performed on a variety of benchmark datasets, validating this explanation.

HiCLIP: Contrastive Language-Image Pretraining with Hierarchy-aware Attention

Shijie Geng,Jianbo Yuan,Yu Tian,Yuxiao Chen,Yongfeng Zhang

The success of large-scale contrastive vision-language pretraining (CLIP) has benefited both visual recognition and multimodal content understanding. The concise design brings CLIP the advantage in inference efficiency against other vision-language models with heavier cross-attention fusion layers, making it a popular choice for a wide spectrum of downstream tasks. However, CLIP does not explicitly capture the hierarchical nature of high-level and fine-grained semantics conveyed in images and texts, which is arguably critical to vision-language understanding and reasoning. To this end, we equip both the visual and language branches in CLIP with hierarchy-aware attentions, namely Hierarchy-aware CLIP (HiCLIP), to progressively discover semantic hierarchies layer-by-layer from both images and texts in an unsupervised manner. As a result, such hierarchical aggregation significantly improves the cross-modal alignment. To demonstrate the advantages of HiCLIP, we conduct qualitative analysis on its unsupervised hierarchy induction during inference, as well as extensive quantitative experiments on both visual recognition and vision-language downstream tasks.

****

Quantile Risk Control: A Flexible Framework for Bounding the Probability of High-Loss Predictions

Jake Snell,Thomas P Zollo,Zhun Deng,Toniann Pitassi,Richard Zemel

Rigorous guarantees about the performance of predictive algorithms are necessary in order to ensure their responsible use. Previous work has largely focused on bounding the expected loss of a predictor, but this is not sufficient in many risk-sensitive applications where the distribution of errors is important. In this work, we propose a flexible framework to produce a family of bounds on quantiles of the loss distribution incurred by a predictor. Our method takes advantage of the order statistics of the observed loss values rather than relying on the sample mean alone. We show that a quantile is an informative way of quantifying predictive performance, and that our framework applies to a variety of quantile-based metrics, each targeting important subsets of the data distribution. We analy ze the theoretical properties of our proposed method and demonstrate its ability to rigorously control loss quantiles on several real-world datasets.

Dynamic Neural Network is All You Need: Understanding the Robustness of Dynamic Mechanisms in Neural Networks

Mirazul Haque,Wei Yang

Deep Neural Networks (DNN) based solutions are being used to solve different day-to-day problems. Recently, DNNs are being deployed in real-time systems, and lowering the energy consumption and response time has become the need of the hour. To address this scenario, researchers have proposed early-exit Dynamic Neural Networks (DyNNs), where the computation is dynamic based on the input complexity. DyNNs are generally designed and based on larger static DNNs (SDNN). As the DyNNs decrease the energy consumption, it also becomes important to evaluate the robustness of DyNNs to ensure safety. However, there has not been a significant number of works focusing on the robustness of DyNNs. To address this issue, we propose systematic studies to evaluate the robustness of DyNNs. For that purpose, we propose four research questions. These studies are performed on three models and two datasets. Through the studies, we find that DyNNs are more robust than SDNNs, and DyNNs can be used to generate adversarial samples efficiently. We also provide insight into the design choices through research studies. Finally, we propose a novel attack that can decrease the effectiveness of the DyNNs and can be used to evaluate design choices in DyNN.

AutoMoE: Neural Architecture Search for Efficient Sparsely Activated Transformers

Ganesh Jawahar,Subhabrata Mukherjee,Xiaodong Liu,Young Jin Kim,Muhammad Abdul-Mageed,Laks V. S. Lakshmanan,Ahmed Hassan Awadallah,Sebastien Bubeck,Jianfeng Gao

Neural architecture search (NAS) has demonstrated promising results on identifying efficient Transformer architectures which outperform manually designed ones for natural language tasks like neural machine translation (NMT). Existing NAS methods operate on a space of dense architectures, where all of the sub-architecture weights are activated for every input. Motivated by the recent advances in sparsely activated models like the Mixture-of-Experts (MoE) model, we introduce sparse architectures with conditional computation into the NAS search space. Given this expressive search space which subsumes prior densely activated architectures, we develop a new framework AutoMoE to search for efficient sparsely activated sub-Transformers. AutoMoE sparse models obtain (i) 3x FLOPs reduction over manually designed dense Transformers and (ii) 23% FLOPs reduction over state-of-the-art NAS-generated dense sub-Transformers with parity in BLEU score on benchmark datasets for NMT. AutoMoE consists of three training phases: (a) Heterogeneous search space design with dense and sparsely activated Transformer modules (e.g., how many experts? where to place them? what should be their sizes?}; (b) SuperNet training that jointly trains several subnetworks sampled from the large search space by weight-sharing; (c) Evolutionary search for the architecture with the optimal trade-off between task performance and computational constraint like FLOPs and latency.

Learning Shareable Bases for Personalized Federated Image Classification

Hong-You Chen,Jike zhong,Mingda Zhang,Xuhui Jia,Hang Qi,Boqing Gong,Wei-Lun Chao,Li Zhang

Personalized federated learning (PFL) aims to leverage the collective wisdom of clients' data while constructing customized models that are tailored to individual client's data distributions. The existing work of PFL mostly aims to personalize for participating clients. In this paper, we focus on a less studied but practically important scenario---generating a personalized model for a new client efficiently. Different from most previous approaches that learn a whole or partial network for each client, we explicitly model the clients' overall meta distribution and embed each client into a low dimension space. We propose FedBasis, a novel PFL algorithm that learns a set of few, shareable basis models, upon which each client only needs to learn the coefficients for combining them into a perso nalized network. FedBasis is parameter-efficient, robust, and more accurate compared to other competitive PFL baselines, especially in a low data regime, without increasing the inference cost. To demonstrate its applicability, we further present a PFL evaluation protocol for image classification, featuring larger data discrepancies across clients in both the image and label spaces as well as more faithful training and test splits.

Curriculum-inspired Training for Selective Neural Networks

Rui Liu,Reza Soroushmehr,Barzan Mozafari

We consider the problem of training neural network models for selective classification, where the models have the reject option to abstain from predicting certain examples as needed. Recent advances in curriculum learning have demonstrated the benefit of leveraging the example difficulty scores in training deep neural networks for typical classification settings. Example difficulty scores are even more important in selective classification as a lower prediction error rate can be achieved by rejecting hard examples and accepting easy ones. In this paper, we propose a curriculum-inspired method to train selective neural network models by leveraging example difficulty scores. Our method tailors the curriculum idea to selective neural network training by calibrating the ratio of easy and hard examples in each mini-batch, and exploiting difficulty ordering at the mini-batch level. Our experimental results demonstrate that our method outperforms both the state-of-the-art and alternative methods using vanilla curriculum techniques for training selective neural network models.

****

A Probabilistic Framework For Modular Continual Learning

Lazar Valkov,Akash Srivastava,Dipak Chaudhari,Swarat Chaudhuri,Charles Sutton

Continual learning (CL) algorithms seek to accumulate and transfer knowledge across a sequence of tasks and achieve better performance on each successive task. Modular approaches, which use a different composition of modules for each task and avoid forgetting by design, have been shown to be a promising direction to CL. However, searching through the large space of possible module compositions remains a challenge. In this work, we develop a scalable probabilistic search framework as a solution to this challenge. Our framework has two distinct components. The first is designed to transfer knowledge across similar input domains. To this end, it models each module’s training input distribution and uses a Bayesian model to find the most promising module compositions for a new task. The second component targets transfer across tasks with disparate input distributions or different input spaces and uses Bayesian optimisation to explore the space of module compositions. We show that these two methods can be easily combined and evaluate the resulting approach on two benchmark suites designed to capture different desiderata of CL techniques. The experiments show that our framework offers superior performance compared to state-of-the-art CL baselines.

****

Knowledge-Grounded Reinforcement Learning

Zih-Yun Chiu,Yi-Lin Tuan,William Yang Wang,Michael C. Yip

Receiving knowledge, abiding by laws, and being aware of regulations are common behaviors in human society. Bearing in mind that reinforcement learning (RL) algorithms benefit from mimicking humanity, in this work, we propose that an RL agent can act on external guidance in both its learning process and model deployment, making the agent more socially acceptable. We introduce the concept, Knowledge-Grounded RL (KGRL), with a formal definition that an agent learns to follow external guidelines and develop its own policy. Moving towards the goal of KGRL, we propose a novel actor model with an embedding-based attention mechanism that can attend to either a learnable internal policy or external knowledge. The proposed method is orthogonal to training algorithms, and the external knowledge can be flexibly recomposed, rearranged, and reused in both training and inference stages. Through experiments on tasks with discrete and continuous action space, our KGRL agent is shown to be more sample efficient and generalizable, and it has flexibly rearrangeable knowledge embeddings and interpretable behaviors.

Git Re-Basin: Merging Models modulo Permutation Symmetries

Samuel Ainsworth,Jonathan Hayase,Siddhartha Srinivasa

The success of deep learning is due in large part to our ability to solve certain massive non-convex optimization problems with relative ease. Though non-convex optimization is NP-hard, simple algorithms -- often variants of stochastic gradient descent -- exhibit surprising effectiveness in fitting large neural networks in practice. We argue that neural network loss landscapes often contain (nearly) a single basin after accounting for all possible permutation symmetries of hidden units a la Entezari et al. 2021. We introduce three algorithms to permute the units of one model to bring them into alignment with a reference model in order to merge the two models in weight space. This transformation produces a functionally equivalent set of weights that lie in an approximately convex basin near the reference model. Experimentally, we demonstrate the single basin phenomenon across a variety of model architectures and datasets, including the first (to our knowledge) demonstration of zero-barrier linear mode connectivity between independently trained ResNet models on CIFAR-10. Additionally, we identify intriguing phenomena relating model width and training time to mode connectivity. Finally, we discuss shortcomings of the linear mode connectivity hypothesis, including a counterexample to the single basin theory.

****

The Tilted Variational Autoencoder: Improving Out-of-Distribution Detection

Griffin Floto,Stefan Kremer,Mihai Nica

A problem with using the Gaussian distribution as a prior for the variational autoencoder (VAE) is that the set on which Gaussians have high probability density is small as the latent dimension increases. This is an issue because VAEs try to attain both a high likelihood with respect to a prior distribution and at the same time, separation between points for better reconstruction. Therefore, a small volume in the high-density region of the prior is problematic because it restricts the separation of latent points. To ameliorate this, we propose a simple generalization of the Gaussian distribution, called the tilted Gaussian, which has a maximum probability density occurring on a sphere instead of a single point. The tilted Gaussian has exponentially more volume in high-density regions than the standard Gaussian as a function of the distribution dimension. We empirically demonstrate that this simple change in the prior distribution improves VAE performance on the task of detecting unsupervised out-of-distribution (OOD) samples. We also introduce a new OOD testing procedure, called the Will-It-Move test, where the tilted Gaussian achieves remarkable OOD performance.

The Role of Coverage in Online Reinforcement Learning

Tengyang Xie,Dylan J Foster,Yu Bai,Nan Jiang,Sham M. Kakade

Coverage conditions---which assert that the data logging distribution adequately covers the state space---play a fundamental role in determining the sample complexity of offline reinforcement learning. While such conditions might seem irrelevant to online reinforcement learning at first glance, we establish a new connection by showing---somewhat surprisingly---that the mere existence of a data distribution with good coverage can enable sample-efficient online RL. Concretely, we show that coverability---that is, existence of a data distribution that satisfies a ubiquitous coverage condition called concentrability---can be viewed as a structural property of the underlying MDP, and can be exploited by standard algorithms for sample-efficient exploration, even when the agent does not know said distribution. We complement this result by proving that several weaker notions of coverage, despite being sufficient for offline RL, are insufficient for online RL. We also show that existing complexity measures for online RL, including Bellman rank and Bellman-Eluder dimension, fail to optimally capture coverability, and propose a new complexity measure, the self-normalized coefficient, to provide a unification.

Learning Mixture Models with Simultaneous Data Partitioning and Parameter Estimation

Parth Vipul Sangani,Arjun Shashank Kashettiwar,Durga S,Ganesh Ramakrishnan,Risha bh K Iyer,Abir De

We study a new framework of learning mixture models via data partitioning called PRESTO, wherein we optimize a joint objective function on the model parameters and the partitioning, with each model tailored to perform well on its specific partition. We connect PRESTO to a number of past works in data partitioning, mixture models, and clustering, and show that PRESTO generalizes several loss functions including the k-means and Bregman clustering objective, the Gaussian mixture model objective, mixtures of support vector machines, and mixtures of linear regression. We then propose a new joint discrete-continuous optimization algorithm which achieves a bounded approximation guarantee for any general loss function, thereby achieving guarantees for the afore-mentioned problems as well. We study PRESTO in the context of resource efficient deep learning, where we train smaller resource constrained models on each partition and show that it outperforms existing data partitioning and model pruning/knowledge distillation approaches, which in contrast to PRESTO, require large initial (teacher) models.

Estimating Treatment Effects using Neurosymbolic Program Synthesis

Abbavaram Gowtham Reddy,Vineeth N. Balasubramanian

Estimating treatment effects from observational data is a central problem in causal inference. Methods to solve this problem exploit inductive biases and heuristics from causal inference to design multi-head neural network architectures and regularizers. In this work, we propose to use neurosymbolic program synthesis, a data-efficient, and interpretable technique, to solve the treatment effect estimation problem. We theoretically show that neurosymbolic programming can solve the treatment effect estimation problem. By designing a Domain Specific Language (DSL) for treatment effect estimation based on the inductive biases used in literature, we argue that neurosymbolic programming is a better alternative to treatment effect estimation than traditional models. Our empirical study reveals that our model, which implicitly encodes inductive biases in a DSL, achieves better performance on benchmark datasets than the state-of-the-art models.

Stateful Active Facilitator: Coordination and Environmental Heterogeneity in Cooperative Multi-Agent Reinforcement Learning

Dianbo Liu,Vedant Shah,Oussama Boussif,Cristian Meo,Anirudh Goyal,Tianmin Shu,Michael Curtis Mozer,Nicolas Heess,Yoshua Bengio

In cooperative multi-agent reinforcement learning, a team of agents works together to achieve a common goal. Different environments or tasks may require varying degrees of coordination among agents in order to achieve the goal in an optimal way. The nature of coordination will depend on properties of the environment—its spatial layout, distribution of obstacles, dynamics, etc. We term this variation of properties within an environment as heterogeneity. Existing literature has not sufficiently addressed the fact that different environments may have different levels of heterogeneity. We formalize the notions of coordination level and heterogeneity level of an environment and present HECOGrid, a suite of multi-agent RL environments that facilitates empirical evaluation of different MARL approaches across different levels of coordination and environmental heterogeneity by providing a quantitative control over coordination and heterogeneity levels of the environment. Further, we propose a Centralized Training Decentralized Execution learning approach called Stateful Active Facilitator (SAF) that enables agents to work efficiently in high-coordination and high-heterogeneity environments through a differentiable and shared knowledge source used during training and dynamic selection from a shared pool of policies. We evaluate SAF and compare its performance

against baselines IPPO and MAPPO on HECOGrid. Our results show
that SAF consistently outperforms the baselines across different tasks and different
heterogeneity and coordination levels.

UNDERSTANDING HTML WITH LARGE LANGUAGE MODELS

Izzeddin Gur,Ofir Nachum,Yingjie Miao,Mustafa Safdari,Austin V Huang,Sharan Narang,Aakanksha Chowdhery,Noah Fiedel,Aleksandra Faust

Large language models (LLM) have shown exceptional performance on a variety of natural language tasks. Yet, their capabilities for HTML understanding – i.e., parsing the raw HTML of a webpage, with applications to automation of web-based tasks, crawling, and browser-assisted retrieval – have not been fully explored. We contribute HTML understanding models (fine-tuned LLMs) and an in-depth analysis of their capabilities under three tasks: (i) Semantic Classification of HTML elements, (ii) Description Generation for HTML inputs, and (iii) Autonomous Web Navigation of HTML pages. While previous work has developed dedicated architectures and training procedures for HTML understanding, we show that LLMs pretrained on standard natural language corpora transfer remarkably well to HTML understanding tasks. For instance, fine-tuned LLMs are 12% more accurate at semantic classification compared to models trained exclusively on the task dataset. Moreover, when fine-tuned on data from the MiniWoB benchmark, LLMs successfully complete 50% more tasks using 192x less data compared to the previous best supervised model. To promote further research on LLMs for HTML understanding, we create and open-source a large-scale HTML dataset distilled and auto-labeled from CommonCrawl. We show evidence that T5-based models due to the bidirectional encoder-decoder architecture are the best choice and that for practitioners larger models are not necessarily better.

Kuiper: Moderated Asynchronous Federated Learning on Heterogeneous Mobile Devices with Non-IID Data

Dipesh Tamboli,Pranjal Jain,Atul Sharma,Biplab Banerjee,Saurabh Bagchi,Somali Chaterji

Federated learning allows multiple clients to jointly learn an ML model while keeping their data private. While synchronous federated learning (Sync-FL) requires the devices to share local gradients synchronously to provide better guarantees, it suffers from the problem of stragglers. This is the scenario where the faster clients have to wait for the slower ones, slowing the entire training process. Conventional techniques completely drop the updates from the stragglers and lose the opportunity to learn from the data they hold, which is especially important in a non-iid setting. Asynchronous learning (Async-FL) provides a potential solution to allow the clients to function at their own pace, which typically achieves faster convergence. Since edge devices have a low compute, it is hard to train a video action recognition task on them. We present Kuiper, a variant of Async-FL, to help heterogeneous edge devices with limited resources learn a heavy model on video-action-recognition tasks with data distributed non-IID. Kuiper introduces a novel aggregation scheme, which solves the straggler problem while considering the different data distribution at different clients. Kuiper shows a 11% faster convergence compared to Oort15 [OSDI-21], up to 12% and 9% improvement in test accuracy compared to FedBuff16 [AISTAT-22] and Oort [OSDI-21] on HMDB51, and 10% and 9% on UCF101.

Learning Achievement Structure for Structured Exploration in Domains with Sparse Reward

Zihan Zhou,Animesh Garg

We propose Structured Exploration with Achievements (SEA), a multi-stage reinforcement learning algorithm designed for achievement-based environments, a particular type of environment with an internal achievement set. SEA first uses offline data to learn a representation of the known achievements with a determinant loss function, then recovers the dependency graph of the learned achievements with a heuristic algorithm, and finally interacts with the environment online to lear n policies that master known achievements and explore new ones with a controller built with the recovered dependency graph. We empirically demonstrate that SEA can recover the achievement structure accurately and improve exploration in hard domains such as Crafter that are procedurally generated with high-dimensional observations like images.

Semi-Autoregressive Energy Flows: Towards Determinant-Free Training of Normalizing Flows

Phillip Si,Zeyi Chen,Subham Sekhar Sahoo,Yair Schiff,Volodymyr Kuleshov

Normalizing flows are a popular approach for constructing probabilistic and generative models. However, maximum likelihood training of flows is challenging due to the need to calculate computationally expensive determinants of Jacobians. This paper takes steps towards addressing this challenge by introducing objectives and model architectures for determinant-free training of flows. Central to our framework is the energy objective, a multidimensional extension of proper scoring rules that admits efficient estimators based on random projections. The energy objective does not require calculating determinants and therefore supports general flow architectures that are not well-suited to maximum likelihood training. In particular, we introduce semi-autoregressive flows, an architecture that can be trained with the energy loss, and that interpolates between fully autoregressive and non-autoregressive models, capturing the benefits of both. We empirically demonstrate that energy flows achieve competitive generative modeling performance while maintaining fast generation and posterior inference.

PINTO: Faithful Language Reasoning Using Prompt-Generated Rationales

PeiFeng Wang,Aaron Chan,Filip Ilievski,Muhao Chen,Xiang Ren

Neural language models (LMs) have achieved impressive results on various language-based reasoning tasks by utilizing latent knowledge encoded in their own pretrained parameters. To make this reasoning process more explicit, recent works retrieve a rationalizing LM's internal knowledge by training or prompting it to generate free-text rationales, which can be used to guide task predictions made by either the same LM or a separate reasoning LM. However, rationalizing LMs require expensive rationale annotation and/or computation, without any assurance that their generated rationales improve LM task performance or faithfully reflect LM decision-making. In this paper, we propose PINTO, an LM pipeline that rationalizes via prompt-based learning, and learns to faithfully reason over rationales via a counterfactual regularization. First, PINTO maps out a suitable reasoning process for the task input by prompting a frozen rationalizing LM to generate a free-text rationale. Second, PINTO's reasoning LM is fine-tuned to solve the task using the generated rationale as context, while regularized to output less confident predictions when the rationale is perturbed. Across four datasets, we show that PINTO significantly improves the generalization ability of the reasoning LM, yielding higher performance on both in-distribution and out-of-distribution test sets. Also, we find that PINTO's rationales are more faithful to its task predictions than those generated by competitive baselines.

Game Theoretic Mixed Experts for Combinational Adversarial Machine Learning

Ethan Rathbun,Kaleel Mahmood,Sohaib Ahmad,Caiwen Ding,Marten van Dijk

Recent advances in adversarial machine learning have shown that defenses considered to be robust are actually susceptible to adversarial attacks which are specifically tailored to target their weaknesses. These defenses include Barrage of Random Transforms (BaRT), Friendly Adversarial Training (FAT), Trash is Treasure (TiT) and ensemble models made up of Vision Transformers (ViTs), Big Transfer models and Spiking Neural Networks (SNNs). It remains an open question, however, as to whether the adversarial examples designed to target one defense will be similarly misclassified by another defense. In this paper, we provide the first adversarial defense transferability study, as well as a game theoretic framework for ensemble adversarial attacks and defenses. Our framework is called Game theoretic Mixed Experts (GaME) and is designed to find the Mixed-Nash strategy for an attacker that can employ compositional adversarial attacks. We show that this fr

amework creates an ensemble of defenses with greater robustness than a combinational defense with a uniform or random probability distribution. Overall, our framework and analyses advance the field of adversarial machine learning by yielding new insights into compositional attack and defense formulations.

Return Augmentation gives Supervised RL Temporal Compositionality
Keiran Paster,Silviu Pitis,Sheila A. McIlraith,Jimmy Ba

Offline Reinforcement Learning (RL) methods that use supervised learning or sequence modeling (e.g., Decision Transformer) work by training a return-conditioned policy. A fundamental limitation of these approaches, as compared to value-based methods, is that they have trouble generalizing to behaviors that have a higher return than what was seen at training. Value-based offline-RL algorithms like CQL use bootstrapping to combine training data from multiple trajectories to learn strong behaviors from sub-optimal data. We set out to endow RL via Supervised Learning (RvS) methods with this form of temporal compositionality. To do this, we introduce SuperB, a dynamic programming algorithm for data augmentation that augments the returns in the offline dataset by combining rewards from intersecting trajectories. We show theoretically that SuperB can improve sample complexity and enable RvS to find optimal policies in cases where it previously fell behind the performance of value-based methods. Empirically, we find that SuperB improves the performance of RvS in several offline RL environments, surpassing the prior state-of-the-art RvS agents in AntMaze by orders of magnitude and offering performance competitive with value-based algorithms on the D4RL-gym tasks.

Excess Risk of Two-Layer ReLU Neural Networks in Teacher-Student Settings and its Superiority to Kernel Methods
Shunta Akiyama,Taiji Suzuki

While deep learning has outperformed other methods for various tasks, theoretical frameworks that explain its reason have not been fully established. We investigate the excess risk of two-layer ReLU neural networks in a teacher-student regression model, in which a student network learns an unknown teacher network through its outputs. Especially, we consider the student network that has the same width as the teacher network and is trained in two phases: first by noisy gradient descent and then by the vanilla gradient descent. Our result shows that the student network provably reaches a near-global optimal solution and outperforms any kernel methods estimator (more generally, linear estimators), including neural tangent kernel approach, random feature model, and other kernel methods, in a sense of the minimax optimal rate. The key concept inducing this superiority is the non-convexity of the neural network models. Even though the loss landscape is highly non-convex, the student network adaptively learns the teacher neurons.

Automatic Data Augmentation via Invariance-Constrained Learning
Ignacio Hounie,Luiz F. O. Chamon,Alejandro Ribeiro

Underlying data structures, such as symmetries or invariances to transformations, are often exploited to improve the solution of learning tasks. However, embedding these properties in models or learning algorithms can be challenging and computationally intensive. Data augmentation, on the other hand, induces these symmetries during training by applying multiple transformations to the input data. Despite its ubiquity, its effectiveness depends on the choices of which transformations to apply, when to do so, and how often. In fact, there is both empirical and theoretical evidence that the indiscriminate use of data augmentation can introduce biases that outweigh its benefits. This work tackles these issues by automatically adapting the data augmentation while solving the learning task. To do so, it formulates data augmentation as an invariance-constrained learning problem and leverages Monte Carlo Markov Chain (MCMC) sampling to solve it. The result is a practical algorithm that not only does away with a priori searches for augmentation distributions, but also dynamically controls if and when data augmentation is applied. Our experiments illustrate the performance of this method, which achieves state-of-the-art results in automatic data augmentation benchmarks for CIFAR datasets. Furthermore, this approach can be used to gather insights on

the actual symmetries underlying a learning task.

GEASS: Neural causal feature selection for high-dimensional biological data
Mingze Dong,Yuval Kluger

Identifying nonlinear causal relationships in high-dimensional biological data is an important task. However, current neural network based causality detection approaches for such data suffer from poor interpretability and cannot scale well to the high dimensional regime. Here we present GEASS (Granger fEAture Selection of Spatiotemporal data), which identifies sparse Granger causality mechanisms of high dimensional spatiotemporal data by a single neural network. GEASS maximizes sparsity-regularized modified transfer entropy with a theoretical guarantee of recovering features with spatial/temporal Granger causal relationships. The sparsity regularization is achieved by a novel combinatorial stochastic gate layer to select sparse non-overlapping feature subsets. We demonstrate the efficacy of GEASS in several synthetic datasets and real biological data from single-cell RNA sequencing and spatial transcriptomics.

Unsupervised 3D Scene Representation Learning via Movable Object Inference
Honglin Chen,Wanhee Lee,Hong-Xing Yu,Rahul Mysore Venkatesh,Joshua B. Tenenbaum,
Daniel Bear,Jiajun Wu,Daniel LK Yamins

Unsupervised, category-agnostic, object-centric 3D representation learning for complex scenes remains an open problem in computer vision. While a few recent methods can now discover 3D object radiance fields from a single image without supervision, they are limited to simplistic scenes with objects of a single category, often with a uniform color. This is because they discover objects purely based on appearance cues—objects are made of pixels that look alike. In this work, we propose Movable Object Radiance Fields (MORF), aiming at scaling to complex scenes with diverse categories of objects. Inspired by cognitive science of object learning in babies, MORF learns 3D object representations via movable object inference. During training, MORF first obtains 2D masks of movable objects via a self-supervised movable object segmentation method; it then bridges the gap to 3D object representations via conditional neural rendering in multiple views. During testing, MORF can discover, reconstruct, and move unseen objects from novel categories, all from a single image. Experiments show that MORF extracts accurate object geometry and supports realistic object and scene reconstruction and editing, significantly outperforming the state-of-the-art.

Linearly Mapping from Image to Text Space
Jack Merullo,Louis Castricato,Carsten Eickhoff,Ellie Pavlick

The extent to which text-only language models (LMs) learn to represent the physical, non-linguistic world is an open question. Prior work has shown that pretrained LMs can be taught to ``understand'' visual inputs when the models' parameters are updated on image captioning tasks. We test a stronger hypothesis: that the conceptual representations learned by text-only models are functionally equivalent (up to a linear transformation) to those learned by models trained on vision tasks. Specifically, we show that the image representations from vision models can be transferred as continuous prompts to frozen LMs by training only a single linear projection. Using these to prompt the LM achieves competitive performance on captioning and visual question answering tasks compared to models that tune both the image encoder and text decoder (such as the MAGMA model). We compare three image encoders with increasing amounts of linguistic supervision seen during pretraining: BEIT (no linguistic information), NF-ResNET (lexical category information), and CLIP (full natural language descriptions). We find that all three encoders perform equally well at transferring visual property information to the language model (e.g., whether an animal is large or small), but that image encoders pretrained with linguistic supervision more saliently encode category information (e.g., distinguishing hippo vs.\ elephant) and thus perform significantly better on benchmark language-and-vision tasks. Our results indicate that LMs encode conceptual information structurally similarly to vision-based models, even those that are solely trained on images.

Actor-Critic Alignment for Offline-to-Online Reinforcement Learning

Zishun Yu,Xinhua Zhang

Deep offline reinforcement learning has recently demonstrated considerable promise in leveraging offline datasets, providing high-quality models that significantly reduce the online interactions required for fine-tuning. However, such a benefit is often diminished due to the marked state-action distribution shift, which causes significant bootstrap error and wipes out the good initial policy. Existing solutions resort to constraining the policy shift or balancing the sample replay based on their online-ness. However, they require online estimation of distribution divergence or density ratio. To avoid such complications, we propose deviating from existing actor-critic approaches that directly transfer the state-action value functions. Instead, we post-process them by aligning with the offline learned policy, so that the Q-values for actions *outside* the offline policy are also tamed. As a result, the online fine-tuning can be simply performed as in the standard actor-critic algorithms. We show empirically that the proposed method improves the performance of the fine-tuned robotic agents on various simulated tasks.

Characterizing intrinsic compositionality in transformers with Tree Projections

Shikhar Murty,Pratyusha Sharma,Jacob Andreas,Christopher D Manning

When trained on language data, do transformers learn some arbitrary computation that utilizes the full capacity of the architecture or do they learn a simpler, tree-like computation, hypothesized to underlie compositional meaning systems like human languages? There is an apparent tension between compositional accounts of human language understanding, which are based on a restricted bottom-up computational process, and the enormous success of neural models like transformers, which can route information arbitrarily between different parts of their input. One possibility is that these models, while extremely flexible in principle, in practice learn to interpret language hierarchically, ultimately building sentence representations close to those predictable by a bottom-up, tree-structured model. To evaluate this possibility, we describe an unsupervised and parameter-free method to \emph{functionally project} the behavior of any transformer into the space of tree-structured networks. Given an input sentence, we produce a binary tree that approximates the transformer's representation-building process and a score that captures how ``tree-like'' the transformer's behavior is on the input. While calculation of this score does not require training any additional models, it provably upper-bounds the fit between a transformer and any tree-structured approximation. Using this method, we show that transformers for three different tasks become more tree-like over the course of training, in some cases unsupervisedly recovering the same trees as supervised parsers. These trees, in turn, are predictive of model behavior, with more tree-like models generalizing better on tests of compositional generalization.

What Do We Maximize in Self-Supervised Learning And Why Does Generalization Emerge?

Ravid Shwartz-Ziv,Randall Balestriero,Kenji Kawaguchi,Yann LeCun

In this paper, we provide an information-theoretic (IT) understanding of self-supervised learning methods, their construction, and optimality. As a first step, we demonstrate how IT quantities can be obtained for deterministic networks, as an alternative to the commonly used unrealistic stochastic networks assumption. Secondly, we demonstrate how different SSL models can be (re)discovered based on first principles and highlight what the underlying assumptions of different SSL variants are. Third, we derive a novel generalization bound based on our IT understanding of SSL methods, providing generalization guarantees for the downstream supervised learning task. As a result of this bound, along with our unified view of SSL, we can compare the different approaches and provide general guidelines to practitioners. Consequently, our derivation and insights can contribute to a better understanding of SSL and transfer learning from a theoretical and practical perspective.

SmartFRZ: An Efficient Training Framework using Attention-Based Layer Freezing

Sheng Li,Geng Yuan,Yue Dai,Youtao Zhang,Yanzhi Wang,Xulong Tang

There has been a proliferation of artificial intelligence applications, where model training is key to promising high-quality services for these applications. However, the model training process is both time-intensive and energy-intensive, inevitably affecting the user's demand for application efficiency. Layer freezing, an efficient model training technique, has been proposed to improve training efficiency. Although existing layer freezing methods demonstrate the great potential to reduce model training costs, they still remain shortcomings such as lacking generalizability and compromised accuracy. For instance, existing layer freezing methods either require the freeze configurations to be manually defined before training, which does not apply to different networks, or use heuristic freezing criteria that is hard to guarantee decent accuracy in different scenarios. Therefore, there lacks a generic and smart layer freezing method that can automatically perform ``in-situation'' layer freezing for different networks during training processes. To this end, we propose a generic and efficient training framework (SmartFRZ). The core proposed technique in SmartFRZ is attention-guided layer freezing, which can automatically select the appropriate layers to freeze without compromising accuracy. Experimental results show that SmartFRZ effectively reduces the amount of computation in training and achieves significant training acceleration, and outperforms the state-of-the-art layer freezing approaches.

****

Similarity-Based Cooperation

Caspar Oesterheld,Johannes Treutlein,Roger Baker Grosse,Vincent Conitzer,Jakob Nicolaus Foerster

As ML agents act more autonomously in the world, they will increasingly interact with each other. Unfortunately, in many social dilemmas like the one-shot Prisoner’s Dilemma, standard game theory predicts that ML agents will fail to cooperate with each other. Prior work has shown that one way to enable cooperative outcomes in the one-shot Prisoner’s Dilemma is to make the agents mutually transparent to each other, i.e., to allow them to access one another’s source code (Rubinstein 1997; Tennenholtz 2004) or weights in the case of ML agents. However, full transparency is often unrealistic, whereas partial transparency is commonplace. Moreover, it is difficult to machine-learn to cooperate in the full transparency setting. In this paper, we introduce a more realistic setting in which agents only observe a single number indicating how similar they are to each other. We prove that this allows for the same set of cooperative outcomes as the full transparency setting. We also demonstrate experimentally that cooperation can be learned using simple ML methods.

****

Consistent Data Distribution Sampling for Large-scale Retrieval

Hongyu Ou,Jun Yin,Huanqin Wu,ANAN LIU,Lin Zhao,Tao Chen,Yuekui Yang,TAO YANG

Retrieving candidate items with low latency and computational cost is important for large-scale advertising systems. Negative sampling is a general approach to model million-scale items with rich features in the retrieval. The training-inference inconsistency of data distribution brought from sampling negatives is a key challenge. In this work, we propose a novel negative sampling strategy Consistent Data Distribution Sampling (CDDS) to solve such an issue. Specifically, we employ a relative large-scale of uniform training negatives and batch negatives to adequately train long-tail and hot items respectively, and employ high divergence negatives to improve the learning convergence. To make the above training samples approximate the serving item data distribution, we introduce an auxiliary loss based on an asynchronous item embedding matrix over the entire item pool. Offline experiments on real datasets achieve SOTA performance. Online experiments with multiple advertising scenarios show that our method has achieved significant increases in GMV. The source code will be released in the future.

****

NOVEL FEATURE REPRESENTATION STRATEGIES FOR TIME SERIES FORECASTING WITH PREDICTED FUTURE COVARIATES

Jimeng Shi,Rukmangadh Sai Myana,Vitalii Stebliankin,Azam Shirali,Giri Narasimhan

Accurate time series forecasting is a fundamental challenge in data science. Unlike traditional statistical methods, conventional machine learning models, such as RNNs and CNNs, use historical data consisting of previously measured variables including the forecast variable and all its covariates. However, in many applications, some of the covariates can be predicted with reasonable accuracy for the immediate future. Note that the input may also contain some covariates that cannot be accurately predicted. We consider the problem of predicting water levels at a given location in a river or canal system using historical data and future covariates, some of which (e.g., precipitation, tide) may be predictable. In many applications, for some covariates of interest, it may be possible to use historical data or accurate predictions for the near future. Traditional methods to incorporate future predictable covariates have major limitations. The strategy of simply concatenating the future predicted covariates to the input vector is highly likely to miss the past-future connection. Another strategy that iteratively predicts one step at a time can end up with prediction error accumulation. We propose two novel feature representation strategies to solve those limitations -- shifting and padding, which create a framework for contextually linking the past with the predicted future, while avoiding any accumulation of prediction errors. Extensive experiments on three well-known datasets revealed that our strategies when applied to RNN and CNN backbones, outperform existing methods. Our experiments also suggest a relationship between the amount of shifting and padding and the periodicity of the time series.

Augmentation Component Analysis: Modeling Similarity via the Augmentation Overlaps

Lu Han,Han-Jia Ye,De-Chuan Zhan

Self-supervised learning aims to learn a embedding space where semantically similar samples are close. Contrastive learning methods pull views of samples together and push different samples away, which utilizes semantic invariance of augmentation but ignores the relationship between samples. To better exploit the power of augmentation, we observe that semantically similar samples are more likely to have similar augmented views. Therefore, we can take the augmented views as a special description of a sample. In this paper, we model such a description as the augmentation distribution, and we call it augmentation feature. The similarity in augmentation feature reflects how much the views of two samples overlap and is related to their semantical similarity. Without computational burdens to explicitly estimate values of the augmentation feature, we propose Augmentation Component Analysis (ACA) with a contrastive-like loss to learn principal components and an on-the-fly projection loss to embed data. ACA equals an efficient dimension reduction by PCA and extracts low-dimensional embeddings, theoretically preserving the similarity of augmentation distribution between samples. Empirical results show that our method can achieve competitive results against various traditional contrastive learning methods on different benchmarks.

****

Replicable Bandits

Hossein Esfandiari,Alkis Kalavasis,Amin Karbasi,Andreas Krause,Vahab Mirrokni,Grigoris Velegkas

In this paper, we introduce the notion of replicable policies in the context of stochastic bandits, one of the canonical problems in interactive learning. A policy in the bandit environment is called replicable if it pulls, with high probability, the exact same sequence of arms in two different and independent executions (i.e., under independent reward realizations). We show that not only do replicable policies exist, but also they achieve almost the same optimal (non-replicable) regret bounds in terms of the time horizon. More specifically, in the stochastic multi-armed bandits setting, we develop a policy with an optimal problem-dependent regret bound whose dependence on the replicability parameter is also optimal. Similarly, for stochastic linear bandits (with finitely and infinitely ma ny arms) we develop replicable policies that achieve the best-known problem-independent regret bounds with an optimal dependency on the replicability parameter. Our results show that even though randomization is crucial for the exploration-exploitation trade-off, an optimal balance can still be achieved while pulling the exact same arms in two different rounds of executions.

****

NEURAL HAMILTONIAN FLOWS IN GRAPH NEURAL NETWORKS

Qiyu Kang,Kai Zhao,Yang Song,Sijie Wang,Wee Peng Tay

Graph neural networks (GNNs) suffer from oversmoothing and oversquashing problems when node features are updated over too many layers. Embedding spaces can also vary significantly for different data types, leading to the need for different GNN model types. In this paper, we model the embedding of a node feature as a Hamiltonian flow over time. As in physics where Hamiltonian flow conserves the energy over time, its induced GNNs enable a more stable feature updating mechanism. Moreover, since the Hamiltonian flows are defined on a general symplectic manifold, this approach allows us to learn the underlying manifold of the graph in training, in contrast to most of the existing literature that assumes a fixed graph embedding manifold. We test Hamiltonian flows of different forms and demonstrate empirically that our approach achieves better node classification accuracy than popular state-of-the-art GNNs.

Convergence Analysis of Split Learning on Non-IID Data

Yipeng Li,Xinchen Lyu

Split Learning (SL) is one promising variant of Federated Learning (FL), where the AI model is split and trained at the clients and the server collaboratively. By offloading the computation-intensive portions to the server, SL enables efficient model training on resource-constrained clients. Despite its booming applications, SL still lacks rigorous convergence analysis on non-IID data, which is critical for hyperparameter selection. In this paper, we first prove that SL exhibits an $\mathcal{O}(1/\sqrt{T})$ convergence rate for non-convex objectives on non-IID data, where T is the number of total steps. By comparing the convergence analysis and experimental results, SL can outperform FL in terms of convergence rate (w.r.t. per-client training/communication rounds, and hence, the computation efficiency) and exhibit comparable accuracy to FL on mildly non-IID data. In contrast, FL prevails on highly non-IID data.

****

Principal Trade-off Analysis

Alexander Strang,David Robert SeWell,Alexander Kim,Kevin Alcedo,David Rosenbluth

The focus on equilibrium solutions in games underemphasizes the importance of understanding their overall structure. A different set of tools is needed for learning and representing the general structure of a game. In this paper we illustrate "Principle Trade-off Analysis" (PTA), a decomposition method that embeds games into a low dimensional feature space and argue that the embeddings are more revealing than previously demonstrated. Here, we develop an analogy to Principal Component Analysis (PCA). PTA represents an arbitrary two-player zero-sum game as the weighted sum of pairs of orthogonal 2D feature planes. We show that each of the feature planes represent unique strategic trade-offs (cyclic modes) and truncation of the sequence provides insightful model reduction. We demonstrate the validity of PTA on a pair of games (Blotto, Pokemon). In Blotto, PTA identifies game symmetries, and specifies strategic trade-offs associated with distinct win conditions. These symmetries reveal limitations of PTA unaddressed in previous work. For Pokemon, PTA recovers clusters that naturally correspond to Pokemon types, correctly identifies the designed tradeoff between those types, and discovers a rock-paper-scissor (RPS) cycle in the Pokemon generation type - all absent any specific information except game outcomes.

Neural Bregman Divergences for Distance Learning

Fred Lu,Edward Raff,Francis Ferraro

Many metric learning tasks, such as triplet learning, nearest neighbor retrieval, and visualization, are treated primarily as embedding tasks where the ultimate metric is some variant of the Euclidean distance (e.g., cosine or Mahalanobis), and the algorithm must learn to embed points into the pre-chosen space. The study of non-Euclidean geometries is often not explored, which we believe is due to a lack of tools for learning non-Euclidean measures of distance. Recent work has shown that Bregman divergences can be learned from data, opening a promising approach to learning asymmetric distances. We propose a new approach to learning arbitrary Bergman divergences in a differentiable manner via input convex neural networks and show that it overcomes significant limitations of previous works. We also demonstrate that our method more faithfully learns divergences over a set of both new and previously studied tasks, including asymmetric regression, ranking, and clustering. Our tests further extend to known asymmetric, but non-Bregman tasks, where our method still performs competitively despite misspecification, showing the general utility of our approach for asymmetric learning.

****

Offline Reinforcement Learning from Heteroskedastic Data Via Support Constraints

Anikait Singh,Aviral Kumar,quan vuong,Yevgen Chebotar,Sergey Levine

Offline reinforcement learning (RL) learns policies entirely from static datasets, thereby avoiding the challenges associated with online data collection. Practical applications of offline RL will inevitably require learning from datasets where the variability of demonstrated behaviors changes non-uniformly across the state space. For example, at a red light, nearly all human drivers behave similarly by stopping, but when merging onto a highway, some drivers merge quickly, efficiently, and safely, while many hesitate or merge dangerously.

We show that existing popular offline RL methods based on distribution constraints fail to learn from data with such non-uniform change in the variability of demonstrated behaviors, often due to the requirement to stay close to the behavior policy to the same extent across the state space. We demonstrate this failure mode both theoretically and experimentally. Ideally, the learned policy should be free to choose per-state how closely to follow the behavior policy to maximize long-term return, as long as the learned policy stays within the support of the behavior policy. To instantiate this principle, we reweight the data distribution in conservative Q-learning and show that support constraints emerge when doing so. The reweighted distribution is a mixture of the current policy and an additional policy trained to mine poor actions that are likely under the behavior policy. Our method CQL (ReDS) is simple, theoretically motivated, and improves performance across a wide range of offline RL problems in Atari games, navigation, and pixel-based manipulation.

Finding Private Bugs: Debugging Implementations of Differentially Private Stochastic Gradient Descent

Congyu Fang,Hengrui Jia,Ali Shahin Shamsabadi,Nicolas Papernot

It is important to learn with privacy-preserving algorithms when training data contains sensitive information. Differential privacy (DP) proposes to bound the worst-case privacy leakage of a training algorithm. However, the analytic nature of these algorithmic guarantees makes it difficult to verify that an implementation of a differentially private learner is correct. Research in the field focuses on empirically approximating the analytic bound, which only assesses whether an implementation provides the guarantee claimed for a particular dataset or not. It is also typically costly. In this paper, we take a first step towards providing a simple and lightweight methodology for practitioners to identify common implementation mistakes without imposing any changes to their scripts. Our approach stems from measuring distances between models outputted by the training algorithm. We demonstrate that our method successfully identifies specific mistakes made in the implementation of DP-SGD, the de facto algorithm for differentially private deep learning. These mistakes include improper gradient computations or noise miscalibration. Both approaches invalidate assumptions that are essential to obtaining a rigorous privacy guarantee.

A Computationally Efficient Sparsified Online Newton Method

Fnu Devvrit,Sai Surya Duvvuri,Rohan Anil,Vineet Gupta,Cho-Jui Hsieh,Inderjit S D hillon

Second-order methods have huge potential in improving the convergence of deep neural network (DNN) training, but are prohibitive due to their large memory and compute requirements. Furthermore, computing the matrix inverse or the Newton direction, which is needed in second-order methods, requires high precision computation for stable training as the preconditioner could have a large condition number. This paper provides a first attempt at developing computationally efficient sparse preconditioners for DNN training which can also tolerate low precision computation. Our new Sparsified Online Newton (SONew) algorithm emerges from the novel use of the so-called LogDet matrix divergence measure; we combine it with sparsity constraints to minimize the regret in the online convex optimization framework. Our mathematical analysis allows us to reduce the condition number of our sparse preconditioning matrix, thus improving the stability of training with low precision. We conduct experiments on a feed-forward neural-network autoencoder benchmark, where we compare training loss of optimizers when run for a fixed number of epochs. In the float32 experiments, our methods outperform the best-performing first-order optimizers and perform comparably to Shampoo, a state-of-the-art second-order optimizer. However, our method is even more effective in low-precision, where SONew finishes training considerably faster while performing comparably with Shampoo on training loss.

Solving Continual Learning via Problem Decomposition

Gyuhak Kim,Changnan Xiao,Tatsuya Konishi,Zixuan Ke,Bing Liu

This paper is concerned with class incremental learning (CIL) in continual learning (CL). CIL is the popular continual learning paradigm in which a system receives a sequence of tasks with different classes in each task and is expected to learn to predict the class of each test instance without given any task related information for the instance. Although many techniques have been proposed to solve CIL, it remains to be highly challenging due to the difficulty of dealing with catastrophic forgetting (CF). This paper starts from the first principle and proposes a novel method to solve the problem. The definition of CIL reveals that the problem can be decomposed into two probabilities: within-task prediction probability and task-id prediction probability. This paper proposes an effective technique to estimate these two probabilities based on the estimation of feature distributions in the latent space using incremental PCA and Mahalanobis distance. The proposed method does not require a memory buffer to save replay data and it outperforms strong baselines including replay-based methods.

Long Term Fairness via Performative Distributionally Robust Optimization

Garnet Liam Peet-Pare,Nidhi Hegde,Alona Fyshe

Fairness researchers in machine learning (ML) have coalesced around several fairness criteria which provide formal definitions of what it means for an ML model to be fair. However, these criteria have some serious limitations. We identify four key shortcomings of these formal fairness criteria and address them by extending performative prediction to include a distributionally robust objective. Performative prediction is a recent framework developed to understand the effects of when deploying model influences the distribution on which it is making predictions. We prove a convergence result for our proposed repeated distributionally robust optimization (RDRO). We further verify our results empirically and develop experiments to demonstrate the impact of using RDRO on learning fair ML models.

The In-Sample Softmax for Offline Reinforcement Learning

Chenjun Xiao,Han Wang,Yangchen Pan,Adam White,Martha White

Reinforcement learning (RL) agents can leverage batches of previously collected data to extract a reasonable control policy. An emerging issue in this offline RL setting, however, is that the bootstrapping update underlying many of our methods suffers from insufficient action-coverage: standard max operator may select a maximal action that has not been seen in the dataset. Bootstrapping from these inaccurate values can lead to overestimation and even divergence. There are a g rowing number of methods that attempt to approximate an in-sample max, that only uses actions well-covered by the dataset. We highlight a simple fact: it is more straightforward to approximate an in-sample softmax using only actions in the dataset. We show that policy iteration based on the in-sample softmax converges, and that for decreasing temperatures it approaches the in-sample max. We derive an In-Sample Actor-Critic (AC), using this in-sample softmax, and show that it is consistently better or comparable to existing offline RL methods, and is also well-suited to fine-tuning. We release the code at github.com/hwang-ua/inac_pytorch.

LUNA: Language as Continuing Anchors for Referring Expression Comprehension

Yaoyuan Liang,Zhao Yang,Yansong Tang,Jiashuo Fan,Jingang Wang,Wei Wu,Philip Torr,Shao-Lun Huang

Referring expression comprehension aims to localize the description of a natural language expression in an image. Using location priors to remedy inaccuracies in cross-modal alignments is the state of the art for CNN-based methods tackling this problem. Recent Transformer-based models cast aside this idea making the case for steering away from hand-designed components. In this work, we propose LUNA, which uses language as continuing anchors to guide box prediction in a Transformer decoder, and show that language-guided location priors can be effectively exploited in a Transformer-based architecture. Specifically, we first initialize an anchor box from the input expression via a small “proto-decoder”, and then use this anchor as location prior in a modified Transformer decoder for predicting the bounding box. Iterating through each decoder layer, the anchor box is first used as a query for pooling multi-modal context, and then updated based on pooled context. This approach allows the decoder to focus selectively on one part of the scene at a time, which reduces noise in multi-modal context and leads to more accurate box predictions. Our method outperforms existing state-of-the-art methods on the challenging datasets of ReferIt Game, RefCOCO/+/g, and Flickr30K Entities.

Bias Propagation in Federated Learning

Hongyan Chang,Reza Shokri

We show that participating in federated learning can be detrimental to group fairness. In fact, the bias of a few parties against under-represented groups (identified by sensitive attributes such as gender or race) can propagate through the network to all the parties in the network. We analyze and explain bias propagation in federated learning on naturally partitioned real-world datasets. Our analysis reveals that biased parties unintentionally yet stealthily encode their bias in a small number of model parameters, and throughout the training, they steadily increase the dependence of the global model on sensitive attributes. What is important to highlight is that the experienced bias in federated learning is higher than what parties would otherwise encounter in centralized training with a model trained on the union of all their data. This indicates that the bias is due to the algorithm. Our work calls for auditing group fairness in federated learning and designing learning algorithms that are robust to bias propagation.

Causal Confusion and Reward Misidentification in Preference-Based Reward Learning

Jeremy Tien,Jerry Zhi-Yang He,Zackory Erickson,Anca Dragan,Daniel S. Brown

Learning policies via preference-based reward learning is an increasingly popular method for customizing agent behavior, but has been shown anecdotally to be prone to spurious correlations and reward hacking behaviors. While much prior work focuses on causal confusion in reinforcement learning and behavioral cloning, we focus on a systematic study of causal confusion and reward misidentification when learning from preferences. In particular, we perform a series of sensitivity and ablation analyses on several benchmark domains where rewards learned from preferences achieve minimal test error but fail to generalize to out-of-distribution states---resulting in poor policy performance when optimized. We find that t he presence of non-causal distractor features, noise in the stated preferences, and partial state observability can all exacerbate reward misidentification. We also identify a set of methods with which to interpret misidentified learned rewards. In general, we observe that optimizing misidentified rewards drives the policy off the reward's training distribution, resulting in high predicted (learned) rewards but low true rewards. These findings illuminate the susceptibility of preference learning to reward misidentification and causal confusion---failure to consider even one of many factors can result in unexpected, undesirable behavior.

UniKGQA: Unified Retrieval and Reasoning for Solving Multi-hop Question Answering Over Knowledge Graph

Jinhao Jiang,Kun Zhou,Xin Zhao,Ji-Rong Wen

Multi-hop Question Answering over Knowledge Graph~(KGQA) aims to find the answer entities that are multiple hops away from the topic entities mentioned in a natural language question on a large-scale Knowledge Graph (KG).

To cope with the vast search space, existing work usually adopts a two-stage approach: it first retrieves a relatively small subgraph related to the question and then performs the reasoning on the subgraph to find the answer entities accurately.

Although these two stages are highly related, previous work employs very different technical solutions for developing the retrieval and reasoning models, neglecting their relatedness in task essence.

In this paper, we propose UniKGQA, a novel approach for multi-hop KGQA task, by unifying retrieval and reasoning in both model architecture and parameter learning.

For model architecture, UniKGQA consists of a semantic matching module based on a pre-trained language model~(PLM) for question-relation semantic matching, and a matching information propagation module to propagate the matching information along the directed edges on KGs.

For parameter learning, we design a shared pre-training task based on question-relation matching for both retrieval and reasoning models, and then propose retrieval- and reasoning-oriented fine-tuning strategies.

Compared with previous studies, our approach is more unified, tightly relating the retrieval and reasoning stages.

Extensive experiments on three benchmark datasets have demonstrated the effectiveness of our method on the multi-hop KGQA task.

Our codes and data are publicly available at~\url{https://github.com/RUCAIBox/UniKGQA}.

Comparing Human and Machine Bias in Face Recognition

Samuel Dooley,George Zhihong Wei,Ryan Downing,Nathan Shankar,Bradon Michael Thymes,Gudrun Lilja Thorkelsdottir,Tiye A Kurtz-Miott,Rachel Mattson,Olufemi Obiwumi,Valeriia Cherepanova,Micah Goldblum,John P Dickerson,Tom Goldstein

Much recent research has uncovered and discussed serious concerns of bias in facial analysis technologies, finding performance disparities between groups of people based on perceived gender, skin type, lighting condition, etc. These audits are immensely important and successful at measuring algorithmic bias but have two major challenges: the audits (1) use facial recognition datasets which lack quality metadata, like LFW and CelebA, and (2) do not compare their observed algorithmic bias to the biases of their human alternatives. In this paper, we release improvements to the LFW and CelebA datasets which will enable future researchers to obtain measurements of algorithmic bias that are not tainted by major flaws in the dataset (e.g. identical images appearing in both the gallery and test set). We also use these new data to develop a series of challenging facial identification and verification questions that we administered to various algorithms and a large, balanced sample of human reviewers. We find that both computer models and human survey participants perform significantly better at the verification task, generally obtain lower accuracy rates on dark-skinned or female subjects for both tasks, and obtain higher accuracy rates when their demographics match th at of the question. Academic models exhibit comparable levels of gender bias to humans, but are significantly more biased against darker skin types than humans.

****

Sufficient Subgraph Embedding Memory for Continual Graph Representation Learning

Xikun ZHANG,Dongjin Song,Dacheng Tao

Memory replay, which constructs a buffer to store representative samples and retrain the model over the buffer to maintain its performance over existing tasks, has shown great success for continual learning with Euclidean data. Directly applying it to graph data, however, can lead to the memory explosion problem due to the necessity to consider explicit topological connections of representative nodes. To this end, we present Parameter Decoupled Graph Neural Networks (PDGNNs) with Sufficient Subgraph Embedding Memory (SSEM) to fully utilize the explicit topological information for memory replay and reduce the memory space complexity from $\mathcal{O}(nd^L)$ to $\mathcal{O}(n)$, where n is the memory buffer size, d is the average node degree, and L is the range of neighborhood aggregation. Specifically, PDGNNs decouple trainable parameters from the computation subgraphs via $\textit{Sufficient Subgraph Embeddings}$ (SSEs), which compress subgraphs into vectors ($\textit{i.e.}$, SSEs) to reduce the memory consumption. Besides, we discover a $\textit{pseudo-training effect}$ in memory based continual graph learning, which does not exist in continual learning on Euclidean data without topological connection ($\textit{e.g.}$, individual images). Based on the discovery, we develop a novel $\textit{coverage maximization sampling}$ strategy to enhance the performance when the memory budget is tight. Thorough empirical studies demonstrate that PDGNNs with SSEM outperform state-of-the-art techniques for both class-incremental and task-incremental settings.

One cannot stand for everyone! Leveraging Multiple User Simulators to train Task-oriented Dialogue Systems

Yajiao LIU,Xin Jiang,Yichun Yin,Yasheng Wang,Fei Mi,Qun Liu,Xiang Wan,Benyou Wang

User simulators are agents designed to imitate human users; recent advances have found that Task-oriented Dialogue (ToD) systems optimized toward a user simulator could better satisfy the need of human users. However, this might result in a sub-optimal ToD system if it is tailored to only one \textit{ad hoc} user simulator, since human users can behave differently.

In this paper, we propose a framework called MUST to optimize ToD systems via leveraging \textbf{m}ultiple \textbf{u}ser \textbf{s}imula\textbf{t}ors.

The main challenges of MUST fall in 1) how to adaptively specify which user simulator to interact with the ToD system at each optimization step, since the ToD system might be over-fitted to some specific user simulators, and simultaneously under-fitted to some others; 2) how to avoid catastrophic forgetting of the adaption for a simulator that is not selected for several consecutive optimization steps.

To tackle these challenges, we formulate MUST as a Multi-armed bandits (MAB) problem and provide a method called MUST$_{\mathrm{adaptive}}$ that balances \textit{i}) the \textit{boosting adaption} for adaptive interactions between different user simulators and the ToD system and \textit{ii}) the \textit{uniform adaption} to avoid the catastrophic forgetting issue.

With both automatic evaluations and human evaluations, our extensive experimental results on the restaurant search task from MultiWOZ show that the dialogue system trained by our proposed MUST achieves a better performance than those trained by any single user simulator. It also has a better generalization ability when testing with unseen user simulators. Moreover, our method MUST$_{\mathrm{adaptive}}$ is indeed more efficient and effective to leverage multiple user simulators by our visualization analysis.

Is the Performance of My Deep Network Too Good to Be True? A Direct Approach to Estimating the Bayes Error in Binary Classification

Takashi Ishida,Ikko Yamane,Nontawat Charoenphakdee,Gang Niu,Masashi Sugiyama

There is a fundamental limitation in the prediction performance that a machine learning model can achieve due to the inevitable uncertainty of the prediction target. In classification problems, this can be characterized by the Bayes error, which is the best achievable error with any classifier. The Bayes error can be used as a criterion to evaluate classifiers with state-of-the-art performance and can be used to detect test set overfitting. We propose a simple and direct Bayes error estimator, where we just take the mean of the labels that show \emph{uncertainty} of the class assignments. Our flexible approach enables us to perform Bayes error estimation even for weakly supervised data. In contrast to others, our method is model-free and even instance-free. Moreover, it has no hyperparameters and gives a more accurate estimate of the Bayes error than several baselines empirically. Experiments using our method suggest that recently proposed deep networks such as the Vision Transformer may have reached, or is about to reach, the Bayes error for benchmark datasets. Finally, we discuss how we can study the inherent difficulty of the acceptance/rejection decision for scientific articles, by estimating the Bayes error of the ICLR papers from 2017 to 2023.

Learning Deep Operator Networks: The Benefits of Over-Parameterization

Bhavesh Shrimali,Arindam Banerjee

Neural Operators that directly learn mappings between function spaces have received considerable recent attention. Deep Operator Networks (DeepONets), a popular recent class of neural operators have shown promising preliminary results in approximating solution operators of parametric differential equations. Despite the universal approximation guarantees, there is yet no optimization convergence guarantee for DeepONets based on gradient descent (GD). In this paper, we establish such guarantees and show that over-parameterization based on wide layers provably helps. In particular, we present two types of optimization convergence analysis: first, for smooth activations, we bound the spectral norm of the Hessian of DeepONets and use the bound to show geometric convergence of GD based on restricted strong convexity (RSC); and second, for ReLU activations, we show the neural tangent kernel (NTK) of DeepONets at initialization is positive definite, which can be used with the standard NTK analysis to imply geometric convergence. Further, we present empirical results on three canonical operator learning problems: Antiderivative, Diffusion-Reaction equation, and Burger’s equation, and show that wider DeepONets lead to lower training loss on all the problems, thereby supporting the theoretical results

How Useful are Gradients for OOD Detection Really?

Conor Igoe,Youngseog Chung,Ian Char,Jeff Schneider

One critical challenge in deploying machine learning models in real-life applications is out-of-distribution (OOD) detection. Given a predictive model which is accurate on in distribution (ID) data, an OOD detection system can further equip the model with the option to defer prediction when the input is novel and the model has low confidence. Notably, there has been some recent interest in utilizing gradient information in pretrained models for OOD detection. While these methods are competitive, we argue that previous works conflate their performance with the necessity of gradients. In this work, we provide an in-depth analysis of gradient-based methods and elucidate the key components that warrant their OOD detection performance. We further demonstrate that a general, non-gradient-based family of OOD detection methods are just as competitive, casting doubt on the usefulness of gradients for OOD detection

Many-Body Approximation for Tensors

Kazu Ghalamkari,Mahito Sugiyama

We propose a nonnegative tensor decomposition with focusing on the relationship between the modes of tensors. Traditional decomposition methods assume low-rankness in the representation, resulting in difficulties in global optimization and target rank selection. To address these problems, we present an alternative way to decompose tensors, a many-body approximation for tensors, based on an informa tion geometric formulation. A tensor is treated via an energy-based model, where the tensor and its mode correspond to a probability distribution and a random variable, respectively, and many-body approximation is performed on it by taking the interaction between variables into account. Our model can be globally optimized in polynomial time in terms of the KL divergence minimization, which is empirically faster than low-rank approximations keeping comparable reconstruction error. Furthermore, we visualize interactions between modes as tensor networks and reveal a nontrivial relationship between many-body approximation and low-rank approximation.

Faster Last-iterate Convergence of Policy Optimization in Zero-Sum Markov Games

Shicong Cen,Yuejie Chi,Simon Shaolei Du,Lin Xiao

Multi-Agent Reinforcement Learning (MARL)---where multiple agents learn to interact in a shared dynamic environment---permeates across a wide range of critical applications. While there has been substantial progress on understanding the global convergence of policy optimization methods in single-agent RL, designing and analysis of efficient policy optimization algorithms in the MARL setting present significant challenges and new desiderata, which unfortunately, remain highly inadequately addressed by existing theory. In this paper, we focus on the most basic setting of competitive multi-agent RL, namely two-player zero-sum Markov games, and study equilibrium finding algorithms in both the infinite-horizon discounted setting and the finite-horizon episodic setting. We propose a single-loop policy optimization method with symmetric updates from both agents, where the policy is updated via the entropy-regularized optimistic multiplicative weights update (OMWU) method and the value is updated on a slower timescale. We show that, in the full-information tabular setting, the proposed method achieves a finite-time last-iterate linear convergence to the quantal response equilibrium of the regularized problem, which translates to a sublinear convergence to the Nash equilibrium by controlling the amount of regularization. Our convergence results improve upon the best known iteration complexities, and lead to a better understanding of policy optimization in competitive Markov games.

Memorization Capacity of Neural Networks with Conditional Computation

Erdem Koyuncu

Many empirical studies have demonstrated the performance benefits of conditional computation in neural networks, including reduced inference time and power consumption. We study the fundamental limits of neural conditional computation from the perspective of memorization capacity. For Rectified Linear Unit (ReLU) networks without conditional computation, it is known that memorizing a collection of n input-output relationships can be accomplished via a neural network with $O(\sqrt{n})$ neurons. Calculating the output of this neural network can be accomplished using $O(\sqrt{n})$ elementary arithmetic operations of additions, multiplications and comparisons for each input. Using a conditional ReLU network, we show that the same task can be accomplished using only $O(\log n)$ operations per input. This represents an almost exponential improvement as compared to networks without conditional computation. We also show that the $\Theta(\log n)$ rate is the best possible. Our achievability result utilizes a general methodology to synthesize a conditional network out of an unconditional network in a computationally-efficient manner, bridging the gap between unconditional and conditional architectures.

On the Power of Pre-training for Generalization in RL: Provable Benefits and Hardness

Haotian Ye,Xiaoyu Chen,Liwei Wang,Simon Shaolei Du

Generalization in Reinforcement Learning (RL) aims to train an agent during training that generalizes to the target environment. In this work, we first point out that RL generalization is fundamentally different from the generalization in supervised learning, and fine-tuning on the target environment is necessary for good test performance. Therefore, we seek to answer the following question: how much can we expect pre-training over training environments to be helpful for effi cient and effective fine-tuning? On one hand, we give a surprising result showing that asymptotically, the improvement from pre-training is at most a constant factor. On the other hand, we show that pre-training can be indeed helpful in the non-asymptotic regime by designing a policy collection-elimination (PCE) algorithm and proving a distribution-dependent regret bound that is independent of the state-action space. We hope our theoretical results can provide insight towards understanding pre-training and generalization in RL.

****

A Fast, Well-Founded Approximation to the Empirical Neural Tangent Kernel

Mohamad Amin Mohamadi,Danica J. Sutherland

Empirical neural tangent kernels (eNTKs) can provide a good understanding of a given network's representation: they are often far less expensive to compute and applicable more broadly than infinite-width NTKs. For networks with O output units (e.g. an O-class classifier), however, the eNTK on N inputs is of size $NO \times NO$, taking $\mathcal{O}\big((N O)^2\big)$ memory and up to $\mathcal{O}\big((N O)^3 \big)$ computation. Most existing applications have therefore used one of a handful of approximations yielding $N \times N$ kernel matrices, saving orders of magnitude of computation, but with limited to no justification. We prove that one such approximation, which we call ``sum of logits,'' converges to the true eNTK at initialization. Our experiments demonstrate the quality of this approximation for various uses across a range of settings.

****

Weighted Clock Logic Point Process

Ruixuan Yan,Yunshi Wen,Debarun Bhattacharjya,Ronny Luss,Tengfei Ma,Achille Fokoue,Anak Agung Julius

Datasets involving multivariate event streams are prevalent in numerous applications. We present a novel framework for modeling temporal point processes called clock logic neural networks (CLNN) which learn weighted clock logic (wCL) formulas as interpretable temporal rules by which some events promote or inhibit other events. Specifically, CLNN models temporal relations between events using conditional intensity rates informed by a set of wCL formulas, which are more expressive than related prior work. Unlike conventional approaches of searching for generative rules through expensive combinatorial optimization, we design smooth activation functions for components of wCL formulas that enable a continuous relaxation of the discrete search space and efficient learning of wCL formulas using gradient-based methods. Experiments on synthetic datasets manifest our model's ability to recover the ground-truth rules and improve computational efficiency. In addition, experiments on real-world datasets show that our models perform competitively when compared with state-of-the-art models.

****

Simple Emergent Action Representations from Multi-Task Policy Training

Pu Hua,Yubei Chen,Huazhe Xu

The low-level sensory and motor signals in deep reinforcement learning, which exist in high-dimensional spaces such as image observations or motor torques, are inherently challenging to understand or utilize directly for downstream tasks. While sensory representations have been extensively studied, the representations of motor actions are still an area of active exploration. Our work reveals that a space containing meaningful action representations emerges when a multi-task policy network takes as inputs both states and task embeddings. Moderate constraints are added to improve its representation ability. Therefore, interpolated or composed embeddings can function as a high-level interface within this space, providing instructions to the agent for executing meaningful action sequences. Empirical results demonstrate that the proposed action representations are effective for intra-action interpolation and inter-action composition with limited or no additional learning. Furthermore, our approach exhibits superior task adaptation ability compared to strong baselines in Mujoco locomotion tasks. Our work sheds light on the promising direction of learning action representations for efficient, adaptable, and composable RL, forming the basis of abstract action planning and the understanding of motor signal space. Project page: https://sites.google.com/view/emergent-action-representation/

Iterative Task-adaptive Pretraining for Unsupervised Word Alignment

Zhi Li,Gao Xing,Ji Zhang,Yin Zhang

How to establish a closer relationship between pre-training and downstream task is a valuable question. We argue that task-adaptive pretraining should not just performed before task. For word alignment task, we propose an iterative self-supervised task-adaptive pretraining paradigm, tying together word alignment and self-supervised pretraining by code-switching data augmentation. When we get the aligned pairs predicted by the multilingual contextualized word embeddings, we employ these pairs and origin parallel sentences to synthesize code-switched sentences. Then multilingual models will be continuously finetuned on the augmented code-switched dataset. Finally, finetuned models will be used to produce new aligned pairs. This process will be executed iteratively. Our paradigm is suitable for almost all unsupervised word alignment methods based on multilingual pre-trained LMs and doesn't need gold labeled data, extra parallel data or any other external resources. Experimental results on six language pairs demonstrate that our paradigm can consistently improve baseline method. Compared to resource-rich languages, the improvements on relatively low-resource or different morphological languages are more significant. For example, the AER scores of three different alignment methods based on XLM-R are reduced by about $4 \sim 5$ percentage points on language pair En-Hi.

Open-Set 3D Detection via Image-level Class and Debiased Cross-modal Contrastive Learning

Yuheng Lu,Chenfeng Xu,Xiaobao Wei,Xiaodong Xie,Masayoshi Tomizuka,Kurt Keutzer,Shanghang Zhang

Current point-cloud detection methods have difficulty detecting the open-set objects in the real world, due to their limited generalization capability. Moreover, it is extremely laborious and expensive to collect and fully annotate a point-cloud detection dataset with numerous classes of objects, leading to the limited classes of existing point-cloud datasets and hindering the model to learn general representations to achieve open-set point-cloud detection. Instead of seeking a point-cloud dataset with full labels, we resort to ImageNet1K to broaden the vocabulary of the point-cloud detector. We propose OS-3DETIC, an Open-Set 3D DETector using Image-level Class supervision. Specifically, we take advantage of two modalities, the image modality for recognition and the point-cloud modality for localization, to generate pseudo labels for unseen classes. Then we propose a novel debiased cross-modal cross-task contrastive learning method to transfer the knowledge from image modality to point-cloud modality during training. Without hurting the latency during inference, OS-3DETIC makes the well-known point-cloud detector capable of achieving open-set detection. Extensive experiments demonstrate that the proposed OS-3DETIC achieves at least 10.77 % mAP improvement (absolute value) and 9.56 % mAP improvement (absolute value) by a wide range of baselines on the SUN-RGBD dataset and ScanNet dataset, respectively. Besides, we conduct sufficient experiments to shed light on why the proposed OS-3DETIC works.

****

Tight Non-asymptotic Inference via Sub-Gaussian Intrinsic Moment Norm

Huiming Zhang,Haoyu Wei,Guang Cheng

In non-asymptotic statistical inferences, variance-type parameters of sub-Gaussian distributions play a crucial role. However, direct estimation of these parameters based on the empirical moment generating function (MGF) is infeasible. To this end, we recommend using a sub-Gaussian intrinsic moment norm [Buldygin and Kozachenko (2000), Theorem 1.3] through maximizing a series of normalized moments. Importantly, the recommended norm can not only recover the exponential moment bounds for the corresponding MGFs, but also lead to tighter Hoeffiding's sub-Gaussian concentration inequalities. In practice, intrinsic moment norm can be robustly and consistently estimated via a simple plug-in approach. Our theoretical results are applied to non-asymptotic analysis, including the multi-armed bandit.

Interaction-Based Disentanglement of Entities for Object-Centric World Models

Akihiro Nakano,Masahiro Suzuki,Yutaka Matsuo

Perceiving the world compositionally in terms of space and time is essential to understanding object dynamics and solving downstream tasks. Object-centric learning using generative models has improved in its ability to learn distinct representations of individual objects and predict their interactions, and how to utilize the learned representations to solve untrained, downstream tasks is a focal question. However, as models struggle to predict object interactions and track the objects accurately, especially for unseen configurations, using object-centric representations in downstream tasks is still a challenge. This paper proposes STEDIE, a new model that disentangles object representations, based on interactions, into interaction-relevant relational features and interaction-irrelevant global features without supervision. Empirical evaluation shows that the proposed model factorizes global features, unaffected by interactions from relational features that are necessary to predict outcome of interactions. We also show that STEDIE achieves better performance in planning tasks and understanding causal relationships. In both tasks, our model not only achieves better performance in terms of reconstruction ability but also utilizes the disentangled representations to solve the tasks in a structured manner.

****

CodeT5Mix: A Pretrained Mixture of Encoder-decoder Transformers for Code Understanding and Generation

Yue Wang,Hung Le,Akhilesh Deepak Gotmare,Junnan Li,Steven Hoi

Pretrained language models (LMs) trained on vast source code have achieved prominent progress in a wide range of code intelligence tasks. Despite their success, they either adopt specific types of network architectures (encoder-only or decoder-only) for different downstream tasks or rely on a single architecture (encoder-decoder or UniLM-style encoder) for all tasks. The latter approach usually results in a sub-optimal performance on a subset of tasks. To address these limitations, we propose “CodeT5Mix”, a mixture of encoder-decoder Transformers for code where its components can be flexibly combined based on the target tasks during finetuning, while still enjoying the mutual benefits from the joint pretraining. To endow the model with both code understanding and generation capabilities, we pretrain CodeT5Mix using a mixture of denoising, contrastive learning, matching, and Causal Language Modeling (CLM) tasks on large-scale multilingual code corpora in nine programming languages. Additionally, we design a weight sharing strategy in decoders except the feedforward layers, which act as task-specific experts to reduce the interference across tasks of various types. We extensively evaluate CodeT5Mix on seven tasks in four different modes and achieve state-of-the-art (SoTA) performance on most tasks such as text-to-code retrieval, code completion and generation, and math programming. Particularly, we demonstrate that CodeT5Mix can be used as a unified semi-parametric retrieval-augmented generator with SoTA code generation performance.

Neural Image-based Avatars: Generalizable Radiance Fields for Human Avatar Modeling

YoungJoong Kwon,Dahun Kim,Duygu Ceylan,Henry Fuchs

We present a method that enables synthesizing novel views and novel poses of arbitrary human performers from sparse multi-view images. A key ingredient of our method is a hybrid appearance blending module that combines the advantages of the implicit body NeRF representation and image-based rendering. Existing generalizable human NeRF methods that are conditioned on the body model have shown robustness against the geometric variation of arbitrary human performers. Yet they often exhibit blurry results when generalized onto unseen identities. Meanwhile, image-based rendering shows high-quality results when sufficient observations are available, whereas it suffers artifacts in sparse-view settings. We propose Neural Image-based Avatars (NIA) that exploits the best of those two methods: to maintain robustness under new articulations and self-occlusions while directly leveraging the available (sparse) source view colors to preserve appearance details of new subject identities. Our hybrid design outperforms recent methods on both in-domain identity generalization as well as challenging cross-dataset generalization settings. Also, in terms of the pose generalization, our method outperforms even the per-subject optimized animatable NeRF methods.

****

Federated Neural Bandits

Zhongxiang Dai,Yao Shu,Arun Verma,Flint Xiaofeng Fan,Bryan Kian Hsiang Low,Patrick Jaillet

Recent works on neural contextual bandits have achieved compelling performances due to their ability to leverage the strong representation power of neural networks (NNs) for reward prediction. Many applications of contextual bandits involve multiple agents who collaborate without sharing raw observations, thus giving rise to the setting of federated contextual bandits}. Existing works on federated contextual bandits rely on linear or kernelized bandits, which may fall short when modeling complex real-world reward functions. So, this paper introduces the federated neural-upper confidence bound (FN-UCB) algorithm. To better exploit the federated setting, FN-UCB adopts a weighted combination of two UCBs: UCB^{a} allows every agent to additionally use the observations from the other agents to accelerate exploration (without sharing raw observations), while UCB^{b} uses an NN with aggregated parameters for reward prediction in a similar way to federated averaging for supervised learning. Notably, the weight between the two UCBs required by our theoretical analysis is amenable to an interesting interpretation, which emphasizes UCB^{a} initially for accelerated exploration and relies more on UCB^{b} later after enough observations have been collected to train the NNs for accurate reward prediction (i.e., reliable exploitation). We prove sub-linear upper bounds on both the cumulative regret and the number of communication rounds of FN-UCB, and empirically demonstrate its competitive performance.

****

Compositional Task Representations for Large Language Models

NAN SHAO,Zefan Cai,Hanwei xu,Chonghua Liao,Yanan Zheng,Zhilin Yang

Large language models have shown a remarkable cross-task generalization ability. Most prior work assumed that prompts effectively extract knowledge from language models to facilitate generalization to new tasks. This perspective led to numerous studies on improving prompts. In contrast, we introduce a new perspective, compositional generalization, that views each task as a composition of latent codes and generalizes to test tasks by a new composition of seen codes. To this end, we propose a novel prompt-free approach, Compositional Task Representations (CTR), that employs multi-task training to learn a discrete, compositional codebook. Empirically, our CTR substantially outperforms prompt-based methods in zero-label learning on average. According to our analysis, some of the learned CTR codes are interpretable to human and demonstrate a certain degree of controllability.

What do large networks memorize?

Michal Lukasik,Aditya Krishna Menon,Ankit Singh Rawat,Vaishnavh Nagarajan,Sanjiv Kumar

The success of modern neural models has prompted renewed study of the connection between memorisation and generalisation: such models typically generalise well, despite being able to perfectly fit ("memorise") completely random labels.

To more carefully study this issue, Feldman (2019); Feldman & Zhang (2020) provided a simple metric to quantify the degree of memorisation of a specific training example, and empirically quantified the corresponding memorisation profile of a ResNet model on image classification benchmarks.

While an exciting first glimpse into how real-world models memorise, these studies leave open several questions about memorisation of practical networks.

In particular, how is memorisation affected by increasing model size, and by distilling a large model into a smaller one?

We present a systematic empirical analysis of these questions.

On standard image classification benchmarks, we find that training examples exhi bit a diverse set of memorisation trajectories across model sizes, with some samples having increased memorisation under larger models.

Further, we find that distillation tends to inhibit memorisation of the student model, while also improving generalisation.

Finally, we show that computationally tractable measures of memorisation do not capture the properties we identify for memorisation in the sense of Feldman (2019), despite highly correlating to the latter.

TILDE-Q: a Transformation Invariant Loss Function for Time-Series Forecasting

Hyunwook Lee,Chunggi Lee,Hongkyu Lim,Sungahn Ko

Time-series forecasting has caught increasing attention in the AI research field due to its importance in solving real-world problems across different domains, such as energy, weather, traffic, and economy. As shown in various types of data, it has been a must-see issue to deal with drastic changes, temporal patterns, and shapes in sequential data that previous models are weak in prediction. This is because most cases in time-series forecasting aim to minimize L_p norm distances as loss functions, such as mean absolute error (MAE) or mean square error (MSE). These loss functions are vulnerable to not only considering temporal dynamics modeling but also capturing the shape of signals. In addition, these functions often make models misbehave and return uncorrelated results to the original time-series. To become an effective loss function, it has to be invariant to the set of distortions between two time-series data instead of just comparing exact values. In this paper, we propose a novel loss function, called TILDE-Q (Transformation Invariant Loss function with Distance EQuilibrium), that not only considers the distortions in amplitude and phase but also allows models to capture the shape of time-series sequences. In addition, TILDE-Q supports modeling periodic and non-periodic temporal dynamics at the same time. We evaluate the effectiveness of TILDE-Q by conducting extensive experiments with respect to periodic and non-periodic conditions of data, from naive models to state-of-the-art models. The experiment results indicate that the models trained with TILDE-Q outperform those trained with other training metrics (e.g., MSE, dynamic time warping (DTW), temporal distortion index (TDI), and longest common subsequence (LCSS)).

A Picture of the Space of Typical Learning Tasks

Rahul Ramesh,Jialin Mao,Itay Griniasty,Rubing Yang,Han Kheng Teoh,Mark Transtrum,James Sethna,Pratik Chaudhari

We develop a technique to analyze representations learned by deep networks when they are trained on different tasks using supervised, multi-task, meta- and contrastive learning. We develop a technique to visualize such representations using an isometric embedding of the space of probabilistic models into a lower-dimensional space, i.e., one that preserves pairwise distances. We discover the following surprising phenomena that shed light upon the structure in the space of learning tasks: (1) the manifold of probabilistic models trained on different tasks using different representation learning methods is effectively low-dimensional; (2) supervised learning on one task results in a surprising amount of progress on seemingly dissimilar tasks; progress on other tasks is larger if the training task has diverse classes; (3) the structure of the space of tasks indicated by our visualization technique is consistent with parts of the Wordnet phylogenetic tree; (4) fine-tuning a model upon a sub-task does not change the representation much if the model was trained for a large number of epochs; (5) episodic meta-learning algorithms fit similar models eventually as that of supervised learning, even if the two traverse different trajectories during training; (6) contrastive learning methods trained on different datasets learn similar representations. We use classification tasks constructed from the CIFAR-10 and Imagenet datasets to study these phenomena.

REPAIR: REnormalizing Permuted Activations for Interpolation Repair

Keller Jordan,Hanie Sedghi,Olga Saukh,Rahim Entezari,Behnam Neyshabur

In this paper we empirically investigate the conjecture from Entezari et al. (2021) which states that if permutation invariance is taken into account, then ther e should be no loss barrier to the linear interpolation between SGD solutions. We conduct our investigation using standard computer vision architectures trained on CIFAR-10 and ImageNet. First, we observe a general phenomenon in which interpolated deep networks suffer a collapse in the variance of their activations. We demonstrate that an appropriate rescaling of the pre-activations of the interpolated networks ameliorates this problem and significantly reduces the barrier. Second, by combining this with an algorithm for finding permutations based on maximizing correlations between the activations of matched neurons, we are able to reduce the interpolation barrier for a standard ResNet18 trained on CIFAR-10 to 1.5% absolute test error. We explore the interaction between our method and the choice of normalization layer, and demonstrate its robustness across a variety of architectures and training sets.

Multi-View Masked Autoencoders for Visual Control

Younggyo Seo,Junsu Kim,Stephen James,Kimin Lee,Jinwoo Shin,Pieter Abbeel

This paper investigates how to leverage data from multiple cameras to learn representations beneficial for visual control. To this end, we present the Multi-View Masked Autoencoder (MV-MAE), a simple and scalable framework for multi-view representation learning. Our main idea is to mask multiple viewpoints from video frames at random and train a video autoencoder to reconstruct pixels of both masked and unmasked viewpoints. This allows the model to learn representations that capture useful information of the current viewpoint but also the cross-view information from different viewpoints. We evaluate MV-MAE on challenging RLBench visual manipulation tasks by training a reinforcement learning agent on top of frozen representations. Our experiments demonstrate that MV-MAE significantly outperforms other multi-view representation learning approaches. Moreover, we show that the number of cameras can differ between the representation learning phase and the behavior learning phase. By training a single-view control agent on top of multi-view representations from MV-MAE, we achieve 62.3% success rate while the single-view representation learning baseline achieves 42.3%.

Boosting Adversarial Training with Masked Adaptive Ensemble

Fudong Lin,Xu Yuan,Nian-Feng Tzeng

Adversarial training (AT) can help improve the robustness of a deep neural network (DNN) against potential adversarial attacks by intentionally injecting adversarial examples into the training data, but this way inevitably incurs standard accuracy degradation to some extent, thereby calling for a trade-off between standard accuracy and robustness. Besides, the prominent AT solutions are vulnerable to sparse attacks, due to “robustness overfitting” upon dense attacks, often adopted by AT to produce a threat model. To tackle such shortcomings, this paper proposes a novel framework, including a detector and a classifier bridged by our newly developed adaptive ensemble. Specifically, a Guided Backpropagation-based detector is designed to sniff adversarial examples, driven by our empirical observation. Meanwhile, a classifier with two encoders is employed for extracting visual representations respectively from clean images and adversarial examples. The adaptive ensemble approach also enables us to mask off a random subset of image patches within input data, eliminating potential adversarial effects when encountering malicious inputs with negligible standard accuracy degradation. As such, our approach enjoys improved robustness, able to withstand both dense and sparse attacks, while maintaining high standard accuracy. Experimental results exhibit that our detector and classifier outperform their state-of-the-art counterparts, in terms of detection accuracy, standard accuracy, and adversarial robustness. For example, on CIFAR-10, our detector achieves the best detection accuracy of 99.6% under dense attacks and of 98.5% under sparse attacks. Our classifier achieves the best standard accuracy of 91.2% and the best robustness against dense attack (or sparse attack) of 57.5% (or 54.8%).

Diffusion-GAN: Training GANs with Diffusion

Zhendong Wang,Huangjie Zheng,Pengcheng He,Weizhu Chen,Mingyuan Zhou

Generative adversarial networks (GANs) are challenging to train stably, and a pr omising remedy of injecting instance noise into the discriminator input has not been very effective in practice. In this paper, we propose Diffusion-GAN, a novel GAN framework that leverages a forward diffusion chain to generate Gaussian-mixture distributed instance noise. Diffusion-GAN consists of three components, including an adaptive diffusion process, a diffusion timestep-dependent discriminator, and a generator. Both the observed and generated data are diffused by the adaptive diffusion process via different noise-to-data ratios at each timestep. The timestep-dependent discriminator learns to distinguish the diffused real data from the diffused generated data at each diffusion timestep. The generator learns from the discriminator's feedback by backpropagating through the forward diffusion chain, whose length is adaptively adjusted to balance the noise and data levels. We theoretically show that the discriminator's timestep-dependent strategy gives consistent and helpful guidance to the generator, enabling it to match the true data distribution. We demonstrate the advantages of Diffusion-GAN over strong GAN baselines on various datasets, showing that it can produce more realistic images with higher stability and data efficiency than state-of-the-art GANs.

Contextual Subspace Approximation with Neural Householder Transforms
Kerrick Johnstonbaugh,Michael Przystupa,Jacob Keller,Martin Jagersand

Choosing an appropriate action representation is an integral part of solving robotic manipulation problems. Published approaches include latent action models which compress the control space into a low dimensional manifold. These involve training a conditional autoencoder, where the current observation and a low-dimensional action are passed through a neural network decoder to compute high dimensional actuation commands. Such models can have a large number of parameters, and can be difficult to interpret from a user perspective. In this work, we propose that similar performance gains in robotics tasks can be achieved by restructuring the neural network to map observations to a basis for a context-dependent linear actuation subspace. This results in an action interface wherein a user’s actions determine a linear combination of a state-conditioned actuation basis. We introduce the Neural Householder Transform (NHT) as a method for computing this basis. Our results show that reinforcement learning agents trained with NHT in kinematic manipulation and locomotion environments tend to be more robust to hyperparameter choice and achieve higher final success rates compared to agents trained with alternative action representations. NHT agents outperformed agents trained with joint velocity/torque actions, agents trained with an SVD actuation basis, and agents trained with a LASER action interface in the WAMWipe, WAMGrasp, and HalfCheetah environments.

Mind the Pool: Convolutional Neural Networks Can Overfit Input Size
Bilal Alsallakh,David Yan,Narine Kokhlikyan,Vivek Miglani,Orion Reblitz-Richardson,Pamela Bhattacharya

We demonstrate how convolutional neural networks can overfit the input size: The accuracy drops significantly when using certain sizes, compared with favorable ones. This issue is inherent to pooling arithmetic, with standard downsampling layers playing a major role in favoring certain input sizes and skewing the weights accordingly. We present a solution to this problem by depriving these layers from the arithmetic cues they use to overfit the input size. Through various examples, we show how our proposed spatially-balanced pooling improves the generalization of the network to arbitrary input sizes and its robustness to translational shifts.

Towards Unsupervised Time Series Representation Learning: A Decomposition Perspective
Yan Li,Xinjiang Lu,Jingjing Gu,Haishuai Wang,Dejing Dou

Existing contrastive methods of universal time series representation learning mainly rely on distilling invariant patterns at varying scales and building contrastive loss with the help of negative sampling. However, the invariance assumptions may not hold in real-world time-series data, and the infamous negative sampli ng could bring in new biases for representation learning. In this work, we propose a novel contrastive learning approach toward time series representation learning on top of trend-seasonality decomposition, namely TS-DC. TS-DC differentiates itself from prior methods in three folds: 1) a time series decomposition approach is devised to distill different aspects/components of a complex time series; 2) a novel component-wise contrastive loss is proposed in which negative sampling is not necessary; 3) the informative signals of time series can be captured comprehensively by means of adaptive contrasting. Extensive experiments on different public benchmark datasets validate the superior performance of our proposed representation learning method.

Reparameterization through Spatial Gradient Scaling

Alexander Detkov,Mohammad Salameh,Muhammad Fetrat,Jialin Zhang,Robin Luwei,SHANGLING JUI,Di Niu

Reparameterization aims to improve the generalization of deep neural networks by transforming a convolution operation into equivalent multi-branched structures during training. However, there exists a gap in understanding how reparameterization may change and benefit learning processes for neural networks. In this paper, we present a novel spatial gradient scaling method to redistribute learning focus among weights in convolutional neural networks. We prove that spatial gradient scaling achieves the same learning dynamics as a branched reparameterization yet without introducing structural changes into the network. We further propose an analytical approach that dynamically learns scalings for each convolutional layer based on the spatial characteristics of its input feature map gauged by mutual information. Experiments on CIFAR-10, CIFAR-100, and ImageNet show that without searching for reparameterized structures, our proposed scaling method outperforms the state-of-the-art reparameterization methods at a lower computational cost.

Boomerang: Local sampling on image manifolds using diffusion models

Lorenzo Luzi,Ali Siahkoohi,Paul M Mayer,Josue Casco-Rodriguez,Richard Baraniuk

Diffusion models can be viewed as mapping points in a high-dimensional latent space onto a low-dimensional learned manifold, typically an image manifold. The intermediate values between the latent space and image manifold can be interpreted as noisy images which are determined by the noise scheduling scheme employed during pre-training. We exploit this interpretation to introduce Boomerang, a local image manifold sampling approach using the dynamics of diffusion models. We call it Boomerang because we first add noise to an input image, moving it closer to the latent space, then bring it back to the image space through diffusion dynamics. We use this method to generate images which are similar, but nonidentical, to the original input images on the image manifold. We are able to set how close the generated image is to the original based on how much noise we add. Additionally, the generated images have a degree of stochasticity, allowing us to locally sample as many times as we want without repetition. We show three applications for which Boomerang can be used. First, we provide a framework for constructing privacy-preserving datasets having controllable degrees of anonymity. Second, we show how to use Boomerang for data augmentation while staying on the image manifold. Third, we introduce a framework for image super-resolution with 8x upsampling. Boomerang does not require any modification to the training of diffusion models and can be used with pretrained models on a single, inexpensive GPU.

TOWARD RELIABLE NEURAL SPECIFICATIONS

Chuqin Geng,Nham Le,Xiaojie Xu,Zhaoyue Wang,Arie Gurfinkel,Xujie Si

Having reliable specifications is an unavoidable challenge in achieving verifiable correctness, robustness, and interpretability of AI systems. Existing specifications for neural networks are in the flavor of “data as specification”, that is, the local neighborhood centering around a reference input is considered to be correct (or robust). However, our empirical study shows that such specifications fail to certify any test data points, making it impractical for real-world applications. We propose a new family of specifications called “neural representati on as specification”, which uses the intrinsic information of neural networks — neural activation patterns (NAP) rather than input data to specify the correctness and/or robustness of neural network predictions. We present a simple statistical approach to extracting dominant neural activation patterns. We analyze NAPs from a statistical point of view and find that a single NAP can cover a large number of training and testing data points whereas ad hoc data-as-specification can only cover a single training data point and often zero testing data points. To show the effectiveness of discovered NAPs, we formally verify several important properties, such as a particular type of misclassification never happens for a given NAP, and there is no ambiguity among different NAPs. We show that by using NAP, we can verify the prediction of the entire input space, while still recalling 84% of the data. Thus, we argue that using NAPs is a more reliable and extensible specification for neural network verification.

****

A second order regression model shows edge of stability behavior
Atish Agarwala,Jeffrey Pennington,Fabian Pedregosa

Recent studies of learning algorithms have shown that there is a regime with an initial increase in the largest eigenvalue of the loss Hessian (progressive sharpening), followed by a stabilization of the eigenvalue near the maximum value which allows convergence (edge of stability). We consider a class of predictive models that are quadratic in the parameters, which we call second-order regression models. This is in contrast with the neural tangent kernel regime, where the predictive function is linear in the parameters. For quadratic objectives in two dimensions, we prove that this second order regression model exhibits both progressive sharpening and edge of stability behavior. We then show that in higher dimensions, the model shows this behavior generically without the structure of a neural network, due to a non-linearity induced in the learning dynamics. Finally, we show that edge of stability behavior in neural networks is correlated with the behavior in quadratic regression models.

****

Unsupervised Learning for Combinatorial Optimization Needs Meta Learning
Haoyu Peter Wang,Pan Li

A general framework of unsupervised learning for combinatorial optimization (CO) is to train a neural network whose output gives a problem solution by directly optimizing the CO objective. Albeit with some advantages over traditional solvers, current frameworks optimize an averaged performance over the distribution of historical problem instances, which misaligns with the actual goal of CO that looks for a good solution to every future encountered instance. With this observation, we propose a new objective of unsupervised learning for CO where the goal of learning is to search for good initialization for future problem instances rather than give direct solutions. We propose a meta-learning-based training pipeline for this new objective. Our method achieves good performance. We observe that even the initial solution given by our model before fine-tuning can significantly outperform the baselines under various evaluation settings including evaluation across multiple datasets, and the case with big shifts in the problem scale. The reason we conjecture is that meta-learning-based training lets the model be loosely tied to each local optimum for a training instance while being more adaptive to the changes of optimization landscapes across instances.

Latent Topology Induction for Understanding Contextualized Representations
Yao Fu,Mirella Lapata

Recently, there has been considerable interests in understanding pretrained language models. This work studies the hidden geometry of the representation space of language models from a unique topological perspective. We hypothesize that there exist a network of latent anchor states summarizing the topology (neighbors and connectivity) of the representation space. we infer this latent network in a fully unsupervised way using a structured variational autoencoder. We show that such network exists in pretrained representations, but not in baseline random or positional embeddings. We connect the discovered topological structure to their linguistic interpretations. In this latent network, leave nodes can be grounded to word surface forms, anchor states can be grounded to linguistic categories, and connections between nodes and states can be grounded to phrase constructions and syntactic templates. We further show how such network evolves as the embeddings become more contextualized, with observational and statistical evidence demonstrating how contextualization helps words “receive meaning” from their topological neighbors via the anchor states. We demonstrate these insights with extensive experiments and visualizations.

DyG2Vec: Representation Learning for Dynamic Graphs With Self-supervision
Mohammad Ali Alomrani,Mahdi Biparva,Yingxue Zhang,Mark Coates

The challenge in learning from dynamic graphs for predictive tasks lies in extracting fine-grained temporal motifs from an ever-evolving graph. Moreover, task labels are often scarce, costly to obtain, and highly imbalanced for large dynamic graphs. Recent advances in self-supervised learning on graphs demonstrate great potential, but focus on static graphs. State-of-the-art (SoTA) models for dynamic graphs are not only incompatible with the self-supervised learning (SSL) paradigm but also fail to forecast interactions beyond the very near future. To address these limitations, we present DyG2Vec, an SSL-compatible, efficient model for representation learning on dynamic graphs. DyG2Vec uses a window-based mechanism to generate task-agnostic node embeddings that can be used to forecast future interactions. DyG2Vec significantly outperforms SoTA baselines on benchmark datasets for downstream tasks while only requiring a fraction of the training/inference time. We adapt two SSL evaluation mechanisms to make them applicable to dynamic graphs and thus show that SSL pre-training helps learn more robust temporal node representations, especially for scenarios with few labels.

Unsupervised Meta-learning via Few-shot Pseudo-supervised Contrastive Learning
Huiwon Jang,Hankook Lee,Jinwoo Shin

Unsupervised meta-learning aims to learn generalizable knowledge across a distribution of tasks constructed from unlabeled data. Here, the main challenge is how to construct diverse tasks for meta-learning without label information; recent works have proposed to create, e.g., pseudo-labeling via pretrained representations or creating synthetic samples via generative models. However, such a task construction strategy is fundamentally limited due to heavy reliance on the immutable pseudo-labels during meta-learning and the quality of the representations or the generated samples. To overcome the limitations, we propose a simple yet effective unsupervised meta-learning framework, coined Pseudo-supervised Contrast (PsCo), for few-shot classification. We are inspired by the recent self-supervised learning literature; PsCo utilizes a momentum network and a queue of previous batches to improve pseudo-labeling and construct diverse tasks in a progressive manner. Our extensive experiments demonstrate that PsCo outperforms existing unsupervised meta-learning methods under various in-domain and cross-domain few-shot classification benchmarks. We also validate that PsCo is easily scalable to a large-scale benchmark, while recent prior-art meta-schemes are not.

****

PromptBoosting: Black-Box Text Classification with Ten Forward Passes
Bairu Hou,Joe O'Connor,Jacob Andreas,Shiyu Chang,Yang Zhang

We describe PromptBoosting, a query-efficient procedure for building a text classifier from a neural language model (LM) without access to the LM’s parameters, gradients, or hidden representations. This form of “black-box” classifier training has become increasingly important as the cost of training and inference in large-scale LMs grows. But existing black-box LM classifier learning approaches are themselves computationally inefficient, typically specializing LMs to the target task by searching in a large space of (discrete or continuous) prompts using zeroth-order optimization methods. Instead of directly optimizing in prompt space, PromptBoosting obtains a small pool of prompts via a gradient-free approach and then constructs a large pool of weak learners by pairing these prompts with different elements of the LM’s output distribution. These weak learners are then ensembled using the AdaBoost algorithm. The entire learning process requires only a small number of forward passes and no backward pass. Experiments show that P romptBoosting achieves state-of-the-art performance in multiple black-box few-shot classification tasks, and matches or outperforms full fine-tuning in both few-shot and standard learning paradigms, while training 10x faster than existing black-box methods.

****

Decepticons: Corrupted Transformers Breach Privacy in Federated Learning for Language Models

Liam H Fowl,Jonas Geiping,Steven Reich,Yuxin Wen,Wojciech Czaja,Micah Goldblum,Tom Goldstein

Privacy is a central tenet of Federated learning (FL), in which a central server trains models without centralizing user data. However, gradient updates used in FL can leak user information. While the most industrial uses of FL are for text applications (e.g. keystroke prediction), the majority of attacks on user privacy in FL have focused on simple image classifiers and threat models that assume honest execution of the FL protocol from the server. We propose a novel attack that reveals private user text by deploying malicious parameter vectors, and which succeeds even with mini-batches, multiple users, and long sequences. Unlike previous attacks on FL, the attack exploits characteristics of both the Transformer architecture and the token embedding, separately extracting tokens and positional embeddings to retrieve high-fidelity text. We argue that the threat model of malicious server states is highly relevant from a user-centric perspective, and show that in this scenario, text applications using transformer models are much more vulnerable than previously thought.

****

Adaptive Optimization in the ∞-Width Limit

Etai Littwin,Greg Yang

Recent works have developed detailed understanding of large neural networks' behaviors via their infinite-width limits, e.g., the neural tangent kernel (NTK) and the feature learning (μ) limits. These theories were developed for stochastic gradient descent. Yet, in practice, all large NN are trained using Adam or other adaptive gradient optimizers (AGO), which are not covered by such previous works. Here, we close this gap via the Tensor Programs framework. Specifically, for deep MLPs, we derive the NTK and μ parametrizations as well as their infinite-width limits. We find 1) The NTK limit of AGO, in contrast to that of SGD, now depends nonlinearly on the loss derivative but nevertheless still fails to learn features; 2) this is fixed by the μ limit of AGO (as in the case of SGD). To obtain these results, we extend the Tensor Programs language with a new instruction that allows one to express the gradient processing done by AGOs.

Pyramidal Denoising Diffusion Probabilistic Models

Dohoon Ryu,Jong Chul Ye

Recently, diffusion model have demonstrated impressive image generation performances, and have been extensively studied in various computer vision tasks. Unfortunately, training and evaluating diffusion models consume a lot of time and computational resources. To address this problem, here we present a novel pyramidal diffusion model that can generate high resolution images starting from much coarser resolution images using a {\em single} score function trained with a positional embedding. This enables a neural network to be much lighter and also enables time-efficient image generation without compromising its performances. Furthermore, we show that the proposed approach can be also efficiently used for multi-scale super-resolution problem using a single score function.

****

Guiding Energy-based Models via Contrastive Latent Variables

Hankook Lee,Jongheon Jeong,Sejun Park,Jinwoo Shin

An energy-based model (EBM) is a popular generative framework that offers both explicit density and architectural flexibility, but training them is difficult since it is often unstable and time-consuming. In recent years, various training techniques have been developed, e.g., better divergence measures or stabilization in MCMC sampling, but there often exists a large gap between EBMs and other generative frameworks like GANs in terms of generation quality. In this paper, we p ropose a novel and effective framework for improving EBMs via contrastive representation learning (CRL). To be specific, we consider representations learned by contrastive methods as the true underlying latent variable. This contrastive latent variable could guide EBMs to understand the data structure better, so it can improve and accelerate EBM training significantly. To enable the joint training of EBM and CRL, we also design a new class of latent-variable EBMs for learning the joint density of data and the contrastive latent variable. Our experimental results demonstrate that our scheme achieves lower FID scores, compared to prior-art EBM methods (e.g., additionally using variational autoencoders or diffusion techniques), even with significantly faster and more memory-efficient training. We also show conditional and compositional generation abilities of our latent-variable EBMs as their additional benefits, even without explicit conditional training. The code is available at https://github.com/hankook/CLEL.

Deep Watermarks for Attributing Generative Models

Guangyu Nie,Changhoon Kim,Yezhou Yang,Yi Ren

Generative models have enabled the creation of contents that are indistinguishable from those taken from the Nature. Open-source development of such models raised concerns about the risks in their misuse for malicious purposes. One potential risk mitigation strategy is to attribute generative models via watermarking. Current watermarking methods exhibit significant tradeoff between robust attribution accuracy and generation quality, and also lack principles for designing watermarks to improve this tradeoff. This paper investigates the use of latent semantic dimensions as watermarks, from where we can analyze the effects of design variables, including the choice of watermarking dimensions, watermarking strength, and the capacity of watermarks, on the accuracy-quality tradeoff. Compared with previous SOTA, our method requires minimum computation and is more applicable to large-scale models. We use StyleGAN2 and the latent diffusion model to demonstrate the efficacy of our method.

Steerable Equivariant Representation Learning

Sangnie Bhardwaj,Willie McClinton,Tongzhou Wang,Guillaume Lajoie,Chen Sun,Phillip Isola,Dilip Krishnan

Pre-trained deep image representations are useful for post-training tasks such as classification through transfer learning, image retrieval, and object detection. Data augmentations are a crucial aspect of pre-training robust representations in both supervised and self-supervised settings. Data augmentations explicitly or implicitly promote \emph{invariance} in the embedding space to the input image transformations. This invariance reduces generalization to those downstream tasks which rely on sensitivity to these particular data augmentations. In this paper, we propose a method of learning representations that are instead \emph{equivariant} to data augmentations. We achieve this equivariance through the use of \emph{steerable} representations. Our representations can be manipulated directly in embedding space via learned linear maps. We demonstrate that our resulting steerable and equivariant representations lead to better performance on transfer learning and robustness: e.g. we improve linear probe top-1 accuracy by between 1\% to 3\% for transfer; and ImageNet-C accuracy by upto 3.4\%. We further show that the steerability of our representations provides significant speedup (nearly $50\times$) for test-time augmentations; by applying a large number of augmentations for out-of-distribution detection, we significantly improve OOD AUC on the ImageNet-C dataset over an invariant representation.

Differentially Private Diffusion Models

Tim Dockhorn,Tianshi Cao,Arash Vahdat,Karsten Kreis

While modern machine learning models rely on increasingly large training datasets, data is often limited in privacy-sensitive domains. Generative models trained with differential privacy (DP) on sensitive data can sidestep this challenge, providing access to synthetic data instead. However, training DP generative models is highly challenging due to the noise injected into training to enforce DP. We propose to leverage diffusion models (DMs), an emerging class of deep generati ve models, and introduce Differentially Private Diffusion Models (DPDMs), which enforce privacy using differentially private stochastic gradient descent (DP-SGD). We motivate why DP-SGD is well suited for training DPDMs, and thoroughly investigate the DM parameterization and the sampling algorithm, which turn out to be crucial ingredients in DPDMs. Furthermore, we propose noise multiplicity, a simple yet powerful modification of the DM training objective tailored to the DP setting to boost performance. We validate our novel DPDMs on widely-used image generation benchmarks and achieve state-of-the-art (SOTA) performance by large margins. For example, on MNIST we improve the SOTA FID from 48.4 to 5.01 and downstream classification accuracy from 83.2% to 98.1% for the privacy setting DP-$(\varepsilon=10, \delta=10^{-5})$. Moreover, on standard benchmarks, classifiers trained on DPDM-generated synthetic data perform on par with task-specific DP-SGD-trained classifiers, which has not been demonstrated before for DP generative models.

Outlier-Robust Group Inference via Gradient Space Clustering

Yuchen Zeng,Kristjan Greenewald,Kangwook Lee,Justin Solomon,Mikhail Yurochkin

Traditional machine learning models focus on achieving good performance on the overall training distribution, but they often underperform on minority groups. Existing methods can improve the worst-group performance, but they can have several limitations: (i) they require group annotations, which are often expensive and sometimes infeasible to obtain, and/or (ii) they are sensitive to outliers. Most related works fail to solve these two issues simultaneously as they focus on conflicting perspectives of minority groups and outliers. We address the problem of learning group annotations in the presence of outliers by clustering the data in the space of gradients of the model parameters. We show that data in the gradient space has a simpler structure while preserving information about minority groups and outliers, making it suitable for standard clustering methods like DBSCAN. Extensive experiments demonstrate that our method significantly outperforms state-of-the-art both in terms of group identification and downstream worst-group performance.

Broken Neural Scaling Laws

Ethan Caballero,Kshitij Gupta,Irina Rish,David Krueger

We present a smoothly broken power law functional form (referred to by us as a broken neural scaling law (BNSL)) that accurately models and extrapolates the scaling behaviors of deep neural networks (i.e. how the evaluation metric of interest varies as the amount of compute used for training, number of model parameters, training dataset size, or upstream performance varies) for various architectures and for each of various tasks within a large and diverse set of upstream and downstream tasks, in zero-shot, prompted, and fine-tuned settings. This set includes large-scale vision, language, audio, video, diffusion, generative modeling, multimodal learning, contrastive learning, AI alignment, robotics, out-of-distribution generalization, continual learning, uncertainty estimation / calibration, adversarial robustness, molecules, computer programming/coding, math word problems, arithmetic, unsupervised/self-supervised learning, and reinforcement learning (single agent and multi-agent). When compared to other functional forms for neural scaling behavior, this functional form yields extrapolations of scaling behavior that are considerably more accurate on this set. Moreover, this functional form accurately models and extrapolates scaling behavior that other functional forms are incapable of expressing such as the non-monotonic transitions present in the scaling behavior of phenomena such as double descent and the delayed, sharp inflection points present in the scaling behavior of tasks such as arithmetic. Lastly, we use this functional form to glean insights about the limit of the predictability of scaling behavior. See arXiv for longer version of this paper. Code is available at https://github.com/ethancaballero/broken_neural_scaling_laws

Learning to perceive objects by prediction

Tushar Arora,JOHN DAY,Li Erran Li,Ming Bo Cai

The representation of objects is the building block of higher-level concepts. Infants develop the notion of objects without supervision, for which the prediction error of future sensory input is likely a major teaching signal. We assume that the goal of representing objects distinctly is to allow the prediction of the coherent motion of all parts of an object independently from the background while keeping track of relatively fewer parameters of the object's motion. To realize this, we propose a framework to extract object-centric representations from single 2D images by learning to predict future scenes containing moving objects. The model learns to explicitly infer objects' locations in a 3D environment, generate 2D segmentation masks of objects, and perceive depth. Importantly, the model requires no supervision or pre-training but assumes rigid-body motion and only needs the observer's self-motion at training time. Further, by evaluating on a new synthetic dataset with more complex textures of objects and background, we found our model overcomes the reliance on clustering colors for segmenting objects, which is a limitation for previous models not using motion information. Our work demonstrates a new approach to learning symbolic representation grounded in sensation and action.

Avoiding spurious correlations via logit correction
Sheng Liu,Xu Zhang,Nitesh Sekhar,Yue Wu,Prateek Singhal,Carlos Fernandez-Granda
Empirical studies suggest that machine learning models trained with empirical risk minimization (ERM) often rely on attributes that may be spuriously correlated with the class labels. Such models typically lead to poor performance during inference for data lacking such correlations. In this work, we explicitly consider a situation where potential spurious correlations are present in the majority of training data. In contrast with existing approaches, which use the ERM model outputs to detect the samples without spurious correlations and either heuristically upweight or upsample those samples, we propose the logit correction (LC) loss, a simple yet effective improvement on the softmax cross-entropy loss, to correct the sample logit. We demonstrate that minimizing the LC loss is equivalent to maximizing the group-balanced accuracy, so the proposed LC could mitigate the negative impacts of spurious correlations. Our extensive experimental results further reveal that the proposed LC loss outperforms state-of-the-art solutions on multiple popular benchmarks by a large margin, an average 5.5% absolute improvement, without access to spurious attribute labels. LC is also competitive with oracle methods that make use of the attribute labels.

LEARNING CONTEXT-AWARE ADAPTIVE SOLVERS TO ACCELERATE QUADRATIC PROGRAMMING
Haewon Jung,Junyoung Park,Jinkyoo Park
Quadratic programming (QP) is an important sub-field of mathematical optimization. The alternating direction method of multipliers (ADMM) is a successful method to solve QP. Even though ADMM shows promising results in solving various types of QP, its convergence speed is known to be highly dependent on the step-size parameter ρ. Due to the absence of a general rule for setting ρ, it is often tuned manually or heuristically. In this paper, we propose CA-ADMM (Context-aware Adaptive ADMM)) which learns to adaptively adjust ρ to accelerate ADMM. CA-ADMM extracts the spatio-temporal context, which captures the dependency of the primal and dual variables of QP and their temporal evolution during the ADMM iterations. CA-ADMM chooses ρ based on the extracted context. Through extensive numerical experiments, we validated that CA-ADMM effectively generalizes to unseen QP problems with different sizes and classes (i.e., having different QP parameter structures). Furthermore, we verified that CA-ADMM could dynamically adjust ρ considering the stage of the optimization process to accelerate the convergence speed further.

Learning Latent Structural Causal Models
Jithendaraa Subramanian,Yashas Annadani,Ivaxi Sheth,Nan Rosemary Ke,Tristan Deleu,Stefan Bauer,Derek Nowrouzezahrai,Samira Ebrahimi Kahou
Causal learning has long concerned itself with the accurate recovery of underlying causal mechanisms. Such causal modelling enables better explanations of out-o

f-distribution data. Prior works on causal learning assume that the high-level causal variables are given. However, in machine learning tasks, one often operates on low-level data like image pixels or high-dimensional vectors. In such settings, the entire Structural Causal Model (SCM) -- structure, parameters, \textit{and} high-level causal variables -- is unobserved and needs to be learnt from low-level data. We treat this problem as Bayesian inference of the latent SCM, given low-level data. For linear Gaussian additive noise SCMs, we present a tractable approximate inference method which performs joint inference over the causal variables, structure and parameters of the latent SCM from random, known interventions. Experiments are performed on synthetic datasets and a causally generated image dataset to demonstrate the efficacy of our approach. We also perform image generation from unseen interventions, thereby verifying out of distribution generalization for the proposed causal model.

Pre-Training for Robots: Leveraging Diverse Multitask Data via Offline Reinforcement Learning

Aviral Kumar,Anikait Singh,Frederik Ebert,Yanlai Yang,Chelsea Finn,Sergey Levine

Recent progress in deep learning highlights the tremendous potential of utilizing diverse datasets for achieving effective generalization and makes it enticing to consider leveraging broad datasets for attaining more robust generalization in robotic learning as well. However, in practice we likely will want to learn a new skill in a new environment that is unlikely to be contained in the prior data. Therefore we ask: how can we leverage existing diverse offline datasets in combination with small amounts of task-specific data to solve new tasks, while still enjoying the generalization benefits of training on large amounts of data? In this paper, we demonstrate that end-to-end offline RL can be an effective approach for doing this, without the need for any representation learning or vision-based pre-training. We present pre-training for robots (PTR), a framework based on offline RL that attempts to effectively learn new tasks by combining pre-training on existing robotic datasets with rapid fine-tuning on a new task, with as a few as 10 demonstrations. At its core, PTR applies an existing offline RL method such as conservative Q-learning (CQL), but extends it to include several crucial design decisions that enable PTR to actually work and outperform a variety of prior methods. To the best of our knowledge, PTR is the first offline RL method that succeeds at learning new tasks in a new domain on a real WidowX robot with as few as 10 task demonstrations, by effectively leveraging an existing dataset of diverse multi-task robot data collected in a variety of toy kitchens. We present an accompanying overview video at https://www.youtube.com/watch?v=yAWgyLJD5lY&ab_channel=PTRICLR

Safe Exploration Incurs Nearly No Additional Sample Complexity for Reward-Free RL

Ruiquan Huang,Jing Yang,Yingbin Liang

Reward-free reinforcement learning (RF-RL), a recently introduced RL paradigm, relies on random action-taking to explore the unknown environment without any reward feedback information. While the primary goal of the exploration phase in RF-RL is to reduce the uncertainty in the estimated model with minimum number of trajectories, in practice, the agent often needs to abide by certain safety constraint at the same time. It remains unclear how such safe exploration requirement would affect the corresponding sample complexity in order to achieve the desired optimality of the obtained policy in planning. In this work, we make a first attempt to answer this question. In particular, we consider the scenario where a safe baseline policy is known beforehand, and propose a unified Safe reWard-frEe ExploraTion (SWEET) framework. We then particularize the SWEET framework to the tabular and the low-rank MDP settings, and develop algorithms coined Tabular-SWEET and Low-rank-SWEET, respectively. Both algorithms leverage the concavity and continuity of the newly introduced truncated value functions, and are guaranteed to achieve zero constraint violation during exploration with high probability. Furthermore, both algorithms can provably find a near-optimal policy subject to any constraint in the planning phase. Remarkably, the sample complexities under both algorithms match or even outperform the state of the art in their constraint-free counterparts up to some constant factors, proving that safety constraint hardly increases the sample complexity for RF-RL.

S^6-DAMON: Bridging Self-Supervised Speech Models and Real-time Speech Recognition

Yonggan Fu,Zhifan Ye,Shunyao Zhang,Jiayi Yuan,Zhongzhi Yu,Yingyan Lin

There has been an growing demand for deep neural network (DNN) powered automatic speech recognition (ASR) on mobile platforms for real-time speech recognition. However, ubiquitous on-device ASR systems are still hindered by two bottlenecks: (1) the lack of large-scale transcribed speech data especially for low-resource spoken languages and (2) the large gap between DNNs' prohibitive complexity and mobiles' limited resources. In parallel, speech models pretrained via self-supervised learning (SSL) have emerged to reduce the reliance on the availability of transcribed speech data, which however further enlarges the efficiency gap because they often adopt large transformers to ensure expressive speech representations. Thus, it is highly desired to trim down the complexity of speech SSL models to enable real-time on-device ASR. This is particularly challenging since only structured sparsity can favor hardware efficiency in commercial devices, under which the speech representation learned by SSL could easily be demolished. To this end, we develop a framework dubbed S^6-DAMON to pursue structured sparsity in speech SSL models via data-model co-compression. On the data side, leveraging both the duration of each phoneme and the pauses between the words/phonemes of human utterances, we propose a salient audio token detector, dubbed SALAD, to remove input audio tokens that are redundant; On the model side, we identify that the failure of the SOTA ASR pruning method under structured sparsity is caused by the sparsity discrepancy between finetuning/deployment and their limited learnability of sparsity distributions, and then tackle it via a new ASR pruning pipeline dubbed SAFARI, which adopts a three-step pipeline - sparsify, finetune, and adjust sparsity. Extensive experiments validate that S^6-DAMON can enable real-time ASR with limited transcribed speech data requirements while maintaining decent recognition performance. All source codes will be released upon acceptance.

Teaching Algorithmic Reasoning via In-context Learning

Hattie Zhou,Azade Nova,Aaron Courville,Hugo Larochelle,Behnam Neyshabur,Hanie Sedghi

Large language models (LLMs) have shown increasing in-context learning capabilities through scaling up model and data size. Despite this progress, LLMs are still unable to solve algorithmic reasoning problems. While providing a rationale with the final answer has led to further improvements in multi-step reasoning problems, Anil et al. 2022 showed that even simple algorithmic reasoning tasks such as parity are far from solved. In this work, we identify and study four key stages for successfully teaching algorithmic reasoning to LLMs: (1) formulating algorithms as skills, (2) teaching multiple skills simultaneously (skill accumulation), (3) teaching how to combine skills (skill composition) and (4) teaching how to use skills as tools. We show that it is possible to teach algorithmic reasoning to LLMs via in-context learning, which we refer to as Algorithmic Prompting. We evaluate our approach on a variety of arithmetic and quantitative reasoning tasks, and demonstrate significant boosts in performance over existing prompting techniques. In particular, for long parity, addition, multiplication and subtraction and parity tasks, we achieve an error reduction of approximately 10x, 9x, 5x and 2x respectively compared to the best available baselines.

Offline Q-learning on Diverse Multi-Task Data Both Scales And Generalizes

Aviral Kumar,Rishabh Agarwal,Xinyang Geng,George Tucker,Sergey Levine

The potential of offline reinforcement learning (RL) is that high-capacity models trained on large, heterogeneous datasets can lead to agents that generalize broadly, analogously to similar advances in vision and NLP. However, recent works argue that offline RL methods encounter unique challenges to scaling up model capacity. Drawing on the learnings from these works, we re-examine previous design choices and find that with appropriate choices: ResNets, cross-entropy based distributional backups, and feature normalization, offline Q-learning algorithms exhibit strong performance that scales with model capacity. Using multi-task Atari as a testbed for scaling and generalization, we train a single policy on 40 games with near-human performance using up-to 80 million parameter networks, finding that model performance scales favorably with capacity. In contrast to prior work, we extrapolate beyond dataset performance even when trained entirely on a large (400M transitions) but highly suboptimal dataset (51% human-level performance). Compared to return-conditioned supervised approaches, offline Q-learning scales similarly with model capacity and has better performance, especially when the dataset is suboptimal. Finally, we show that offline Q-learning with a diverse dataset is sufficient to learn powerful representations that facilitate rapid transfer to novel games and fast online learning on new variations of a training game, improving over existing state-of-the-art representation learning approaches.

Disentangled Conditional Variational Autoencoder for Unsupervised Anomaly Detection

Asif Ahmed Neloy,Maxime Turgeon

Recently, generative models have shown promising performance in anomaly detection tasks. Specifically, autoencoders learn representations of high-dimensional data, and their reconstruction ability can be used to assess whether a new instance is likely to be anomalous. However, the primary challenge of unsupervised anomaly detection (UAD) is in learning appropriate disentangled features and avoiding information loss, while incorporating known sources of variation to improve the reconstruction. In this paper, we propose a novel architecture of generative autoencoder by combining the frameworks of β-VAE, conditional variational autoencoder (CVAE), and the principle of total correlation (TC). We show that our architecture improves the disentanglement of latent features, optimizes TC loss more efficiently, and improves the ability to detect anomalies in an unsupervised manner with respect to high-dimensional instances, such as in imaging datasets. Through both qualitative and quantitative experiments on several benchmark datasets, we demonstrate that our proposed method excels in terms of both anomaly detection and capturing disentangled features. Our analysis underlines the importance of learning disentangled features for UAD tasks.

Diffusion-based Image Translation using disentangled style and content representation

Gihyun Kwon,Jong Chul Ye

Diffusion-based image translation guided by semantic texts or a single target image has enabled flexible style transfer which is not limited to the specific domains.

Unfortunately, due to the stochastic nature of diffusion models, it is often difficult to maintain the original content of the image during the reverse diffusion.

To address this, here we present a novel diffusion-based unsupervised image translation method, dubbed as DiffuseIT, using disentangled style and content representation.

Specifically, inspired by the slicing Vision Transformer, we extract intermediate keys of multihead self attention layer from ViT model and used them as the content preservation loss. Then, an image guided style transfer is performed by matching the [CLS] classification token from the denoised samples and target image, whereas additional CLIP loss is used for the text-driven style transfer.

To further accelerate the semantic change during the reverse diffusion, we also propose a novel semantic divergence loss and resampling strategy.

Our experimental results show that the proposed method outperforms state-of-the-art baseline models in both text-guided and image-guided translation tasks.

An Analytic Framework for Robust Training of Differentiable Hypothesis

Ramin Barati,Reza Safabakhsh,Mohammad Rahmati

The reliability of a learning model is key to the successful deployment of machine learning in various industries. Creating a robust model, particularly one unaffected by adversarial attacks, requires a comprehensive understanding of the adversarial examples phenomenon. However, it is difficult to describe the phenomenon due to the complicated nature of the problems in machine learning. Consequently, many studies investigate the phenomenon by proposing a simplified model of how adversarial examples occur and validate it by predicting some aspect of the phenomenon. While these studies cover many different characteristics of the adversarial examples, they have not reached a holistic approach to the geometric and analytic modeling of the phenomenon. We observe the phenomenon in many applications of machine learning, and its effects seems to be independent of the choice of the hypothesis class. In this paper, we propose a formalization of robustness in learning theoretic terms and give a geometrical description of the phenomenon in analytic classifiers. We then utilize the proposal to devise a robust classification learning rule for differentiable hypothesis classes and showcase our framework on synthetic and real-world data.

Federated Learning with Heterogeneous Label Noise: A Dual Structure Approach

Xinyuan Ji,Zhaowei Zhu,Wei Xi,Olga Gadyatskaya,Zonglin Di,Yang Liu

The performance of federated learning relies heavily on the label quality of each distributed client. In this paper, we consider a federated learning setting with heterogeneous label noise, where each local client might observe training labels with heterogeneous noise rates, which may even drawn from different subsets of the label space. The above high heterogeneity poses challenges for applying the existing label noise learning approaches to each client locally. We formalize the study of federated learning from heterogeneous label noise by firstly identifying two promising label noise generation models. Then, we propose a dual structure approach named FedDual. Intuitively, if there exists a model that filters out the wrongly labeled instances from the local dataset, the effect of label noise can be mitigated. Considering the heterogeneity of local datasets, in addition to the globally shared model, each client in FedDual maintains a local and personalized denoising model. The personalized denoising models can combine information from the global model or other pre-trained models to ensure the performance of denoising. Under this framework, we instantiate our approach with several local sample cleaning methods. We present substantial experiments on MNIST, CIFAR10, and CIFAR100 to demonstrate that FedDual can effectively recognize heterogeneous label noise in different clients and improve the performance of the aggregated model.

****

Mixture of Quantized Experts (MoQE): Complementary Effect of Low-bit Quantization and Robustness

Young Jin Kim,Raffy Fahim,Hany Hassan

Large Mixture of Experts (MoE) models could achieve state-of-the-art quality on various language tasks, including machine translation task, thanks to the efficient model scaling capability with expert parallelism. However, it has brought a fundamental issue of larger memory consumption at deployment time. Furthermore, this results in significant inference speed degradation at auto-regressive decoding steps due to the increased memory transfers. In this paper, we propose a simple weight-only quantization method using ultra low-bit such as 2-bit, 3-bit and 4-bits to effectively mitigate the increased memory and latency issues of MoE models. We show that low-bit quantization together with the MoE architecture delivers a reliable model performance while reducing the memory size significantly even without any additional training. Especially, expert layers in MoE models are much more robust to the quantization than conventional feedforward networks (FFN) layers. In our comprehensive analysis, we show that MoE models with 2-bit and 80\% sparse expert weights can deliver better model performance than the dense model trained on the same dataset. We present how quantization of different parts of models affects the performance with various experiments using a large MoE model (5.3 B). As a result of low-bit quantization, we show the model size can be reduced by 4.9X smaller than the original half precision floating point (fp16)

MoE model. This cuts down the model size of 5.3B parameters from 8.4x of the dense model to only 1.7x of the dense model after 2-bit quantization. It still preserves 1.88\% higher accuracy than the dense model. Combined with an optimized GPU runtime implementation, it also achieves 2.7X speed-up which is even slightly faster than the FLOPs equivalent dense model.

Implicit Regularization for Group Sparsity

Jiangyuan Li,Thanh V Nguyen,Chinmay Hegde,Raymond K. W. Wong

We study the implicit regularization of gradient descent towards structured sparsity via a novel neural reparameterization, which we call a diagonally grouped linear neural network. We show the following intriguing property of our reparameterization: gradient descent over the squared regression loss, without any explicit regularization, biases towards solutions with a group sparsity structure. In contrast to many existing works in understanding implicit regularization, we prove that our training trajectory cannot be simulated by mirror descent. We analyze the gradient dynamics of the corresponding regression problem in the general noise setting and obtain minimax-optimal error rates. Compared to existing bounds for implicit sparse regularization using diagonal linear networks, our analysis with the new reparameterization shows improved sample complexity. In the degenerate case of size-one groups, our approach gives rise to a new algorithm for sparse linear regression. Finally, we demonstrate the efficacy of our approach with several numerical experiments.

HesScale: Scalable Computation of Hessian Diagonals

Mohamed Elsayed,A. Rupam Mahmood

Second-order optimization uses curvature information about the objective function, which can help in faster convergence. However, such methods typically require expensive computation of the Hessian matrix, preventing their usage in a scalable way. The absence of efficient ways of computation drove the most widely used methods to focus on first-order approximations that do not capture the curvature information. In this paper, we develop \textit{HesScale}, a scalable approach to approximating the diagonal of the Hessian matrix, to incorporate second-order information in a computationally efficient manner. We show that HesScale has the same computational complexity as backpropagation. Our results on supervised classification show that HesScale achieves high approximation accuracy, allowing for scalable and efficient second-order optimization.

****

Divide-and-Cluster: Spatial Decomposition Based Hierarchical Clustering

Narendra Ahuja,Akshat Sharma,Divyam Goel

This paper is about increasing the computational efficiency of clustering algorithms. Many clustering algorithms are based on properties of relative locations of points, globally or locally, e.g., interpoint distances and nearest neighbor distances. This amounts to using a lower dimensional space than the full dimensionality D of the space in which the points are embedded. We present a clustering algorithm, Divide-and-Cluster (DAC), which detects local clusters in small neighborhoods obtained by recursive tessellation of space, and then merges them hierarchically, following the Divide-and-Conquer paradigm. This significantly reduces computation time which may otherwise grow nonlinearly number n of points. We define locality as hypercubical neighborhoods in a recursive hypercubical decomposition of space, represented by a tree. Clusters are detected within each hypercube, and merged with those from neighboring hypercubes while traversing up the tree. We expect DAC to perform better than many other algorithms because (a) as clusters merge into larger clusters (components), their number steadily decreases vs the number of points, and (b) we cluster only neighboring components. The ordering of component appearances also simultaneously yields a cluster hierarchy (tree). Further, our use of small neighborhoods allows piecewise uniform approximation of large, nonuniform, arbitrary shaped clusters, thus avoiding the need for global cluster models. We experimentally verify the correctness of detected clusters on a variety of datasets, posing a variety of challenges, as well as show that DAC’s runtime is significantly better than representative algorithms o f other types, particularly for increasing values of n.

Implicit regularization in Heavy-ball momentum accelerated stochastic gradient descent

Avrajit Ghosh,He Lyu,Xitong Zhang,Rongrong Wang

It is well known that the finite step-size (h) in Gradient descent (GD) implicitly regularizes solutions to flatter minimas. A natural question to ask is \textit{Does the momentum parameter β (say) play a role in implicit regularization in Heavy-ball (H.B) momentum accelerated gradient descent (GD+M)?}. To answer this question, first, we show that the trajectory traced by discrete H.B momentum update (GD+M) is $O(h^2)$ close to a continuous trajectory induced by a modified loss, which consists of an original loss and an implicit regularizer. This implicit regularizer for (GD+M) is indeed stronger than that of (GD) by factor of $(\frac{1+\beta}{1-\beta})$, thus explaining why (GD+M) shows better generalization performance and higher test accuracy than (GD). Furthermore, we extend our analysis to stochastic version of gradient descent with momentum (SGD+M) and propose a deterministic continuous trajectory that is $O(h^2)$ close to the discrete update of (SGD+M) in a strong approximation sense. We explore the implicit regularization in (SGD+M) and (GD+M) through a series of experiments validating our theory.

ORCA: Interpreting Prompted Language Models via Locating Supporting Evidence in the Ocean of Pretraining Data

Xiaochuang Han,Yulia Tsvetkov

Prompting large pretrained language models leads to strong performance in a variety of downstream tasks. However, it is still unclear from where the model learns task-specific knowledge, especially in zero-shot setups. In this work, we propose a novel method ORCA to identify evidence of the model's task-specific competence in prompt-based learning. Through an instance attribution approach to model interpretability, by iteratively using gradient information related to the downstream task, ORCA locates a very small subset of pretraining data that directly supports the model's predictions in a given task; we call this subset supporting data evidence. We show that supporting data evidence offers new insights about the prompted language models. For example, in the tasks of sentiment analysis and textual entailment, BERT shows a substantial reliance on BookCorpus---the smaller corpus of BERT's two pretraining corpora---as well as on pretraining examples that mask out synonyms to the task labels used in prompts.

Real-time variational method for learning neural trajectory and its dynamics

Matthew Dowling,Yuan Zhao,Il Memming Park

Latent variable models have become instrumental in computational neuroscience for reasoning about neural computation. This has fostered the development of powerful offline algorithms for extracting latent neural trajectories from neural recordings. However, despite the potential of real-time alternatives to give immediate feedback to experimentalists, and enhance experimental design, they have received markedly less attention. In this work, we introduce the exponential family variational Kalman filter (eVKF), an online recursive Bayesian method aimed at inferring latent trajectories while simultaneously learning the dynamical system generating them. eVKF works for arbitrary likelihoods and utilizes the constant base measure exponential family to model the latent state stochasticity. We derive a closed-form variational analog to the predict step of the Kalman filter which leads to a provably tighter bound on the ELBO compared to another online variational method. We validate our method on synthetic and real-world data, and, notably, show that it achieves competitive performance.

****

Large Language Models are Human-Level Prompt Engineers

Yongchao Zhou,Andrei Ioan Muresanu,Ziwen Han,Keiran Paster,Silviu Pitis,Harris Chan,Jimmy Ba

By conditioning on natural language instructions, large language models (LLMs) h ave displayed impressive capabilities as general-purpose computers. However, task performance depends significantly on the quality of the prompt used to steer the model, and most effective prompts have been handcrafted by humans. Inspired by classical program synthesis and the human approach to prompt engineering, we propose Automatic Prompt Engineer (APE) for automatic instruction generation and selection. In our method, we treat the instruction as the "program," optimized by searching over a pool of instruction candidates proposed by an LLM in order to maximize a chosen score function. To evaluate the quality of the selected instruction, we evaluate the zero-shot performance of another LLM following the selected instruction. Experiments on 24 NLP tasks show that our automatically generated instructions outperform the prior LLM baseline by a large margin and achieve better or comparable performance to the instructions generated by human annotators on 21/24 tasks. We conduct extensive qualitative and quantitative analyses to explore the performance of APE. We show that APE-engineered prompts can be applied to steer models toward truthfulness and/or informativeness, as well as to improve few-shot learning performance by simply prepending them to standard in-context learning prompts.

Do Not Blindly Imitate the Teacher: Loss Perturbation for Knowledge Distillation

Rongzhi Zhang,Jiaming Shen,Tianqi Liu,Jialu Liu,Michael Bendersky,Marc Najork,Chao Zhang

Knowledge distillation (KD) is a popular model compression technique to transfer knowledge from large teacher models to a small student model. Typically, the student learns to imitate the teacher by minimizing the KL divergence of its output distribution with the teacher's output distribution. We argue that such a learning objective is sub-optimal because there exists a discrepancy between the teacher's output distribution and the ground truth label distribution, and forcing the student to blindly imitate the unreliable teacher output distribution leads to inferior performance. To this end, we propose a novel knowledge distillation objective PTLoss by first representing the vanilla KL-based distillation loss function via a Maclaurin series and then perturbing the leading-order terms in this series. This perturbed loss improves the student generalizability by effectively distilling knowledge from a shifted distribution closer to the ground truth data. We also propose a method to compute this shifted teacher distribution, named Proxy Teacher, which enables us to select the perturbation coefficients in PTLoss. We theoretically show the perturbed loss reduces the deviation from the true population risk compared to the vanilla KL-based distillation loss functions. Experiments on three tasks with teachers of different scales show that our method significantly outperforms vanilla distillation loss functions and other perturbation methods.

Fast Yet Effective Graph Unlearning through Influence Analysis

Kun Wu,Jie Shen,Yue Ning,Wendy Hui Wang

Recent evolving data privacy policies and regulations have led to increasing interest in the machine unlearning problem. In this paper, we consider Graph Neural Networks (GNNs) as the target model, and study the problem of edge unlearning in GNNs, i.e., learning a new GNN model as if a specified set of edges never existed in the original training graph. Despite its practical importance, the problem remains elusive due to the non-convexity nature of GNNs. Our main technical contribution is three-fold: 1) we cast the problem of edge unlearning as estimating the influence functions of the edges to be removed; 2) we design a computationally and memory efficient algorithm named EraEdge for edge influence estimation and unlearning; 3) under standard regularity conditions, we prove that the sequence of iterates produced by our algorithm converges to the desired model. A comprehensive set of experiments on three prominent GNN models and four benchmark graph datasets demonstrate that our algorithm achieves significant speed-up gains over retraining from scratch without sacrificing the model accuracy too much. Furthermore, our algorithm outperforms the existing GNN unlearning approach in terms of both training time and accuracy of the target GNN model.

Faster Hyperparameter Search for GNNs via Calibrated Dataset Condensation
Mucong Ding,Xiaoyu Liu,Tahseen Rabbani,Teresa Ranadive,Tai-Ching Tuan,Furong Huang

Dataset condensation aims to reduce the computational cost of training multiple models on a large dataset by condensing the training dataset into a small synthetic set. State-of-the-art approaches rely on matching the model gradients for the real and synthetic data and have recently been applied to condense large-scale graphs for node classification tasks. Although dataset condensation may be efficient when training multiple models for hyperparameter optimization, there is no theoretical guarantee on the generalizability of the condensed data: data condensation often generalizes poorly across hyperparameters/architectures in practice, while we find and prove this overfitting is much more severe on graphs. In this paper, we consider a different condensation objective specifically geared towards hyperparameter search. We aim to generate the synthetic dataset so that the validation-performance rankings of the models, with different hyperparameters, on the condensed and original datasets are comparable. We propose a novel hyperparameter-calibrated dataset condensation algorithm, which obtains the synthetic validation data by matching the hyperparameter gradients computed via implicit differentiation and efficient inverse Hessian approximation. HCDC employs a supernet with differentiable hyperparameters, making it suitable for modeling GNNs with widely different convolution filters. Experiments demonstrate that the proposed framework effectively maintains the validation-performance rankings of GNNs and speeds up hyperparameter/architecture search on graphs.

Spatiotemporal Modeling of Multivariate Signals with Graph Neural Networks and Structured State Space Models
Siyi Tang,Jared Dunnmon,Liangqiong Qu,Khaled Kamal Saab,Christopher Lee-Messer,Daniel Rubin

Multivariate signals are prevalent in various domains, such as healthcare, transportation systems, and space sciences. Modeling spatiotemporal dependencies in multivariate signals is challenging due to (1) long-range temporal dependencies and (2) complex spatial correlations between sensors. To address these challenges, we propose representing multivariate signals as graphs and introduce GraphS4mer, a general graph neural network (GNN) architecture that captures both spatial and temporal dependencies in multivariate signals. Specifically, (1) we leverage Structured State Spaces model (S4), a state-of-the-art sequence model, to capture long-term temporal dependencies and (2) we propose a graph structure learning layer in GraphS4mer to automatically learn the underlying graph structures in the data. We evaluate our proposed model on three distinct tasks and show that GraphS4mer consistently improves over existing models, including (1) seizure detection from electroencephalography signals, outperforming a previous GNN with self-supervised pretraining by 3.1 points in AUROC; (2) sleep staging from polysomnography signals, a 4.1 points improvement in macro-F1 score compared to existing sleep staging models; and (3) traffic forecasting, reducing MAE by 8.8% compared to existing GNNs and by 1.4% compared to transformer-based models.

Pruning Deep Neural Networks from a Sparsity Perspective
Enmao Diao,Ganghua Wang,Jiawei Zhang,Yuhong Yang,Jie Ding,Vahid Tarokh

In recent years, deep network pruning has attracted significant attention in order to enable the rapid deployment of AI into small devices with computation and memory constraints. Pruning is often achieved by dropping redundant weights, neurons, or layers of a deep network while attempting to retain a comparable test performance. Many deep pruning algorithms have been proposed with impressive empirical success. However, existing approaches lack a quantifiable measure to estimate the compressibility of a sub-network during each pruning iteration and thus may under-prune or over-prune the model. In this work, we propose PQ Index (PQI) to measure the potential compressibility of deep neural networks and use this to develop a Sparsity-informed Adaptive Pruning (SAP) algorithm. Our extensive experiments corroborate the hypothesis that for a generic pruning procedure, PQI decreases first when a large model is being effectively regularized and then incr eases when its compressibility reaches a limit that appears to correspond to the beginning of underfitting. Subsequently, PQI decreases again when the model collapse and significant deterioration in the performance of the model start to occur. Additionally, our experiments demonstrate that the proposed adaptive pruning algorithm with proper choice of hyper-parameters is superior to the iterative pruning algorithms such as the lottery ticket-based pruning methods, in terms of both compression efficiency and robustness.

High-dimensional Continuum Armed and High-dimensional Contextual Bandit: with Applications to Assortment and Pricing

Junhui Cai,Ran Chen,Martin J. Wainwright,Linda H. Zhao

The bandit problem with high-dimensional continuum arms and high-dimensional contextual covariates is often faced by decision-makers but remains unsolved. Existing bandit algorithms are impracticable due to the complexity of the double-layer high dimensionality. We formulate this problem as a high-dimensional continuum armed contextual bandit with high-dimensional covariates and propose a novel model that captures the effect of the arm and contextual on the reward with a low-rank representation matrix. The representation matrix is endowed with interpretability and predictive power. We further propose an efficient bandit algorithm based on a low-rank matrix estimator with theoretical justifications. The generality of our model allows wide applications including business and healthcare. In particular, we apply our method to assortment and pricing, both of which are important decisions for firms such as online retailers. Our method can solve the assortment-pricing problem simultaneously while most existing methods address them separately. We demonstrate the effectiveness of our method to jointly optimize assortment and pricing for revenue maximization for a giant online retailer.

■■What learning algorithm is in-context learning? Investigations with linear models

Ekin Akyürek,Dale Schuurmans,Jacob Andreas,Tengyu Ma,Denny Zhou

Neural sequence models, especially transformers, exhibit a remarkable capacity for in-context learning. They can construct new predictors from sequences of labeled examples $(x, f(x))$ presented in the input without further parameter updates. We investigate the hypothesis that transformer-based in-context learners implement standard learning algorithms implicitly, by encoding context-specific parametric models in their hidden representations, and updating these implicit models as new examples appear in the context. Using linear regression as a model problem, we offer three sources of evidence for this hypothesis. First, we prove by construction that transformers can implement learning algorithms for linear models based on gradient descent and closed-form computation of regression parameters. Second, we show that trained in-context learners closely match the predictors computed by gradient descent, ridge regression, and exact least-squares regression, transitioning between different predictors as transformer depth and dataset noise vary. Third, we present preliminary evidence that in-context learners share algorithmic features with these predictors: learners' late layers encode weight vectors and moment matrices. These results suggest that in-context learning is understandable in algorithmic terms, and that (at least in the linear case) learners may work by rediscovering standard estimation algorithms.

Learning to represent and predict evolving visual signals via polar straightening

Pierre-Étienne H Fiquet,Eero P Simoncelli

Observer motion and continuous deformations of objects and textures imbue natural videos with distinct temporal structures, enabling the prediction of future frames from past ones. Conventional methods proceed by estimating local motion, or optic flow, and then using this to predict future frames by warping and copying content. Here, we explore a more direct methodology, in which frames are transformed into an alternative representation where temporal structure and evolution are more readily accessible. As a base case, a rigidly translating pattern can be described in the frequency domain as a linear combination of sinusoids, each with constant amplitude and phase that cycles at a rate proportional to its frequency. This fundamental property of Fourier representation reduces prediction to angular extrapolation. Motivated by the geometry of this well-known case, we formulate a self-supervised learning problem which seeks a transformation of video frames to facilitate next-frame prediction in these natural polar coordinates. We construct a network architecture in which pairs of convolutional channels are used to factorize signals into slowly evolving amplitudes and linearly advancing phases. We train this network to predict future frames, and compare its performance with that of conventional methods using optic flow, and other learned predictive neural networks, evaluated on natural videos from the DAVIS dataset. We find that the polar predictor achieves high prediction performance while remaining interpretable and fast, thereby demonstrating the potential of a flow-free video processing methodology that is trained end-to-end to predict natural video content.

On Representation Learning Under Class Imbalance
Ravid Shwartz-Ziv,Micah Goldblum,Yucen Lily Li,C. Bayan Bruss,Andrew Gordon Wilson

Unlike carefully curated academic benchmarks, real-world datasets are often highly class-imbalanced, involving training and test sets which contain few examples from certain minority classes. While there is a common understanding that neural network generalization is negatively impacted by imbalance, the source of this problem and its resolution are unclear. Through extensive empirical investigation, we study foundational learning behaviors for various models such as neural networks, gradient-boosted decision trees, and SVMs across a range of domains and find that (1) contrary to conventional wisdom, re-balancing the training set to include a higher proportion of minority samples degrades performance on imbalanced test sets; (2) minority samples are hard to fit, yet algorithms which fit them, such as oversampling, do not improve generalization. Motivated by the observation that re-balancing class-imbalanced training data is ineffective, we show that several existing techniques for improving representation learning are effective in this setting: (3) self-supervised pre-training is insensitive to imbalance and can be used for feature learning before fine-tuning on labels; (4) Bayesian inference is effective because neural networks are especially underspecified under class imbalance; (5) flatness-seeking regularization pulls decision boundaries away from minority samples, especially when we seek minima that are particularly flat on the minority samples’ loss.

Gradient Descent Converges Linearly for Logistic Regression on Separable Data
Kyriakos Axiotis,Maxim Sviridenko

We show that running gradient descent on the logistic regression objective guarantees loss $f(x) \leq 1.1 \cdot f(x^*) + \epsilon$, where the error ϵ decays exponentially with the number of iterations. This is in contrast to the common intuition that the absence of strong convexity precludes linear convergence of first-order methods, and highlights the importance of variable learning rates for gradient descent. For separable data, our analysis proves that the error between the predictor returned by gradient descent and the hard SVM predictor decays as $\mathrm{poly}(1/t)$, exponentially faster than the previously known bound of $O(\log\log t / \log t)$. Our key observation is a property of the logistic loss that we call multiplicative smoothness and is (surprisingly) little-explored: As the loss decreases, the objective becomes (locally) smoother and therefore the learning rate can increase. Our results also extend to sparse logistic regression, where they lead to an exponential improvement of the sparsity-error tradeoff.

Interpretable (meta)factorization of clinical questionnaires to identify general dimensions of psychopathology
Ka Chun Lam,Bridget W Mahony,Armin Raznahan,Francisco Pereira

Psychiatry research aims at understanding manifestations of psychopathology in b ehavior, in terms of a small number of latent constructs. These are usually inferred from questionnaire data using factor analysis. The resulting factors and relationship to the original questions are not necessarily interpretable. Furthermore, this approach does not provide a way to separate the effect of confounds from those of constructs, and requires explicit imputation for missing data. Finally, there is no clear way to integrate multiple sets of constructs estimated from different questionnaires. An important question is whether there is a universal, compact set of constructs that would span all the psychopathology issues listed across those questionnaires. We propose a new matrix factorization method designed for questionnaires aimed at promoting interpretability, through bound and sparsity constraints. We provide an optimization procedure with theoretical convergence guarantees, and validate automated methods to detect latent dimensionality on synthetic data. We first demonstrate the method on a commonly used general-purpose questionnaire. We then show it can be used to extract a broad set of 15 psychopathology factors spanning 21 questionnaires from the Healthy Brain Network study. We show that our method preserves diagnostic information against competing methods, even as it imposes more constraints. Finally, we demonstrate that it can be used for defining a short, general questionnaire that allows recovery of those 15 meta-factors, using data more efficiently than other methods.

Enhancing Meta Learning via Multi-Objective Soft Improvement Functions

Runsheng Yu,Weiyu Chen,Xinrun Wang,James Kwok

Meta-learning tries to leverage information from similar learning tasks. In the commonly-used bilevel optimization formulation, the shared parameter is learned in the outer loop by minimizing the average loss over all tasks. However, the converged solution may be comprised in that it only focuses on optimizing on a small subset of tasks. To alleviate this problem, we consider meta-learning as a multi-objective optimization (MOO) problem, in which each task is an objective. However, existing MOO solvers need to access all the objectives’ gradients in each iteration, and cannot scale to the huge number of tasks in typical meta-learning settings. To alleviate this problem, we propose a scalable gradient-based solver with the use of mini-batch. We provide theoretical guarantees on the Pareto optimality or Pareto stationarity of the converged solution. Empirical studies on various machine learning settings demonstrate that the proposed method is efficient, and achieves better performance than the baselines, particularly on improving the performance of the poorly-performing tasks and thus alleviating the compromising phenomenon.

Discrete Predictor-Corrector Diffusion Models for Image Synthesis

Jose Lezama,Tim Salimans,Lu Jiang,Huiwen Chang,Jonathan Ho,Irfan Essa

We introduce Discrete Predictor-Corrector diffusion models (DPC), extending predictor-corrector samplers in Gaussian diffusion models to the discrete case. Predictor-corrector samplers are a class of samplers for diffusion models, which improve on ancestral samplers by correcting the sampling distribution of intermediate diffusion states using MCMC methods. In DPC, the Langevin corrector, which does not have a direct counterpart in discrete space, is replaced with a discrete MCMC transition defined by a learned corrector kernel. The corrector kernel is trained to make the correction steps achieve asymptotic convergence, in distribution, to the correct marginal of the intermediate diffusion states. Equipped with DPC, we revisit recent transformer-based non-autoregressive generative models through the lens of discrete diffusion, and find that DPC can alleviate the compounding decoding error due to the parallel sampling of visual tokens. Our experiments show that DPC improves upon existing discrete latent space models for class-conditional image generation on ImageNet, and outperforms continuous diffusion models and GANs, according to standard metrics and user preference studies.

Instruction-Following Agents with Jointly Pre-Trained Vision-Language Models

Hao Liu,Lisa Lee,Kimin Lee,Pieter Abbeel

Humans are excellent at understanding language and vision to accomplish a wide range of tasks. In contrast, creating general instruction-following embodied agen ts remains a difficult challenge. Prior work that uses pure language-only models lack visual grounding, making it difficult to connect language instructions with visual observations. On the other hand, methods that use pre-trained vision-language models typically come with divided language and visual representations, requiring designing specialized network architecture to fuse them together. We propose a simple yet effective model for robots to solve instruction-following tasks in vision-based environments. Our InstructRL method consists of a multimodal transformer that encodes visual observations and language instructions, and a policy transformer that predicts actions based on encoded representations. The multimodal transformer is pre-trained on millions of image-text pairs and natural language text, thereby producing generic cross-modal representations of observations and instructions. The policy transformer keeps track of the full history of observations and actions, and predicts actions autoregressively. We show that this unified transformer model outperforms all state-of-the-art pre-trained or trained-from-scratch methods in both single-task and multi-task settings. Our model also shows better model scalability and generalization ability than prior work.

Infusing Lattice Symmetry Priors in Neural Networks Using Soft Attention Masks

Mattia Atzeni,Mrinmaya Sachan,Andreas Loukas

Infusing inductive biases and knowledge priors in artificial neural networks is a promising approach for achieving sample efficiency in current deep learning models. Core knowledge priors of human intelligence have been studied extensively in developmental science and recent work has postulated the idea that research on artificial intelligence should revolve around the same basic priors. As a step towards this direction, in this paper, we introduce LatFormer, a model that incorporates lattice geometry and topology priors in attention masks.

Our study of the properties of these masks motivates a modification to the standard attention mechanism, where attention weights are scaled using soft attention masks generated by a convolutional neural network. Our experiments on ARC and on synthetic visual reasoning tasks show that LatFormer requires 2-orders of magnitude fewer data than standard attention and transformers in these tasks. Moreover, our results on ARC tasks that incorporate geometric priors provide preliminary evidence that deep learning can tackle this complex dataset, which is widely viewed as an important open challenge for AI research.

Counterfactual Vision-Language Data Synthesis with Intra-Sample Contrast Learning

Zhecan Wang,Yicheng He,Wenhao Li,Haoxuan You,Long Chen,Noel C Codella,Yulei Niu,Kai-Wei Chang,Shih-Fu Chang

Existing Visual Learning (VL) benchmarks often contain exploitative biases. Most former works only attempted to mitigate biases in semantically low-level and conventional visual-question-answering typed datasets like VQA and GQA. However, these methods cannot generalize to recently emerging highly semantic VL datasets like VCR and are also difficult to scale due to many severe problems like high-cost labors, drastically disrupting the data distribution\textit{, etc.}To resolve those problems and also address other unique biases on VCR-like datasets, we first conduct in-depth analysis and identify important biases in VCR dataset. We further propose a generalized solution that synthesizes counterfactual image and text data based on the original query's semantic focus while producing less distortion to the data distribution. To utilize our synthesized data, we also design an innovative intra-sample contrastive training strategy to assist QA learning in Visual Commonsense Reasoning (VCR). Moreover, our synthesized VL data also serve as a highly-semantic debiased benchmark for evaluating future VL models' robustness. Extensive experiments show that our proposed synthesized data and training strategy improve existing VL models' performances on both the original VCR dataset and our proposed debiased benchmark.

OPTQ: Accurate Quantization for Generative Pre-trained Transformers

Elias Frantar,Saleh Ashkboos,Torsten Hoefler,Dan Alistarh

Generative Pre-trained Transformer models, known as GPT or OPT, set themselves a part through breakthrough performance across complex language modelling tasks, but also by their extremely high computational and storage costs. Specifically, due to their massive size, even inference for large, highly-accurate GPT models may require multiple performant GPUs, which limits the usability of such models. While there is emerging work on relieving this pressure via model compression, the applicability and performance of existing compression techniques is limited by the scale and complexity of GPT models. In this paper, we address this challenge, and propose OPTQ, a new one-shot weight quantization method based on approximate second-order information, that is both highly-accurate and highly-efficient. Specifically, OPTQ can quantize GPT models with 175 billion parameters in approximately four GPU hours, reducing the bitwidth down to 3 or 4 bits per weight, with negligible accuracy degradation relative to the uncompressed baseline. Our method more than doubles the compression gains relative to previously-proposed one-shot quantization methods, preserving accuracy, allowing us for the first time to execute an 175 billion-parameter model inside a single GPU for generative inference. Moreover, we also show that our method can still provide reasonable accuracy in the extreme quantization regime, in which weights are quantized to 2-bit or even ternary quantization levels.

We show experimentally that these improvements can be leveraged for end-to-end inference speedups over FP16, of around 3.25x when using high-end GPUs (NVIDIA A100) and 4.5x when using more cost-effective ones (NVIDIA A6000). The implementation is available at https://github.com/IST-DASLab/gptq.

ConserWeightive Behavioral Cloning for Reliable Offline Reinforcement Learning

Tung Nguyen,Qinqing Zheng,Aditya Grover

The goal of offline reinforcement learning (RL) is to learn near-optimal policies from static logged datasets, thus sidestepping expensive online interactions. Behavioral cloning (BC) provides a straightforward solution to offline RL by mimicking offline trajectories via supervised learning. Recent advances~\cite{chen2021decision, janner2021offline, emmons2021rvs} have shown that by conditioning on desired future returns, BC can perform competitively to their value-based counterparts, while enjoying much more simplicity and training stability. However, the distribution of returns in the offline dataset can be arbitrarily skewed and suboptimal, which poses a unique challenge for conditioning BC on expert returns at test-time. We propose ConserWeightive Behavioral Cloning (\name), a simple and effective method for improving the performance of conditional BC for offline RL with two key components: trajectory weighting and conservative regularization. Trajectory weighting addresses the bias-variance tradeoff in conditional BC and provides a principled mechanism to learn from both low return trajectories (typically plentiful) and high return trajectories (typically few). Further, we analyze the notion of conservatism in existing BC methods, and propose a novel conservative regularizer that explicitly encourages the policy to stay close to the data distribution. The regularizer helps achieve more reliable performance, and removes the need for ad-hoc tuning of the conditioning value during evaluation. We instantiate \name{} in the context of Reinforcement Learning via Supervised Learning (RvS)~\cite{emmons2021rvs} and Decision Transformer (DT)~\citep{chen2021decision}, and empirically show that it significantly boosts the performance and stability of prior methods on various offline RL benchmarks.

ADVL: Adaptive Distillation for Vision-Language Tasks

Zhecan Wang,Noel C Codella,Haoxuan You,Long Chen,Yen-Chun Chen,Yulei Niu,Jianwei Yang,Luowei Zhou,Lu Yuan,Kai-Wei Chang,Shih-Fu Chang

Large-scale image-text pairs, such as image-captions and image-phrases, enable the strong representation of vision-language (VL) models. Nevertheless, they lose diversity and complexity due to the constraints in collecting data. Meanwhile, models pre-trained with image-only or text-only data (we call them unimodal pretrained models) continue to flourish and impress the community. Compared to image-text pairs, unimodal data has less constraints during the collection process resulting in more diverse styles. A natural question is how to leverage unimodal pretrained models to benefit downstream VL tasks? Most existing works focus on fu sing VL information in the expensive pre-training stage. They directly plug in unimodal pre-trained encoders into a VL framework and redo an additional pre-training step on paired image-text data. This causes additional computation expense and the unimodal pretrained knowledge might be forgotten. In this paper, we take a different route and investigate how to fuse VL information in the finetuning stage oaly. To directly transfer pretrained knowledge from unimodal models to help downstream VL tasks, we propose ADVL, which avoids redoing any pre-training step and is generalizable to be applied of top of various VL models. To comprehensively demonstrate the effectiveness of ADVL, we conduct evaluation across three mostly recognized highly semantic VL benchmarks: VCR, VQA, and SNLI-VE under three settings, low-shot, full-shot and domainshifted settings. Results show that ADVL consistently improves the performance with different VL base models across all settings. It even achieves state-of-theart (SOTA) performance on VCR among models pre-trained with image-text data and delivers competitive results on VQA and SNLI-VE, Based on our analysis, we also discover that ADVL can improve the robustness of VL models and regulate them to better use vision information.

A new characterization of the edge of stability based on a sharpness measure aware of batch gradient distribution

Sungyoon Lee,Cheongjae Jang

For full-batch gradient descent (GD), it has been empirically shown that the sharpness, the top eigenvalue of the Hessian, increases and then hovers above $2/\text{(learning rate)}$, and this is called ``the edge of stability'' phenomenon. However, it is unclear why the sharpness is somewhat larger than $2/\text{(learning rate)}$ and how this can be extended to general mini-batch stochastic gradient descent (SGD). We propose a new sharpness measure (interaction-aware-sharpness) aware of the \emph{interaction} between the batch gradient distribution and the loss landscape geometry. This leads to a more refined and general characterization of the edge of stability for SGD. Moreover, based on the analysis of a concentration measure of the batch gradient, we propose a more accurate scaling rule, Linear and Saturation Scaling Rule (LSSR), between batch size and learning rate.

****

$\mathrm{SE}(3)$-Equivariant Attention Networks for Shape Reconstruction in Function Space

Evangelos Chatzipantazis,Stefanos Pertigkiozoglou,Edgar Dobriban,Kostas Daniilidis

We propose a method for 3D shape reconstruction from unoriented point clouds. Our method consists of a novel SE(3)-equivariant coordinate-based network (TF-ONet), that parametrizes the occupancy field of the shape and respects the inherent symmetries of the problem. In contrast to previous shape reconstruction methods that align the input to a regular grid, we operate directly on the irregular point cloud. Our architecture leverages equivariant attention layers that operate on local tokens. This mechanism enables local shape modelling, a crucial property for scalability to large scenes. Given an unoriented, sparse, noisy point cloud as input, we produce equivariant features for each point. These serve as keys and values for the subsequent equivariant cross-attention blocks that parametrize the occupancy field. By querying an arbitrary point in space, we predict its occupancy score. We show that our method outperforms previous SO(3)-equivariant methods, as well as non-equivariant methods trained on SO(3)-augmented datasets. More importantly, local modelling together with SE(3)-equivariance create an ideal setting for SE(3) scene reconstruction. We show that by training only on single, aligned objects and without any pre-segmentation, we can reconstruct novel scenes containing arbitrarily many objects in random poses without any performance loss.

****

PBES: PCA Based Exemplar Sampling Algorithm for Continual Learning

Sahil Nokhwal,Nirman Kumar

Traditional machine learning is both data and computation intensive. The most powerful models require huge quantities of data to train and the training is highly time-consuming. In the streaming or incremental model of machine learning, the data is received and processed in a streaming manner, i.e., the entire data stream is not stored, and the models are updated incrementally. While this is closer to the learning process of humans, a common problem associated with this is “catastrophic forgetting” (CF), i.e., because the entire data is not stored, but just a sketch of it, as more and more data arrives, the older data has invariably a smaller representation in the stored sketch, and this causes models to perform badly on tasks that are closer to older data. One of the approaches to solve this problem stores an “exemplar set” of data items from the stream – but this raises the central question: how to choose which items to store? Current approaches to solve this are based on herding, which is a way to select a random looking sample by a deterministic algorithm. We propose a novel selection approach based on Principal Component analysis and median sampling. This approach avoids the pitfalls due to outliers and is both simple to implement and use across various incremental machine learning models. It also has independent usage as a sampling algorithm. We achieve better performance compared to state-of-the-art methods.

****

3D-IntPhys: Learning 3D Visual Intuitive Physics for Fluids, Rigid Bodies, and Granular Materials

Haotian Xue,Antonio Torralba,Daniel LK Yamins,Joshua B. Tenenbaum,Yunzhu Li,Hsiao-Yu Tung

Given a visual scene, humans have strong intuitions about how a scene can evolve over time under given actions. The intuition, often termed visual intuitive physics, is a critical ability that allows us to make effective plans to manipulate the scene to achieve desired outcomes without relying on extensive trial and error. In this paper, we present a framework capable of learning 3D-grounded visual intuitive physics models purely from unlabeled images. Our method is composed of a conditional Neural Radiance Field (NeRF)-style visual frontend and a 3D point-based dynamics prediction backend, in which we impose strong relational and structural inductive bias to capture the structure of the underlying environment. Unlike existing intuitive point-based dynamics works that rely on the supervision of dense point trajectory from simulators, we relax the requirements and only assume access to multi-view RGB images and (imperfect) instance masks. This enables the proposed model to handle scenarios where accurate point estimation and tracking are hard or impossible. We evaluate the models on three challenging scenarios involving fluid, granular materials, and rigid objects, where standard detection and tracking methods are not applicable. We show our model can make long-horizon future predictions by learning from raw images and significantly outperforms models that do not employ an explicit 3D representation space. We also show that, once trained, our model can achieve strong generalization in complex scenarios under extrapolate settings.

Continual Learning of Language Models

Zixuan Ke,Yijia Shao,Haowei Lin,Tatsuya Konishi,Gyuhak Kim,Bing Liu

Language models (LMs) have been instrumental for the rapid advance of natural language processing. This paper studies continual learning of LMs, in particular, continual domain-adaptive pre-training (or continual DAP-training). Existing research has shown that further pre-training an LM using a domain corpus to adapt the LM to the domain can improve the end-task performance in the domain. This paper proposes a novel method to continually DAP-train an LM with a sequence of unlabeled domain corpora to adapt the LM to these domains to improve their endtask performances. The key novelty of our method is a soft-masking mechanism that directly controls the update to the LM. A novel proxy is also proposed to preserve the general knowledge in the original LM. Additionally, it contrasts the representations of the previously learned domain knowledge (including the general knowledge in the pre-trained LM) and the knowledge from the current full network to a

chieve knowledge integration. The method not only overcomes catastrophic forgetting, but also achieves knowledge transfer to improve end-task performances. Empirical evaluation demonstrates the effectiveness of the proposed method.

Min-Max Multi-objective Bilevel Optimization with Applications in Robust Machine Learning

Alex Gu,Songtao Lu,Parikshit Ram,Tsui-Wei Weng

We consider a generic min-max multi-objective bilevel optimization problem with applications in robust machine learning such as representation learning and hyperparameter optimization. We design MORBiT, a novel single-loop gradient descent-ascent bilevel optimization algorithm, to solve the generic problem and present a novel analysis showing that MORBiT converges to the first-order stationary point at a rate of $\widetilde{\mathcal{O}}(n^{1/2} K^{-2/5})$ for a class of weakly convex problems with n objectives upon K iterations of the algorithm. Our analysis utilizes novel results to handle the non-smooth min-max multi-objective setup and to obtain a sublinear dependence in the number of objectives n. Experimental results on robust representation learning and robust hyperparameter optimization showcase (i) the advantages of considering the min-max multi-objective setup, and (ii) convergence properties of the proposed \morbit.

The Plug and Play of Language Models for Text-to-image Generation

Can Qin,Ning Yu,Chen Xing,Shu Zhang,Stefano Ermon,Yun Fu,Caiming Xiong,Ran Xu

Text-to-image (T2I) models enable controllable image generation through user-provided captions. A text encoder is typically used to map captions to a latent space, and it has been shown to be critical for model's performance. However, replacing or upgrading the text encoder in a T2I model is challenging due to the tight bond between the current encoder and the image decoder. It requires training the model from scratch, which can be prohibitively expensive. To address this problem, we introduce a more efficient approach to align a pre-trained language model with the latent space of an existing T2I model. We propose a Model Translation Network (MTN) and a new training objective to align the representation spaces of the two text encoders using only a corpus of unlabeled text. We empirically find that MTN can be trained efficiently and can boost the performance of existing T2I models by upgrading their text encoder. Moreover, we find that MTN can align multilingual language models such as XLM-Roberta, thus allowing existing T2I models to generate high-quality images from captions beyond English.
****

Learning Arborescence with An Efficient Inference Algorithm

Nan Jiang,Maxwell J Jacobson,Yexiang Xue

We consider a class of structured learning problems on arborescence (i.e., the directed spanning tree) from the input graph. The key step involved in this problem is predicting the minimal weight arborescence (MWA) from the learned model. In literature, there are two lines of research for predicting MWA: the Chu-Liu Edmonds (CLE) and the Lovasz methods. The CLE method is easy to implement while it takes $\mathcal{O}(n)$ cycle contractions. Here n is the graph size. The Lovasz method reduces to the multi-pair shortest path (MPSP) problem and takes only $\mathcal{O}(\log n)$ contractions. Nevertheless, in the CPU setting, MPSP has the same time complexity as finding MWA. The Lovasz method only attains time efficiency under a sufficient GPU setting. Both the aforementioned methods are painfully slow for large-scale learning tasks. In this research, we find the general MPSP problem can be simplified when working with machine learning models. This is because the learning model predicts edge weights for all pairs of vertices and the graph we process is always complete. Therefore, we only need to handle those paths that directly enter every weakly connected component (WCC) while the classic Lovasz method needs to handle all possible paths. This allows us to propose LAzy LoVAz (Lava) method that enjoys $\mathcal{O}(\log n)$ contractions as well as efficient performance in both CPU and GPU settings. In experiments, we consider synthetic datasets and two real-world learning tasks, i.e., graph-based dependency parsing and unsupervised parsing on ListOps. The empirical results exhibit important gains of our Lava method to the classic CLE and Lovasz methods,

that Lava boosts the training time for arborescence learning tasks.

Towards Understanding Ensemble, Knowledge Distillation and Self-Distillation in Deep Learning
Zeyuan Allen-Zhu,Yuanzhi Li
We formally study how \emph{ensemble} of deep learning models can improve test accuracy, and how the superior performance of ensemble can be distilled into a single model using \emph{knowledge distillation}. We consider the challenging case where the ensemble is simply an average of the outputs of a few independently trained neural networks with the \emph{same} architecture, trained using the \emph{same} algorithm on the \emph{same} data set, and they only differ by the random seeds used in the initialization.

We show that ensemble/knowledge distillation in \emph{deep learning} works very differently from traditional learning theory (such as boosting or NTKs). We develop a theory showing that when data has a structure we refer to as ``multi-view'', then ensemble of independently trained neural networks can provably improve test accuracy, and such superior test accuracy can also be provably distilled into a single model. Our result sheds light on how ensemble works in deep learning in a way that is completely different from traditional theorems, and how the ``dark knowledge'' is hidden in the outputs of the ensemble and can be used in distillation.

A Score-Based Model for Learning Neural Wavefunctions
Xuan Zhang,Shenglong Xu,Shuiwang Ji
Quantum Monte Carlo coupled with neural network wavefunctions has shown success in finding the ground state of quantum many-body systems. The existing optimization approaches compute the energy by sampling local energy from an explicit probability distribution given by the wavefunction. In this work, we provide a new optimization framework for obtaining properties of quantum many-body ground state using score-based neural networks. This new framework does not require explicit probability distribution and performs the sampling via Langevin dynamics. Our method is based on the key observation that the local energy is directly related to the score, defined as the gradient of the logarithmic wavefunction. Inspired by the score matching and the diffusion Monte Carlo methods, we derive a weighted score matching objective, which guides our score-based models to correctly converge to the ground state. We first validate our approach with experiments on quantum harmonic traps, and further results show that it can accurately learn the ground states of atomic systems. By implicitly modeling the high-dimensional data distribution, our work paves the way toward a more efficient representation of quantum systems.

Benchmarking Algorithms for Domain Generalization in Federated Learning
Ruqi Bai,Saurabh Bagchi,David I. Inouye
In this paper, we present a unified platform to study domain generalization in the federated learning (FL) context and conduct extensive empirical evaluations of the current state-of-the-art domain generalization algorithms adapted to FL. In particular, we perform a fair comparison of nine existing algorithms in solving domain generalization {either centralized domain generalization algorithms adapted to the FL context or existing FL domain generalization algorithms } to comprehensively explore the challenges introduced by FL. These challenges include statistical heterogeneity among clients, the number of clients, the number of communication rounds, etc. The evaluations are conducted on three diverse datasets including PACS (image dataset covering photo, sketch, cartoon, and painting domains), iWildCam (image dataset with 323 domains), and Py150 (natural language processing dataset with 8421 domains). The experiments show that the challenges brought by federated learning stay unsolved in the realistic experiment setting. Furthermore, the code base supports fair and reproducible new algorithm evaluation with easy implementation.

The Vendi Score: A Diversity Evaluation Metric for Machine Learning

Dan Friedman,Adji Bousso Dieng

Diversity is an important criterion for many areas of machine learning (ML), including generative modeling and dataset curation. Yet little work has gone into understanding, formalizing, and measuring diversity in ML. In this paper we address the diversity evaluation problem by proposing the Vendi Score, which connects and extends ideas from ecology and quantum statistical mechanics to ML. The Vendi Score is defined as the exponential of the Shannon entropy of the eigenvalues of a similarity matrix. This matrix is induced by a user-defined similarity function applied to the sample to be evaluated for diversity. In taking a similarity function as input, the Vendi Score enables its user to specify any desired form of diversity. Importantly, unlike many existing metrics in ML, the Vendi Score doesn’t require a reference dataset or distribution over samples or labels, it is therefore general and applicable to any generative model, decoding algorithm, and dataset from any domain where similarity can be defined. We showcase the Vendi Score on molecular generative modeling where we found it addresses shortcomings of the current diversity metric of choice in that domain. We also applied the Vendi Score to generative models of images and decoding algorithms of text where we found it confirms known results about diversity in those domains. Furthermore, we used the Vendi Score to measure mode collapse, a known shortcoming of generative adversarial networks (GANs). In particular, the Vendi Score revealed that even GANs that capture all the modes of a labelled dataset can be less diverse than the original dataset. Finally, the interpretability of the Vendi Score allowed us to diagnose several benchmark ML datasets for diversity, opening the door for diversity-informed data augmentation

Forward Super-Resolution: How Can GANs Learn Hierarchical Generative Models for Real-World Distributions

Zeyuan Allen-Zhu,Yuanzhi Li

Generative adversarial networks (GANs) are among the most successful models for learning high-complexity, real-world distributions. However, in theory, due to the highly non-convex, non-concave landscape of the minmax training objective, GAN remains one of the least understood deep learning models. In this work, we formally study how GANs can efficiently learn certain hierarchically generated distributions that are close to the distribution of real-life images. We prove that when a distribution has a structure that we refer to as \emph{forward super-resolution}, then simply training generative adversarial networks using stochastic gradient descent ascent (SGDA) can learn this distribution efficiently, both in sample and time complexities.

We also provide empirical evidence that our assumption ``forward super-resolution'' is very natural in practice, and the underlying learning mechanisms that we study in this paper (to allow us efficiently train GAN via GDA in theory) simulates the actual learning process of GANs on real-world problems.

Spotlight: Mobile UI Understanding using Vision-Language Models with a Focus

Gang Li,Yang Li

Mobile UI understanding is important for enabling various interaction tasks such as UI automation and accessibility. Previous mobile UI modeling often depends on the view hierarchy information of a screen, which directly provides the structural data of the UI, with the hope to bypass challenging tasks of visual modeling from screen pixels. However, view hierarchies are not always available, and are often corrupted with missing object descriptions or misaligned structure information. As a result, despite the use of view hierarchies could offer short-term gains, it may ultimately hinder the applicability and performance of the model. In this paper, we propose Spotlight, a vision-only approach for mobile UI understanding. Specifically, we enhance a vision-language model that only takes the screenshot of the UI and a region of interest on the screen---the focus---as the input. This general architecture of Spotlight is easily scalable and capable of performing a range of UI modeling tasks. Our experiments show that our model esta

blishes SoTA results on several representative UI tasks and outperforms previous methods that use both screenshots and view hierarchies as inputs. Furthermore, we explore multi-task learning and few-shot prompting capacities of the proposed models, demonstrating promising results in the multi-task learning direction.

A Control-Centric Benchmark for Video Prediction
Stephen Tian,Chelsea Finn,Jiajun Wu

Video is a promising source of knowledge for embodied agents to learn models of the world's dynamics. Large deep networks have become increasingly effective at modeling complex video data in a self-supervised manner, as evaluated by metrics based on human perceptual similarity or pixel-wise comparison. However, it remains unclear whether current metrics are accurate indicators of performance on downstream tasks. We find empirically that for planning robotic manipulation, existing metrics can be unreliable at predicting execution success. To address this, we propose a benchmark for action-conditioned video prediction in the form of a control benchmark that evaluates a given model for simulated robotic manipulation through sampling-based planning. Our benchmark, Video Prediction for Visual Planning (VP^2), includes simulated environments with 11 task categories and 310 task instance definitions, a full planning implementation, and training datasets containing scripted interaction trajectories for each task category. A central design goal of our benchmark is to expose a simple interface -- a single forward prediction call -- so it is straightforward to evaluate almost any action-conditioned video prediction model. We then leverage our benchmark to study the effects of scaling model size, quantity of training data, and model ensembling by analyzing five highly-performant video prediction models, finding that while scale can improve perceptual quality when modelling visually diverse settings, other attributes such as uncertainty awareness can also aid planning performance.

Continual Learning Based on Sub-Networks and Task Similarity
Zixuan Ke,Bing Liu,Wenhan Xiong,Asli Celikyilmaz,Haoran Li

Continual learning (CL) has two main objectives: preventing catastrophic forgetting (CF) and encouraging knowledge transfer (KT) across tasks. The existing literature mainly tries to overcome CF. Although some papers have focused on both CF and KT, they may still suffer from CF because of their ineffective handling of previous tasks and/or poor task similarity detection mechanisms to achieve KT. This work presents a new CL method that addresses the above issues. First, it overcomes CF by isolating the knowledge of each task via a learned mask that indicates a sub-network. Second, it proposes a novel technique to compute how important each mask is to the new task, which indicates how the new task is similar to an underlying old task. Similar tasks can share the same mask/subnetwork for KT, while dissimilar tasks use different masks/sub-networks for CF prevention. Comprehensive experiments have been conducted using a range of NLP problems, including classification, generation, and extraction to show that the proposed method consistently outperforms prior state-of-the-art baselines.

A Stable and Scalable Method for Solving Initial Value PDEs with Neural Networks
Marc Anton Finzi,Andres Potapczynski,Matthew Choptuik,Andrew Gordon Wilson

Unlike conventional grid and mesh based methods for solving partial differential equations (PDEs), neural networks have the potential to break the curse of dimensionality, providing approximate solutions to problems where using classical solvers is difficult or impossible. While global minimization of the PDE residual over the network parameters works well for boundary value problems, catastrophic forgetting impairs applicability to initial value problems (IVPs). In an alternative local-in-time approach, the optimization problem can be converted into an ordinary differential equation (ODE) on the network parameters and the solution propagated forward in time; however, we demonstrate that current methods based on this approach suffer from two key issues. First, following the ODE produces an uncontrolled growth in the conditioning of the problem, ultimately leading to unacceptably large numerical errors. Second, as the ODE methods scale cubically w ith the number of model parameters, they are restricted to small neural networks, significantly limiting their ability to represent intricate PDE initial conditions and solutions. Building on these insights, we develop Neural-IVP, an ODE based IVP solver which prevents the network from getting ill-conditioned and runs in time linear in the number of parameters, enabling us to evolve the dynamics of challenging PDEs with neural networks.

Shallow Learning In Materio.

Celestine Preetham Lawrence

We introduce Shallow Learning In Materio (SLIM) as a resource-efficient method to realize closed-loop higher-order perceptrons. Our SLIM method provides a rebuttal to the Minsky school's disputes with the Rosenblatt school about the efficacy of learning representations in shallow perceptrons. As a proof-of-concept, here we devise a physically-scalable realization of the parity function. Our findings are relevant to artificial intelligence engineers, as well as neuroscientists and biologists.

Data Subset Selection via Machine Teaching

Stephen Mussmann,Alex Fang,Ludwig Schmidt,Kevin Jamieson

We study the problem of data subset selection: given a fully labeled dataset and a training procedure, select a subset such that training on that subset yields approximately the same test performance as training on the full dataset. We propose an algorithm, inspired by recent work in machine teaching, that has theoretical guarantees, compelling empirical performance, and is model-agnostic meaning the algorithm's only information comes from the predictions of models trained on subsets. Furthermore, we prove lower bounds that show that our algorithm achieves a subset with near-optimal size (under computational hardness assumptions) while training on a number of subsets that is optimal up to extraneous log factors. We then empirically compare our algorithm, machine teaching algorithms, and coreset techniques on six common image datasets with convolutional neural networks. We find that our machine teaching algorithm can find a subset of CIFAR10 of size less than 16k that yields the same performance (5-6% error) as training on the full dataset of size 50k.

Do Summarization Models Synthesize?

Jay DeYoung,Iain James Marshall,Byron C Wallace

Multi-document summarization entails producing concise synopses of collections of inputs. For some applications, the synopsis should accurately \emph{synthesize} inputs with respect to a key property or aspect. For example, a synopsis of film reviews all written about a particular movie should reflect the average critic consensus. As a more consequential example, consider narrative summaries that accompany biomedical \emph{systematic reviews} of clinical trial results. These narratives should fairly summarize the potentially conflicting results from individual trials.

In this paper we ask: To what extent do modern multi-document summarization models implicitly perform this type of synthesis? To assess this we perform a suite of experiments that probe the degree to which conditional generation models trained for summarization using standard methods yield outputs that appropriately synthesize inputs. We find that existing models do partially perform synthesis, but do so imperfectly. In particular, they are over-sensitive to changes in input ordering and under-sensitive to changes in input compositions (e.g., the ratio of positive to negative movie reviews). We propose a simple, general method for improving model synthesis capabilities by generating an explicitly diverse set of candidate outputs, and then selecting from these the string best aligned with the expected aggregate measure for the inputs, or \emph{abstaining} when the model produces no good candidate. This approach improves model synthesis performance. Our hope is that by highlighting the need for synthesis (in some summarization settings), this work motivates further research into multi-document summarization methods and learning objectives that explicitly account for the need to synt

hesize.

CHiLS: Zero-Shot Image Classification with Hierarchical Label Sets
Zachary Novack,Saurabh Garg,Zachary Chase Lipton
Open vocabulary models (e.g. CLIP) have shown strong performance on zeroshot classification through their ability generate embeddings for each class based on their (natural language) names. Prior work has focused on improving the accuracy of these models through prompt engineering or by incorporating a small amount of labeled downstream data (via finetuning). In this paper, we propose Classification with Hierarchical Label Sets (or CHiLS), an alternative strategy that proceeds in three steps: (i) for each class, produce a set of subclasses, using either existing label hierarchies or by querying GPT-3; (ii) perform the standard zero-shot CLIP procedure as though these subclasses were the labels of interest; (iii) map the predicted subclass back to its parent to produce the final prediction. Across numerous datasets, CHiLS leads to improved accuracy yielding gains of over 30% in situations where known hierarchies are available and more modest gains when they are not. CHiLS is simple to implement within existing CLIP pipelines and requires no additional training cost.

Multi-Grid Tensorized Fourier Neural Operator for High Resolution PDEs
Jean Kossaifi,Nikola Borislavov Kovachki,Kamyar Azizzadenesheli,Anima Anandkumar
Memory complexity and data scarcity are two main pressing challenges in learning solution operators of partial differential equations (PDE) at high resolutions. These challenges limited prior neural operator modelsMemory complexity and data scarcity are two main pressing challenges in learning solution operators of partial differential equations (PDE) at high resolutions. These challenges limited prior neural operator modelsMemory complexity and data scarcity are two main pressing challenges in learning solution operators of partial differential equations (PDE) at high resolutions. These challenges limited prior neural operator models to low/mid-resolution problems rather than full scale real-world problems. Yet, these problems possess spatially local structures that is not used by previous approaches. We propose to exploit this natural structure of real-world phenomena to predict solutions locally and unite them into a global solution. Specifically, we introduce a neural operator that scales to large resolutions by leveraging local and global structures through decomposition of both the input domain and the operator's parameter space. It consists of a multi-grid tensorized neural operator (MG-TFNO), a new data efficient and highly parallelizable operator learning approach with reduced memory requirement and better generalization. MG-TFNO employs a novel multi-grid based domain decomposition approach to exploit the spatially local structure in the data. Using the FNO as a backbone, its parameters are represented in a high-order latent subspace of the Fourier domain, through a global tensor factorization, resulting in an extreme reduction in the number of parameters and improved generalization. In addition, the low-rank regularization it applies to the parameters enables efficient learning in low-data regimes, which is particularly relevant for solving PDEs where obtaining ground-truth predictions is extremely costly and samples, therefore, are limited. We empirically verify the efficiency of our method on the turbulent Navier-Stokes equations where we demonstrate superior performance, with 2.5 times lower error, 10X compression of the model parameters, and 1.8X compression of the input domain size. Our tensorization approach yields up to 400x reduction in the number of parameter without loss in accuracy. Similarly, our domain decomposition method gives a 7x reduction in the domain size while slightly improving accuracy. Furthermore, our method can be trained with much fewer samples than previous approaches, outperforming the FNO when trained with just half the samples.

β-Stochastic Sign SGD: A Byzantine Resilient and Differentially Private Gradient Compressor for Federated Learning
Ming Xiang,Lili Su
Federated Learning (FL) is a nascent privacy-preserving learning framework under which the local data of participating clients is kept locally throughout model

training. Scarce communication resources and data heterogeneity are two defining characteristics of FL. Besides, a FL system is often implemented in a harsh environment -- leaving the clients vulnerable to Byzantine attacks. To the best of our knowledge, no gradient compressors simultaneously achieve quantitative Byzantine resilience and privacy preservation. In this paper, we fill this gap via revisiting the stochastic sign SGD \cite{Jin2020}. We propose β-stochastic sign SGD, which contains a gradient compressor that encodes a client's gradient information in sign bits subject to the privacy budget $\beta>0$. We show that as long as $\beta>0$, β-stochastic sign SGD converges in the presence of partial client participation and mobile Byzantine faults, showing that it achieves quantifiable Byzantine-resilience and differential privacy simultaneously. In sharp contrast, when $\beta=0$, the compressor is not differentially private. Notably, for the special case when each of the stochastic gradients involved is bounded with known bounds, our gradient compressor with $\beta=0$ coincides with the compressor proposed in \cite{Jin2020}. As a byproduct, we show that when the clients report sign messages, the popular information aggregation rules simple mean, trimmed mean, median and majority vote are identical in terms of the output signs. Our theories are corroborated by experiments on MNIST and CIFAR-10 datasets.

Sequential Brick Assembly with Efficient Constraint Satisfaction

Seokjun Ahn,Jungtaek Kim,Minsu Cho,Jaesik Park

We address the problem of generating a sequence of LEGO brick assembly with high-fidelity structures, satisfying physical constraints between bricks. The assembly problem is challenging since the number of possible structures increases exponentially with the number of available bricks, complicating the physical constraints to satisfy across bricks. To tackle this problem, our method performs a brick structure assessment to predict the next brick position and its confidence by employing a U-shaped sparse 3D convolutional network. The convolution filter efficiently validates physical constraints in a parallelizable and scalable manner, allowing to process of different brick types. To generate a novel structure, we devise a sampling strategy to determine the next brick position by considering attachable positions under physical constraints. Instead of using handcrafted brick assembly datasets, our model is trained with a large number of 3D objects that allow to create a new high-fidelity structure. We demonstrate that our method successfully generates diverse brick structures while handling two different brick types and outperforms existing methods based on Bayesian optimization, graph generative model, and reinforcement learning, all of which are limited to a single brick type.

Data-Efficient Finetuning Using Cross-Task Nearest Neighbors

Hamish Ivison,Noah A. Smith,Hannaneh Hajishirzi,Pradeep Dasigi

Language models trained on massive prompted multitask datasets like T0 (Sanh et al., 2021) or FLAN (Wei et al., 2021) can generalize to tasks unseen during training. We show that training on a carefully chosen subset of instances can outperform training on all available data on a variety of datasets. We assume access to a small number (250-1000) of unlabeled target task instances, select their nearest neighbors from a pool of multitask data, and use the retrieved data to train target task specific models. Our method is more data-efficient than training a single multitask model, while still outperforming it by large margins. We evaluate across a diverse set of tasks not in the multitask pool we retrieve from, including those used to evaluate T0 and in addition, more complex tasks including legal and scientific document QA. We retrieve small subsets of P3 (the collection of prompted datasets from which T0’s training data was sampled) and finetune T5 models that outperform the 3-billion parameter variant of T0 (T0-3B) by 8-30% on 11 out of 12 evaluation datasets while using at most 2% of the data used to train T0-3B. These models also provide a better initialization than T0-3B for few-shot finetuning on target-task data, as shown by a 3-23% relative improvement over few-shot finetuned T0-3B models on 8 datasets.

Noise Is Not the Main Factor Behind the Gap Between Sgd and Adam on Transformers, But Sign Descent Might Be

Frederik Kunstner,Jacques Chen,Jonathan Wilder Lavington,Mark Schmidt

The success of the Adam optimizer on a wide array of architectures has made it the default in settings where stochastic gradient descent (SGD) performs poorly. However, our theoretical understanding of this discrepancy is lagging, preventing the development of significant improvements on either algorithm. Recent work advances the hypothesis that Adam and other heuristics like gradient clipping outperform SGD on language tasks because the distribution of the error induced by sampling has heavy tails. This suggests that Adam outperform SGD because it uses a more robust gradient estimate. We evaluate this hypothesis by varying the batch size, up to the entire dataset, to control for stochasticity. We present evidence that stochasticity and heavy-tailed noise are not major factors in the performance gap between SGD and Adam. Rather, Adam performs better as the batch size increases, while SGD is less effective at taking advantage of the reduction in noise. This raises the question as to why Adam outperforms SGD in the full-batch setting. Through further investigation of simpler variants of SGD, we find that the behavior of Adam with large batches is similar to sign descent with momentum.

BiAdam: Fast Adaptive Bilevel Optimization Methods

Feihu Huang,Junyi Li,Shangqian Gao

Bilevel optimization recently has attracted increased interest in machine learning due to its many applications such as hyper-parameter optimization and mate learning. Although many bilevel optimization methods recently have been proposed, these methods do not consider using adaptive learning rates. It is well known that adaptive learning rates can accelerate many optimization algorithms including (stochastic) gradient-based algorithms. To fill this gap, in the paper, we propose a novel fast adaptive bilevel framework for solving bilevel optimization problems that the outer problem is possibly nonconvex and the inner problem is strongly convex. Our framework uses unified adaptive matrices including many types of adaptive learning rates, and can flexibly use the momentum and variance reduced techniques. In particular, we provide a useful convergence analysis framework for the bilevel optimization. Specifically, we propose a fast single-loop adaptive bilevel optimization (BiAdam) algorithm based on the basic momentum technique, which achieves a sample complexity of $\tilde{O}(\epsilon^{-4})$ for finding an ϵ-stationary point. Meanwhile, we propose an accelerated version of BiAdam algorithm (VR-BiAdam) by using variance reduced technique, which reaches the best known sample complexity of $\tilde{O}(\epsilon^{-3})$ without relying on large batch-size. To the best of our knowledge, we first study the adaptive bilevel optimization methods with adaptive learning rates. Some experimental results on data hyper-cleaning and hyper-representation learning tasks demonstrate the efficiency of the proposed algorithms.

Building Normalizing Flows with Stochastic Interpolants

Michael Samuel Albergo,Eric Vanden-Eijnden

A generative model based on a continuous-time normalizing flow between any pair of base and target probability densities is proposed. The velocity field of this flow is inferred from the probability current of a time-dependent density that interpolates between the base and the target in finite time. Unlike conventional normalizing flow inference methods based the maximum likelihood principle, which require costly backpropagation through ODE solvers, our interpolant approach leads to a simple quadratic loss for the velocity itself which is expressed in terms of expectations that are readily amenable to empirical estimation. The flow can be used to generate samples from either the base or target, and to estimate the likelihood at any time along the interpolant. In addition, the flow can be optimized to minimize the path length of the interpolant density, thereby paving the way for building optimal transport maps. In situations where the base is a Gaussian density, we also show that the velocity of our normalizing flow can also be used to construct a diffusion model to sample the target as well as estimate its score. However, our approach shows that we can bypass this diffusion completely and work at the level of the probability flow with greater simplicity, opening an avenue for methods based solely on ordinary differential equations as an alternative to those based on stochastic differential equations. Benchmarking on density estimation tasks illustrates that the learned flow can match and surpass conventional continuous flows at a fraction of the cost, and compares well with diffusions on image generation on CIFAR-10 and ImageNet 32×32. The method scales ab-initio ODE flows to previously unreachable image resolutions, demonstrated up to 128×128.

Elicitation Inference Optimization for Multi-Principal-Agent Alignment

Andrew Konya,Yeping Lina Qiu,Michael P Varga,Aviv Ovadya

In multi-principal-agent alignment scenarios spanning governance, markets, diplomacy, and AI, it is infeasible to elicit every principal's view on all perspectives relevant to agent decisions. Elicitation inference optimization (EIO) aims to minimize the n elicitations needed to approximate N principal's views across K perspectives. In this work, we demonstrate an EIO approach where data efficiency (NK/n) increases with scale. We introduce STUMP: an elicitation inference model which integrates an LLM with a latent factor model to enable learning transfer across samples, contexts, and languages. Then, we characterize STUMP's performance on a set of elicitation primitives from which scalable elicitation (sampling) protocols can be constructed. Building from these results, we design and demonstrate two scalable elicitation protocols for STUMP where data efficiency grows boundlessly, scaling like $O(n)$ in the number of elicitations n. This makes it possible to obtain complex, high-dimensional preference signals spanning principal populations at any scale.

****

Dual Student Networks for Data-Free Model Stealing

James Beetham,Navid Kardan,Ajmal Saeed Mian,Mubarak Shah

Data-free model stealing aims to replicate a target model without direct access to either the training data or the target model. To accomplish this, existing methods use a generator to produce samples in order to train a student model to match the target model outputs. To this end, the two main challenges are estimating gradients of the target model without access to its parameters, and generating a diverse set of training samples that thoroughly explores the input space. We propose a Dual Student method where two students are symmetrically trained in order to provide the generator a criterion to generate samples that the two students disagree on. On one hand, disagreement on a sample implies at least one student has classified the sample incorrectly when compared to the target model. This incentive towards disagreement implicitly encourages the generator to explore more diverse regions of the input space. On the other hand, our method utilizes gradients of student models to indirectly estimate gradients of the target model. We show that this novel training objective for the generator network is equivalent to optimizing a lower bound on the generator's loss if we had access to the target model gradients. In other words, our method alters the standard data-free model stealing paradigm by substituting the target model with a separate student model, thereby creating a lower bound which can be directly optimized without additional target model queries or separate synthetic datasets. We show that our new optimization framework provides more accurate gradient estimation of the target model and better accuracies on benchmark classification datasets. Additionally, our approach balances improved query efficiency with training computation cost. Finally, we demonstrate that our method serves as a better proxy model for transfer-based adversarial attacks than existing data-free model stealing methods.

Augmentation Curriculum Learning For Generalization in RL

Dylan Yung,Andrew Szot,Prithvijit Chattopadhyay,Judy Hoffman,Zsolt Kira

Many Reinforcement Learning tasks rely solely on pixel-based observations of the environment. During deployment, these observations can fall victim to visual perturbations and distortions, causing the agent’s policy to significantly degra

de
in performance. This motivates the need for robust agents that can generalize in the face of visual distribution shift. One common technique for doing this is to apply augmentations during training; however, it comes at the cost of performance. We propose Augmentation Curriculum Learning a novel curriculum learning approach that schedules augmentation into training into a weak augmentation phase and strong augmentation phase. We also introduce a novel visual augmentation strategy that proves to aid in the benchmarks we evaluate on. Our method achieves state-of-the-art performance on Deep Mind Control Generalization Benchmark.
****

Composite Slice Transformer: An Efficient Transformer with Composition of Multi-Scale Multi-Range Attentions
Mingu Lee,Saurabh Pitre,Tianyu Jiang,Pierre-David Letourneau,Matthew J Morse,Kanghwan Jang,Joseph Soriaga,Parham Noorzad,Hsin-Pai Cheng,Christopher Lott
Since the introduction of Transformers, researchers have tackled the notoriously expensive quadratic complexity problem. While significant computational efficiency improvements have been achieved, they come at the cost of reduced accuracy trade-offs. In this paper, we propose Composite Slice Transformer (CST), a Transformer-based network equipped with a composition of multi-scale multi-range attentions, boosting both efficiency and modeling capability.
After stacking fixed-length slices of the input sequence, each layer in CST performs a pair of fine-and-coarse-grained attentions with short-long ranges in a sequential manner, coupled with volatile instant positional embedding, enabling efficient token interactions {\em and} improving expressiveness of the model.
In addition to significantly reduced $O(NL+N^2/L^2)$ complexity for sequence length N and slice length L, CST achieves superior performance on a variety of tasks. We show that CST surpasses recently published efficient Transformers on the Long Range Arena benchmark, demonstrating the bidirectional long-range dependency modeling capability of our model. It outperforms the standard Transformer by a margin of 6.9\% in average accuracy across the five classification tasks of the benchmark, while being of complexity comparable to other efficient transformers. Furthermore, on the word-level autoregressive language modeling task with the WikiText-103 dataset, CST performs competitively against the Transformer model with only 2\% gap in the test perplexity while outperforming other efficient Transformers.
****

Graph Fourier MMD for signals on data graphs
Sam Leone,Alexander Tong,Guillaume Huguet,Guy Wolf,Smita Krishnaswamy
While numerous methods have been proposed for computing distances between probability distributions in Euclidean space, relatively little attention has been given to computing such distances for distributions on graphs. However, there has been a marked increase in data that either lies on graph (such as protein interaction networks) or can be modeled as a graph (single cell data), particularly in the biomedical sciences. Thus, it becomes important to find ways to compare signals defined on such graphs. Here, we propose Graph Fourier MMD (GFMMD), a novel a distance between distributions, or non-negative signals on graphs. GFMMD is defined via an optimal witness function that is both smooth on the graph and maximizes difference in expectation between the pair of distributions on the graph. We find an analytical solution to this optimization problem as well as an embedding of distributions that results from this method. We also prove several properties of this method including scale invariance and applicability to disconnected graphs. We showcase it on graph benchmark datasets as well on single cell RNA-sequencing data analysis. In the latter, we use the GFMMD-based gene embeddings to find meaningful gene clusters. We also propose a novel type of score for gene selection called {\em gene localization score} which helps select genes for cellular state space characterization.

Equal Improvability: A New Fairness Notion Considering the Long-term Impact

Ozgur Guldogan,Yuchen Zeng,Jy-yong Sohn,Ramtin Pedarsani,Kangwook Lee

Devising a fair classifier that does not discriminate against different groups is an important problem in machine learning. Although researchers have proposed various ways of defining group fairness, most of them only focused on the immediate fairness, ignoring the long-term impact of a fair classifier under the dynamic scenario where each individual can improve its feature over time. Such dynamic scenarios happen in real world, e.g., college admission and credit loaning, where each rejected sample makes effort to change its features to get accepted afterwards. In this dynamic setting, the long-term fairness should equalize the samples’ feature distribution across different groups after the rejected samples make some effort to improve. In order to promote long-term fairness, we propose a new fairness notion called Equal Improvability (EI), which equalizes the potential acceptance rate of the rejected samples across different groups assuming a bounded level of effort will be spent by each rejected sample. We analyze the properties of EI and its connections with existing fairness notions. To find a classifier that satisfies the EI requirement, we propose and study three different approaches that solve EI regularized optimization problems. Through experiments on both synthetic and real datasets, we demonstrate that the proposed EI-regularized algorithms encourage us to find a fair classifier in terms of EI. Finally, we provide experimental results on dynamic scenarios which highlight the advantages of our EI metric in achieving the long-term fairness. Codes are available in anonymous GitHub repository.

Does progress on ImageNet transfer to real world datasets?

Alex Fang,Simon Kornblith,Ludwig Schmidt

Does progress on ImageNet transfer to real world datasets? We investigate this question by evaluating ImageNet pre-trained models with varying accuracy (57% - 83%) on six practical image classification datasets. In particular, we study datasets collected with the goal of solving real world tasks (e.g., classifying images from camera traps or satellites), as opposed to web-scraped benchmarks collected for comparing models. On multiple datasets, models with higher ImageNet accuracy do not consistently yield performance improvements. For certain tasks, interventions such as data augmentation improve performance even when architectures do not. We hope that future benchmarks will include more diverse datasets to encourage a more comprehensive approach to improving learning algorithms.

****

Competitive Physics Informed Networks

Qi Zeng,Yash Kothari,Spencer H Bryngelson,Florian Tobias Schaefer

Neural networks can be trained to solve partial differential equations (PDEs) by using the PDE residual as the loss function. This strategy is called "physics-informed neural networks" (PINNs), but it currently cannot produce high-accuracy solutions, typically attaining about 0.1% relative error. We present an adversarial approach that overcomes this limitation, which we call competitive PINNs (CPINNs). CPINNs train a discriminator that is rewarded for predicting mistakes the PINN makes. The discriminator and PINN participate in a zero-sum game with the exact PDE solution as an optimal strategy. This approach avoids squaring the large condition numbers of PDE discretizations, which is the likely reason for failures of previous attempts to decrease PINN errors even on benign problems. Numerical experiments on a Poisson problem show that CPINNs achieve errors four orders of magnitude smaller than the best-performing PINN. We observe relative errors on the order of single-precision accuracy, consistently decreasing with each epoch. To the authors' knowledge, this is the first time this level of accuracy and convergence behavior has been achieved. Additional experiments on the nonlinear Schr{\"o}dinger, Burgers', and Allen--Cahn equation show that the benefits of CPINNs are not limited to linear problems.

Decomposed Prompting: A Modular Approach for Solving Complex Tasks

Tushar Khot,Harsh Trivedi,Matthew Finlayson,Yao Fu,Kyle Richardson,Peter Clark,Ashish Sabharwal

Few-shot prompting is a surprisingly powerful way to use Large Language Models (

LLMs) to solve various tasks. However, this approach struggles as the task complexity increases or when the individual reasoning steps of the task themselves are hard to learn, especially when embedded in more complex tasks. To address this, we propose Decomposed Prompting, a new approach to solve complex tasks by decomposing them (via prompting) into simpler sub-tasks that can be delegated to a library of prompting-based LLMs dedicated to these sub-tasks. This modular structure allows each prompt to be optimized for its specific sub-task, further decomposed if necessary, and even easily replaced with more effective prompts, trained models, or symbolic functions if desired.

We show that the flexibility and modularity of Decomposed Prompting allows it to outperform prior work on few-shot prompting using GPT3. On symbolic reasoning tasks, we can further decompose sub-tasks that are hard for LLMs into even simpler solvable sub-tasks. When the complexity comes from the input length, we can recursively decompose the task into the same task but with smaller inputs. We also evaluate our approach on textual multi-step reasoning tasks: on long-context multi-hop QA task, we can more effectively teach the sub-tasks via our separate sub-tasks prompts; and on open-domain multi-hop QA, we can incorporate a symbolic information retrieval within our decomposition framework, leading to improved performance on both tasks. Datasets, Code and Prompts available at https://github.com/allenai/DecomP.

Designing and Using Goal-Conditioned Tools

Ziang Liu,Stephen Tian,Michelle Guo,Karen Liu,Jiajun Wu

When limited by their own morphologies, humans and some species of animals have the remarkable ability to use objects from the environment towards accomplishing otherwise impossible tasks. Embodied agents might similarly unlock a range of additional capabilities through tool use. Recent techniques for jointly optimizing morphology and control via deep learning output effective solutions for tasks such as designing locomotion agents. But while designing a single-goal morphology makes sense for locomotion, manipulation involves a wide variety of strategies depending on the task goals at hand. An agent must be capable of rapidly prototyping specialized tools for different goals. Therefore, we propose the idea of learning a designer policy, rather than a single design. A designer policy is conditioned on task goals, and outputs a design for a tool that helps solve the task. A design-agnostic controller policy can then perform manipulation using these tools. In this work, we introduce a reinforcement learning framework for learning these policies. Through simulated manipulation tasks, we show that this framework is more sample efficient than black-box optimization methods in multi-goal settings. It can also perform zero-shot interpolation or finetuning to tackle previously unseen goals. Finally, we demonstrate that our framework allows tradeoffs between the complexity of design and control policies when required by practical constraints.

Post-mortem on a deep learning contest: a Simpson’s paradox and the complementary roles of scale metrics versus shape metrics

Michael W. Mahoney,charles h martin

To understand better good generalization performance in state-of-the-art neural network (NN) models, and in particular the success of the AlphaHat metric based on Heavy-Tailed Self-Regularization (HT-SR) theory, we analyze of a corpus of models that was made publicly-available for a contest to predict the generalization accuracy of NNs. These models include a wide range of qualities and were trained with a range of architectures and regularization hyperparameters. We break AlphaHat into its two subcomponent metrics: a scale-based metric; and a shape-based metric. We identify what amounts to a Simpson’s paradox: where “scale” metrics (from traditional statistical learning theory) perform well in aggregate, but can perform poorly on subpartitions of the data of a given depth, when regularization hyperparameters are varied; and where “shape” metrics (from HT-SR theory) perform well on each subpartition of the data, when hyperparameters are varied for models of a given depth, but can perform poorly overall when models with varying depths are aggregated. Our results highlight the subtlety of comparing models when both architectures and hyperparameters are varied; the complementary role of implicit scale versus implicit shape parameters in understanding NN model quality; and the need to go beyond one-size-fits-all metrics based on upper bounds from generalization theory to describe the performance of NN models. Our results also clarify further why the AlphaHat metric from HT-SR theory works so well at predicting generalization across a broad range of CV and NLP models.

ProtFIM: Fill-in-Middle Protein Sequence Design via Protein Language Models

Youhan Lee,Hasun Yu

Following the investigation that protein sequence determines its structure and function, engineering protein sequences allows us to optimize the functions of proteins for specific purposes such as enhancement of catalytic activity or binding affinity maturation. In protein engineering, there are many cases where the amino acids in the middle of a protein sequence are changed while maintaining the remaining residues to avoid unwanted functional changes from remaining residues. However, existing research on protein sequence design via protein language models (PLMs) has focused on modifying suffix residues by prompting prefix residues to the model or mutating the overall sequence residues. This is unsuitable for scenarios where the residues located in the middle of the sequence are to be optimized. In this work, we suggest a PLM-based framework to solve the fill-in-middle (FIM) protein engineering tasks. To evaluate the performance of PLMs on the FIM tasks, we design a novel evaluation scheme where PLMs are tasked to generate new sequences while maintaining the secondary structures. Also, we propose a new PROTein language model specialized for the Fill-In-Middle task, ProtFIM. Experiments confirm that ProtFIM performs FIM engineering efficiently, especially for alpha-helix structures, and provides decent protein representations of sequence-function relationships. Finally, we demonstrate an artificial protein sequence design framework composed of ProtFIM and a high-quality structure predictor as a novel tool to optimize protein sequences.

Beyond Deep Learning: An Evolutionary Feature Engineering Approach to Tabular Data Classification

Hengzhe Zhang,Qi Chen,Aimin Zhou,bing xue,Yan Wang,mengjie zhang

In recent years, deep learning has achieved impressive performance in the computer vision and natural language processing domains. In the tabular data classification scenario, with the emergence of the transformer architecture, a number of algorithms have been reported to yield better results than conventional tree-based models. Most of these methods attribute the success of deep learning methods to the expressive feature construction capability of neural networks. Nonetheless, in real practice, manually designed high-order features with traditional machine learning methods are still widely used because neural-network-based features can be easy to over-fitting. In this paper, we propose an evolution-based feature engineering algorithm to imitate the manual feature construction process through trial and improvement. Importantly, the evolutionary method provides an opportunity to optimize cross-validation loss, where gradient methods fail to do so. On a large-scale classification benchmark of 119 datasets, the experimental results demonstrate that the proposed method outperforms existing fine-tuned state-of-the-art tree-based and deep-learning-based classification algorithms.

Proportional Multicalibration

William La Cava,Elle Lett,Guangya Wan

Multicalibration is a desirable fairness criteria that constrains calibration error among flexibly-defined groups in the data while maintaining overall calibration. However, when outcome probabilities are correlated with group membership, multicalibrated models can exhibit a higher percent calibration error among groups with lower base rates than groups with higher base rates. As a result, it remains possible for a decision-maker to learn to trust or distrust model predictions for specific groups. To alleviate this, we propose proportional multicalibration, a criteria that constrains the percent calibration error among groups and within prediction bins. We prove that satisfying proportional multicalibration bou nds a model's multicalibration as well its differential calibration, a stronger fairness criteria inspired by the fairness notion of sufficiency. We provide an efficient algorithm for post-processing risk prediction models for proportional multicalibration and evaluate it empirically. We conduct simulation studies and investigate a real-world application of PMC-postprocessing to prediction of emergency department patient admissions. We observe that proportional multicalibration is a promising criteria for controlling simultenous measures of calibration fairness of a model over intersectional groups with virtually no cost in terms of classification performance.

On The Impact of Machine Learning Randomness on Group Fairness

Prakhar Ganesh,Hongyan Chang,Martin Strobel,Reza Shokri

Statistical measures for group fairness in machine learning reflect the gap in performance of algorithms across different groups. These measures, however, exhibit a high variance, between different training instances, that makes them unreliable for empirical evaluation of fairness. What is the cause of this variance, and how can we reduce it? We investigate the impact of different sources of randomness in machine learning on group fairness. We show that the variance in group fairness measures is mainly due to the high volatility of the learning process on under-represented groups, which itself is largely caused by the stochasticity of data order during training. Based on these findings, we show how to manipulate group level accuracy (i.e. model fairness), with high efficiency and negligible impact on the overall predictive power of the model, by changing the data order.

Using the Training History to Detect and Prevent Overfitting in Deep Learning Models

Hao Li,Gopi Krishnan Rajbahadur,Dayi Lin,Cor-Paul Bezemer,Zhen Jiang

Overfitting of deep learning models on training data leads to poor generalizability on unseen data. Overfitting can be (1) prevented (e.g., using dropout or early stopping) or (2) detected in a trained model (e.g., using correlation-based methods). We propose a method that can both detect and prevent overfitting based on the training history (i.e., validation losses). Our method first trains a time series classifier on training histories of overfit models. This classifier is then used to detect if a trained model is overfit. In addition, our trained classifier can be used to prevent overfitting by identifying the optimal point to stop a model's training. We evaluate our method on its ability to identify and prevent overfitting in real-world samples (collected from papers published in the last 5 years at top AI venues). We compare our method against correlation-based detection methods and the most commonly used prevention method (i.e., early stopping). Our method achieves an F1 score of 0.91 which is at least 5% higher than the current best-performing non-intrusive overfitting detection method. In addition, our method can find the optimal stopping point and avoid overfitting at least 32% earlier than early stopping and achieve at least the same accuracy (often better) as early stopping.

Multi-scale Sinusoidal Embeddings Enable Learning on High Resolution Mass Spectrometry Data

Gennady Voronov

Small molecules in biological samples are studied to provide information about disease states, environmental toxins, natural product drug discovery, and many other applications. The primary window into the composition of small molecule mixtures is tandem mass spectrometry (MS2), which produces data that are of high sensitivity and part per million resolution. We adopt multi-scale sinusoidal embeddings of the mass data in MS2 designed to meet the challenge of learning from the full resolution of MS2 data. Using these embeddings, we provide a new state of the art model for spectral library search, the standard task for initial evaluation of MS2 data. We also investigate the task of chemical property prediction from MS2 data, that has natural applications in high-throughput MS2 experiments and show that an average R^2 of 80\% for novel compounds can be achieved acros s 10 chemical properties prioritized by medicinal chemists. We use dimensionality reduction techniques and experiments with different floating point resolutions to show the essential role multi-scale sinusoidal embeddings play in learning from MS2 data.

Self-Ensemble Protection: Training Checkpoints Are Good Data Protectors

Sizhe Chen,Geng Yuan,Xinwen Cheng,Yifan Gong,Minghai Qin,Yanzhi Wang,Xiaolin Huang

As data becomes increasingly vital, a company would be very cautious about releasing data, because the competitors could use it to train high-performance models, thereby posing a tremendous threat to the company's commercial competence. To prevent training good models on the data, we could add imperceptible perturbations to it. Since such perturbations aim at hurting the entire training process, they should reflect the vulnerability of DNN training, rather than that of a single model. Based on this new idea, we seek perturbed examples that are always unrecognized (never correctly classified) in training. In this paper, we uncover them by model checkpoints' gradients, forming the proposed self-ensemble protection (SEP), which is very effective because (1) learning on examples ignored during normal training tends to yield DNNs ignoring normal examples; (2) checkpoints' cross-model gradients are close to orthogonal, meaning that they are as diverse as DNNs with different architectures. That is, our amazing performance of ensemble only requires the computation of training one model. By extensive experiments with 9 baselines on 3 datasets and 5 architectures, SEP is verified to be a new state-of-the-art, e.g., our small $\ell_\infty=2/255$ perturbations reduce the accuracy of a CIFAR-10 ResNet18 from 94.56% to 14.68%, compared to 41.35% by the best-known method. Code is available at https://github.com/Sizhe-Chen/SEP.

Efficient parametric approximations of neural net function space distance

Nikita Dhawan,Sicong Huang,Juhan Bae,Roger Baker Grosse

It is often useful to compactly summarize important properties of a training dataset so that they can be used later without storing and/or iterating over the entire dataset. We consider a specific case of this: approximating the function space distance (FSD) over the training set, i.e. the average distance between the outputs of two neural networks. We propose an efficient approximation to FSD for ReLU neural networks based on approximating the architecture as a linear network with stochastic gating. Despite requiring only one parameter per unit of the network, our approach outcompetes other parametric approximations with larger memory requirements. Applied to continual learning, our parametric approximation is competitive with state-of-the-art nonparametric approximations which require storing many training examples. Furthermore, we show its efficacy in influence function estimation, allowing influence functions to be accurately estimated without iterating over the full dataset.

Systematic Generalization and Emergent Structures in Transformers Trained on Structured Tasks

Yuxuan Li,James McClelland

Transformer networks have seen great success in natural language processing and machine vision, where task objectives such as next word prediction and image classification benefit from nuanced context sensitivity across high-dimensional inputs. However, there is an ongoing debate about how and when transformers can acquire highly structured behavior and achieve systematic generalization. Here, we explore how well a causal transformer can perform a set of algorithmic tasks, including copying, sorting, and hierarchical compositions of these operations. We demonstrate strong generalization to sequences longer than those used in training by replacing the standard positional encoding typically used in transformers with labels arbitrarily paired with items in the sequence. By finding the layer and head configuration sufficient to solve the task, then performing ablation experiments and representation analysis, we show that two-layer transformers learn generalizable solutions to multi-level problems and develop signs of systematic task decomposition. They also exploit shared computation across related tasks. T hese results provide key insights into how transformer models may be capable of decomposing complex decisions into reusable, multi-level policies in tasks requiring structured behavior.

Energy-Inspired Self-Supervised Pretraining for Vision Models

Ze Wang,Jiang Wang,Zicheng Liu,Qiang Qiu

Motivated by the fact that forward and backward passes of a deep network naturally form symmetric mappings between input and output representations, we introduce a simple yet effective self-supervised vision model pretraining framework inspired by energy-based models (EBMs). In the proposed framework, we model energy estimation and data restoration as the forward and backward passes of a single network without any auxiliary components, e.g., an extra decoder. For the forward pass, we fit a network to an energy function that assigns low energy scores to samples that belong to an unlabeled dataset, and high energy otherwise. For the backward pass, we restore data from corrupted versions iteratively using gradient-based optimization along the direction of energy minimization. In this way, we naturally fold the encoder-decoder architecture widely used in masked image modeling into the forward and backward passes of a single vision model. Our framework accepts a wide range of pretext tasks with different data corruption methods, and permits models to be pretrained from masked image modeling, patch sorting, and image restoration, including super-resolution, denoising, and colorization. We support our findings with extensive experiments, and show the proposed method delivers comparable and even better performance with remarkably fewer epochs of training compared to the state-of-the-art self-supervised vision model pretraining methods. Our findings shed light on further exploring self-supervised vision model pretraining and pretext tasks beyond masked image modeling.

Effectively Modeling Time Series with Simple Discrete State Spaces

Michael Zhang,Khaled Kamal Saab,Michael Poli,Tri Dao,Karan Goel,Christopher Re

Time series modeling is a well-established problem, which often requires that methods (1) expressively represent complicated dependencies, (2) forecast long horizons, and (3) efficiently train over long sequences. State-space models (SSMs) are classical models for time series, and prior works combine SSMs with deep learning layers for efficient sequence modeling. However, we find fundamental limitations with these prior approaches, proving their SSM representations cannot express autoregressive time series processes. We thus introduce SpaceTime, a new state-space time series architecture that improves all three criteria. For expressivity, we propose a new SSM parameterization based on the companion matrix---a canonical representation for discrete-time processes---which enables SpaceTime's SSM layers to learn desirable autoregressive processes. For long horizon forecasting, we introduce a "closed-loop" variation of the companion SSM, which enables SpaceTime to predict many future time-steps by generating its own layer-wise inputs. For efficient training and inference, we introduce an algorithm that reduces the memory and compute of a forward pass with the companion matrix. With sequence length ℓ and state-space size d, we go from $\tilde{O}(d \ell)$ naïvely to $\tilde{O}(d + \ell)$. In experiments, our contributions lead to state-of-the-art results on extensive and diverse benchmarks, with best or second-best AUROC on 6 / 7 ECG and speech time series classification, and best MSE on 14 / 16 Informer forecasting tasks. Furthermore, we find SpaceTime (1) fits AR(p) processes that prior deep SSMs fail on, (2) forecasts notably more accurately on longer horizons than prior state-of-the-art, and (3) speeds up training on real-world ETTh1 data by 73% and 80% relative wall-clock time over Transformers and LSTMs.

Forgetful causal masking makes causal language models better zero-shot learners

Hao Liu,Xinyang Geng,Lisa Lee,Igor Mordatch,Sergey Levine,Sharan Narang,Pieter Abbeel

Large language models (LLM) trained using the next-token-prediction objective, such as GPT3 and PaLM, have revolutionized natural language processing in recent years by showing impressive zero-shot and few-shot capabilities across a wide ra nge of tasks. In this work, we propose a simple technique that significantly boosts the performance of LLMs without adding computational cost. Our key observation is that, by performing the next token prediction task with randomly selected past tokens masked out, we can improve the quality of the learned representations for downstream language understanding tasks. We hypothesize that randomly masking past tokens prevents over-attending to recent tokens and encourages attention to tokens in the distant past. By randomly masking input tokens in the PaLM model, we show that we can significantly improve PaLM's zero-shot performance on the SuperGLUE benchmark from 55.7 to 59.2. Experimental results show that FCM also improves PaLM's zero- and few-shot performance on a diverse suite of tasks, including commonsense reasoning, natural language inference and cloze completion. Moreover, we show that our technique also helps representation learning, significantly improving PaLM's finetuning results on SuperGLUE.

When and Why Vision-Language Models Behave like Bags-Of-Words, and What to Do About It?

Mert Yuksekgonul,Federico Bianchi,Pratyusha Kalluri,Dan Jurafsky,James Zou

Despite the success of large vision and language models (VLMs) in many downstream applications, it is unclear how well they encode the compositional relationships between objects and attributes. Here, we create the Attribution, Relation, and Order (ARO) benchmark to systematically evaluate the ability of VLMs to understand different types of relationships, attributes, and order information. ARO consists of \emph{Visual Genome Attribution}, to test the understanding of objects' properties; \emph{Visual Genome Relation}, to test for relational understanding; and \emph{COCO-Order \& Flickr30k-Order}, to test for order sensitivity in VLMs. ARO is orders of magnitude larger than previous benchmarks of compositionality, with more than 50,000 test cases. We present the settings where state-of-the-art VLMs behave like bags-of-words---i.e. when they have poor relational understanding, can blunder when linking objects to their attributes, and demonstrate a severe lack of order sensitivity. VLMs are predominantly trained and evaluated on large scale datasets with rich compositional structure in the images and captions. Yet, training on these datasets has not been enough to address the lack of compositional understanding, and evaluating on these datasets has failed to surface this deficiency. To understand why these limitations emerge and are not represented in the standard tests, we zoom into the evaluation and training procedures. We demonstrate that it is possible to perform well on image-text retrieval over existing datasets without using the composition and order information. This further motivates the value of using ARO to benchmark VLMs. Given that contrastive pretraining optimizes for retrieval on large datasets with similar shortcuts, we hypothesize that this can explain why the models do not need to learn to represent compositional information. This finding suggests a natural solution: composition-aware hard negative mining. We show that a simple-to-implement modification of contrastive learning significantly improves the performance on tasks requiring understanding of order and compositionality.

A Time Series is Worth 64 Words: Long-term Forecasting with Transformers

Yuqi Nie,Nam H Nguyen,Phanwadee Sinthong,Jayant Kalagnanam

We propose an efficient design of Transformer-based models for multivariate time series forecasting and self-supervised representation learning. It is based on two key components: (i) segmentation of time series into subseries-level patches which are served as input tokens to Transformer; (ii) channel-independence where each channel contains a single univariate time series that shares the same embedding and Transformer weights across all the series. Patching design naturally has three-fold benefit: local semantic information is retained in the embedding; computation and memory usage of the attention maps are quadratically reduced given the same look-back window; and the model can attend longer history. Our channel-independent patch time series Transformer (PatchTST) can improve the long-term forecasting accuracy significantly when compared with that of SOTA Transformer-based models. We also apply our model to self-supervised pre-training tasks an d attain excellent fine-tuning performance, which outperforms supervised training on large datasets. Transferring of masked pre-training performed on one dataset to other datasets also produces SOTA forecasting accuracy.

Fantastic Rewards and How to Tame Them: A Case Study on Reward Learning for Task-oriented Dialogue Systems

Yihao Feng,Shentao Yang,Shujian Zhang,Jianguo Zhang,Caiming Xiong,Mingyuan Zhou,Huan Wang

When learning task-oriented dialogue (ToD) agents, reinforcement learning (RL) techniques can naturally be utilized to train dialogue strategies to achieve user-specific goals. Prior works mainly focus on adopting advanced RL techniques to train the ToD agents, while the design of the reward function is not well studied. This paper aims at answering the question of how to efficiently learn and leverage a reward function for training end-to-end (E2E) ToD agents. Specifically, we introduce two generalized objectives for reward-function learning, inspired by the classical learning-to-rank literature. Further, we utilize the learned reward function to guide the training of the E2E ToD agent. With the proposed techniques, we achieve competitive results on the E2E response-generation task on the Multiwoz 2.0 dataset. Source code and checkpoints are publicly released at https://github.com/Shentao-YANG/Fantastic_Reward_ICLR2023.

Supervision Complexity and its Role in Knowledge Distillation

Hrayr Harutyunyan,Ankit Singh Rawat,Aditya Krishna Menon,Seungyeon Kim,Sanjiv Kumar

Despite the popularity and efficacy of knowledge distillation, there is limited understanding of why it helps. In order to study the generalization behavior of a distilled student, we propose a new theoretical framework that leverages supervision complexity: a measure of alignment between teacher-provided supervision and the student's neural tangent kernel. The framework highlights a delicate interplay among the teacher's accuracy, the student's margin with respect to the teacher predictions, and the complexity of the teacher predictions. Specifically, it provides a rigorous justification for the utility of various techniques that are prevalent in the context of distillation, such as early stopping and temperature scaling. Our analysis further suggests the use of online distillation, where a student receives increasingly more complex supervision from teachers in different stages of their training. We demonstrate efficacy of online distillation and validate the theoretical findings on a range of image classification benchmarks and model architectures.

GLINKX: A Scalable Unified Framework For Homophilous and Heterophilous Graphs

Marios Papachristou,Rishab Goel,Frank Portman,Matthew Miller,Rong Jin

In graph learning, there have been two predominant inductive biases regarding graph-inspired architectures: On the one hand, higher-order interactions and message passing work well on homophilous graphs and are leveraged by GCNs and GATs. Such architectures, however, cannot easily scale to large real-world graphs. On the other hand, shallow (or node-level) models using ego features and adjacency embeddings work well in heterophilous graphs. In this work, we propose a novel scalable shallow method -- GLINKX -- that can work both on homophilous and heterophilous graphs. GLINKX leverages (i) novel monophilous label propagations (ii) ego/node features, (iii) knowledge graph embeddings as positional embeddings, (iv) node-level training, and (v) low-dimensional message passing. Formally, we prove novel error bounds and justify the components of GLINKX. Experimentally, we show its effectiveness of it on several homophilous and heterophilous datasets.

Marich: A Query-efficient & Online Model Extraction Attack using Public Data

Pratik Karmakar,Debabrota Basu

In this paper, we study black-box model stealing attacks where the attacker is only able to query a machine learning model through publicly available APIs. Specifically, our aim is to design a black-box model stealing attack that uses a minimal number of queries to create an informative replica of the target model. Fir

st, we reduce this problem to an online variational optimization problem. At every step, the attacker solves this problem to select the most informative query that maximizes the entropy of the selected queries and simultaneously reduces the mismatch between the target and the stolen models. We propose an online and adaptive algorithm, Marich, that leverages active learning to select the queries. We instantiate efficiency of our attack against different models, including logistic regression, BERT and ResNet18, trained on different text and image datasets. Marich is able to steal a model that can achieve 70-96$\%$ of true model's accuracy using 0.8-10$\%$ samples from the attack datasets which are publicly available and different from the training datasets. Our stolen models also achieve 75-98$\%$ accuracy of membership inference and also show 70-90$\%$ agreement of membership inference with direct membership inference on the target models. Our experiments validate that Marich is query-efficient and capable of creating an informative replica of the target model.

Lovasz Theta Contrastive Learning
Georgios Smyrnis,Matt Jordan,Ananya Uppal,Giannis Daras,Alex Dimakis
We establish a connection between the Lovasz theta function of a graph and the widely used InfoNCE loss. We show that under certain conditions, the minima of the InfoNCE loss are related to minimizing the Lovasz theta function on the empty similarity graph between the samples. Building on this connection, we generalize contrastive learning on weighted similarity graphs between samples. Our Lovasz theta contrastive loss uses a weighted graph that can be learned to take into account similarities between our data. We evaluate our method on image classification tasks, demonstrating an improvement of 1% in the supervised case and up to 4% in the unsupervised case.
****

Transferable Unlearnable Examples
Jie Ren,Han Xu,Yuxuan Wan,Xingjun Ma,Lichao Sun,Jiliang Tang
With more people publishing their personal data online, unauthorized data usage has become a serious concern. The unlearnable examples strategies have been introduced to prevent third parties from training on the data without permission. They add perturbations to the users’ data before publishing, so as to make the models trained on the perturbed published dataset invalidated. These perturbations have been generated for a specific training setting and a target dataset. However, their unlearnable effects significantly decrease when used in other training settings or datasets. To tackle this issue, we propose a novel unlearnable strategy based on Class-wise Separability Discriminant (CSD), which boosts the transferability of the unlearnable perturbations by enhancing the linear separability. Extensive experiments demonstrate the transferability of the unlearnable examples crafted by our proposed method across training settings and datasets.
****

MUG: Interactive Multimodal Grounding on User Interfaces
Tao Li,Gang Li,Jingjie Zheng,Purple Wang,Yang Li
We present MUG, a novel interactive task for multimodal grounding where a user and an agent work collaboratively on an interface screen. Prior works modeled multimodal UI grounding in one round: the user gives a command and the agent responds to the command. Yet, in a realistic scenario, a user command can be ambiguous when the target action is inherently difficult to articulate in natural language. MUG allows multiple rounds of interactions such that upon seeing the agent responses, the user can give further commands for the agent to refine or even correct its actions. Such interaction is critical for improving grounding performances in real-world use cases. To investigate the problem, we create a new dataset that consists of 77,820 sequences of human user-agent interaction on mobile interfaces in which 20% involves multiple rounds of interactions. To establish our benchmark, we experiment with a range of modeling variants and evaluation strategies, including both offline and online evaluation—the online strategy consists of both human evaluation and automatic with simulators. Our experiments show that allowing iterative interaction significantly improves the absolute task completion by 18% over the entire test dataset and 31% over the challenging subset. Our

results lay the foundation for further investigation of the problem.

Tabular Deep Learning when $d \gg n$ by Using an Auxiliary Knowledge Graph
Camilo Ruiz,Hongyu Ren,Kexin Huang,Jure Leskovec

Machine learning models exhibit strong performance on datasets with abundant labeled samples. However, for tabular datasets with extremely high d-dimensional features but limited n samples (i.e. $d \gg n$), machine learning models struggle to achieve strong performance. Here, our key insight is that even in tabular datasets with limited labeled data, input features often represent real-world entities about which there is abundant prior information which can be structured as an auxiliary knowledge graph (KG). For example, in a tabular medical dataset where every input feature is the amount of a gene in a patient's tumor and the label is the patient's survival, there is an auxiliary knowledge graph connecting gene names with drug, disease, and human anatomy nodes. We therefore propose PLATO, a machine learning model for tabular data with $d \gg n$ and an auxiliary KG with input features as nodes. PLATO uses a multilayer perceptron (MLP) to predict the output labels from the tabular data and the auxiliary KG with two methodological components. First, PLATO predicts the parameters in the first layer of the MLP from the auxiliary KG. PLATO thereby reduces the number of trainable parameters in the MLP and integrates auxiliary information about the input features. Second, PLATO predicts different parameters in the first layer of the MLP for every input sample, thereby increasing the MLP’s representational capacity by allowing it to use different prior information for every input sample. Across 10 state-of-the-art baselines and 6 $d \gg n$ datasets, PLATO exceeds or matches the prior state-of-the-art, achieving performance improvements of up to 10.19%. Overall, PLATO uses an auxiliary KG about input features to enable tabular deep learning prediction when $d \gg n$.

Random Laplacian Features for Learning with Hyperbolic Space
Tao Yu,Christopher De Sa

Due to its geometric properties, hyperbolic space can support high-fidelity embeddings of tree- and graph-structured data, upon which various hyperbolic networks have been developed. Existing hyperbolic networks encode geometric priors not only for the input, but also at every layer of the network. This approach involves repeatedly mapping to and from hyperbolic space, which makes these networks complicated to implement, computationally expensive to scale, and numerically unstable to train. In this paper, we propose a simpler approach: learn a hyperbolic embedding of the input, then map once from it to Euclidean space using a mapping that encodes geometric priors by respecting the isometries of hyperbolic space, and finish with a standard Euclidean network. The key insight is to use a random feature mapping via the eigenfunctions of the Laplace operator, which we show can approximate any isometry-invariant kernel on hyperbolic space. Our method can be used together with any graph neural networks: using even a linear graph model yields significant improvements in both efficiency and performance over other hyperbolic baselines in both transductive and inductive tasks.

Replay Memory as An Empirical MDP: Combining Conservative Estimation with Experience Replay
Hongming Zhang,Chenjun Xiao,Han Wang,Jun Jin,bo xu,Martin Müller

Experience replay, which stores transitions in a replay memory for repeated use, plays an important role of improving sample efficiency in reinforcement learning. Existing techniques such as reweighted sampling, episodic learning and reverse sweep update further process the information in the replay memory to make experience replay more efficient. In this work, we further exploit the information in the replay memory by treating it as an empirical \emph{Replay Memory MDP (RM-MDP)}. By solving it with dynamic programming, we learn a conservative value estimate that \emph{only} considers transitions observed in the replay memory. Both value and policy regularizers based on this conservative estimate are developed and integrated with model-free learning algorithms. We design the metric \textit{memory density} to measure the quality of RM-MDP. Our empirical studies quantit

atively find a strong correlation between performance improvement and memory density. Our method combines \emph{Conservative Estimation with Experience Replay (CEER)}, improving sample efficiency by a large margin, especially when the memory density is high. Even when the memory density is low, such a conservative estimate can still help to avoid suicidal actions and thereby improve performance.

Neural Causal Models for Counterfactual Identification and Estimation
Kevin Muyuan Xia,Yushu Pan,Elias Bareinboim
Evaluating hypothetical statements about how the world would be had a different course of action been taken is arguably one key capability expected from modern AI systems. Counterfactual reasoning underpins discussions in fairness, the determination of blame and responsibility, credit assignment, and regret. In this paper, we study the evaluation of counterfactual statements through neural models. Specifically, we tackle two causal problems required to make such evaluations, i.e., counterfactual identification and estimation from an arbitrary combination of observational and experimental data. First, we show that neural causal models (NCMs) are expressive enough and encode the structural constraints necessary for performing counterfactual reasoning. Second, we develop an algorithm for simultaneously identifying and estimating counterfactual distributions. We show that this algorithm is sound and complete for deciding counterfactual identification in general settings. Third, considering the practical implications of these results, we introduce a new strategy for modeling NCMs using generative adversarial networks. Simulations corroborate with the proposed methodology.

Connecting representation and generation via masked vision-language transformer
Xinyang Geng,Lisa Lee,Igor Mordatch,Sergey Levine,Pieter Abbeel,Hao Liu
Recently, there has been great progress in the self-supervised pre-training of multimodal representation models that understand image and language jointly. One particularly popular application of such models is text-to-image generation, which is typically obtained via a two-stage process: in the first stage, a representation model is trained via self-supervised objectives; then in the second stage, a conditional generative decoder is trained on top of the representation to generate natural images. In this work, we aim at bringing representation learning and conditional generation together by unifying the two stages into a single model and training objective. We present UPGen, a unified pre-trained model for both representation learning and generation. UPGen is trained with a simple masked token prediction objective on a flexible mixture of image and language data. We use a pre-trained VQGAN image tokenizer to convert images into discrete tokens, then train a masked token prediction model on both paired image-text datasets and unpaired language datasets, using randomly sampled mask ratios. We show that this masked token prediction model can be directly used to generate images and language by iteratively re-masking and predicting the masked tokens. We demonstrate empirically that UPGen serves as both a good representation learning model and a generative model for both image and language.

Is margin all you need? An extensive empirical study of active learning on tabular data
Dara Bahri,Heinrich Jiang,Tal Schuster,Afshin Rostamizadeh
Given a labeled training set and a collection of unlabeled data, the goal of active learning (AL) is to identify the best unlabeled points to label. In this comprehensive study, we analyze the performance of a variety of AL algorithms on deep neural networks trained on 69 real-world tabular classification datasets from the OpenML-CC18 benchmark. We consider different data regimes and the effect of self-supervised model pre-training. Surprisingly, we find that the classical margin sampling technique matches or outperforms all others, including current state-of-art, in a wide range of experimental settings. To researchers, we hope to encourage rigorous benchmarking against margin, and to practitioners facing tabular data labeling constraints that hyper-parameter-free margin may often be all they need.

Momentum Stiefel Optimizer, with Applications to Suitably-Orthogonal Attention, and Optimal Transport

Lingkai Kong,Yuqing Wang,Molei Tao

The problem of optimization on Stiefel manifold, i.e., minimizing functions of (not necessarily square) matrices that satisfy orthogonality constraints, has been extensively studied. Yet, a new approach is proposed based on, for the first time, an interplay between thoughtfully designed continuous and discrete dynamics. It leads to a gradient-based optimizer with intrinsically added momentum. This method exactly preserves the manifold structure but does not require additional operation to keep momentum in the changing (co)tangent space, and thus has low computational cost and pleasant accuracy. Its generalization to adaptive learning rates is also demonstrated. Notable performances are observed in practical tasks. For instance, we found that placing orthogonal constraints on attention heads of trained-from-scratch Vision Transformer (Dosovitskiy et al., 2020) could markedly improve its performance, when our optimizer is used, and it is better that each head is made orthogonal within itself but not necessarily to other heads. This optimizer also makes the useful notion of Projection Robust Wasserstein Distance (Paty and Cuturi, 2019; Lin et al., 2020) for high-dim. optimal transport even more effective.

****

Target Conditioned Representation Independence (TCRI); from Domain-Invariant to Domain-General Representations

Olawale Elijah Salaudeen,Oluwasanmi O Koyejo

We propose a Target Conditioned Representation Independence (TCRI) objective for domain generalization. TCRI addresses the limitations of existing domain generalization methods due to incomplete constraints. Specifically, TCRI implements regularizers motivated by conditional independence constraints that are sufficient to strictly learn complete sets of invariant mechanisms, which we show are necessary and sufficient for domain generalization. Empirically, we show that TCRI is effective on both synthetic and real-world data. TCRI is competitive with baselines in average accuracy while outperforming them in worst-domain accuracy, indicating desired cross-domain stability.

****

Multi-Task Option Learning and Discovery for Stochastic Path Planning

Naman Shah,Siddharth Srivastava

This paper addresses the problem of reliably and efficiently solving broad classes of long-horizon stochastic path planning problems. Starting with a vanilla RL formulation with a stochastic dynamics simulator and an occupancy matrix of the environment, our approach computes useful options with policies as well as high-level paths that compose the discovered options.

Our main contributions are (1) data-driven methods for creating abstract states that serve as endpoints for helpful options, (2) methods for computing option policies using auto-generated option guides in the form of dense pseudo-reward functions, and (3) an overarching algorithm for composing the computed options. We show that this approach yields strong guarantees of executability and solvability: under fairly general conditions, the computed option guides lead to composable option policies and consequently ensure downward refinability. Empirical evaluation on a range of robots, environments, and tasks shows that this approach effectively transfers knowledge across related tasks and that it outperforms existing approaches by a significant margin.

MolEBM: Molecule Generation and Design by Latent Space Energy-Based Modeling

Deqian Kong,Bo Pang,Tian Han,Ying Nian Wu

Generation of molecules with desired chemical and biological properties such as high drug-likeness, high binding affinity to target proteins, is critical in drug discovery. In this paper, we propose a probabilistic generative model to capture the joint distribution of molecules and their properties. Our model assumes an energy-based model (EBM) in the latent space. Given the latent vector sampled from the latent space EBM, both molecules and molecular properties are conditionally sampled via a top-down molecule generator model and a property regression m odel respectively. The EBM in a low dimensional latent space allows our model to capture complex chemical rules implicitly but efficiently and effectively. Due to the joint modeling with chemical properties, molecule design can be conveniently and naturally achieved by conditional sampling from our learned model given desired properties, in both single-objective and multi-objective optimization settings. The latent space EBM, top-down molecule generator, and property regression model are learned jointly by maximum likelihood, while optimization of properties is accomplished by gradual shifting of the model distribution towards the region supported by molecules with high property values. Our experiments show that our model outperforms state-of-the-art models on various molecule design tasks.

Information-Theoretic Diffusion

Xianghao Kong,Rob Brekelmans,Greg Ver Steeg

Denoising diffusion models have spurred significant gains in density modeling and image generation, precipitating an industrial revolution in text-guided AI art generation. We introduce a new mathematical foundation for diffusion models inspired by classic results in information theory that connect Information with Minimum Mean Square Error regression, the so-called I-MMSE relations. We generalize the I-MMSE relations to \emph{exactly} relate the data distribution to an optimal denoising regression problem, leading to an elegant refinement of existing diffusion bounds. This new insight leads to several improvements for probability distribution estimation, including a theoretical justification for diffusion model ensembling. Remarkably, our framework shows how continuous and discrete probabilities can be learned with the same regression objective, avoiding domain-specific generative models used in variational methods.

Bandwith Enables Generalization in Quantum Kernel Models

Abdulkadir Canatar,Evan Peters,Cengiz Pehlevan,Stefan M. Wild,Ruslan Shaydulin

Quantum computers are known to provide speedups over classical state-of-the-art machine learning methods in some specialized settings. For example, quantum kernel methods have been shown to provide an exponential speedup on a learning version of the discrete logarithm problem. Understanding the generalization of quantum models is essential to realizing similar speedups on practically interesting problems. Recent results demonstrate that generalization is hindered by the exponential size of the quantum feature space. Although these results suggest that quantum models cannot generalize when the number of qubits is large, in this paper we show that these results rely on overly restrictive assumptions. We consider a wider class of models by varying a hyperparameter that we call quantum kernel bandwidth. We analyze the large-qubit limit and provide explicit formulas for the generalization of a quantum model that can be solved in closed form. Specifically, we show that changing the value of bandwidth can take a model from provably not being able to generalize on any target function to good generalization for well-aligned targets. Our analysis shows how the bandwidth controls the spectrum of the kernel integral operator, and thereby the inductive bias of the model. We demonstrate empirically that our theory correctly predicts how varying the bandwidth affects generalization of quantum models on challenging datasets, including those far outside our theoretical assumptions. We discuss the implications of our results for quantum advantage in machine learning.

SpENCNN: Orchestrating Encoding and Sparsity for Fast Homomorphically Encrypted Neural Network Inference

Ran Ran,Xinwei Luo,Wei Wang,Tao Liu,Gang Quan,Wujie Wen

Homomorphic Encryption (HE) is a promising technology for protecting user's data privacy for Machine Learning as a Service (MLaaS) on public clouds. However, the computation overheads associated with the HE operations, which can be orders of magnitude slower than their counterparts for plaintexts, can lead to extremely high latency in neural network inference, seriously hindering its application in practice. While extensive neural network optimization techniques have been proposed, such as sparsification and pruning for plaintext domain, they cannot addr

ess this problem effectively. In this paper, we propose an HE-based CNN inference framework, i.e., SpENCNN, that can effectively exploit the single-instruction-multiple-data (SIMD) feature of the HE scheme to improve the CNN inference latency. In particular, we first develop a HE-group convolution technique that can partition channels among different groups based on the data size and ciphertext size, and then encode them into the same ciphertext in an interleaved manner, so as to dramatically reduce the bottlenecked operations in HE convolution. We further develop a sub-block weight pruning technique that can reduce more costly HE-operations for CNN convolutions. Our experiment results show that the SpENCNN-optimized CNN models can achieve overall speedups of 8.37x, 12.11x, and 19.26x for LeNet, VGG-5, and HEFNet, respectively, with negligible accuracy loss.

No Pairs Left Behind: Improving Metric Learning with Regularized Triplet Objective

A. Ali Heydari,Naghmeh Rezaei,Daniel McDuff,Javier L Prieto

We propose a novel formulation of the triplet objective function that improves metric learning without additional sample mining or overhead costs. Our approach aims to explicitly regularize the distance between the positive and negative samples in a triplet with respect to the anchor-negative distance. As an initial validation, we show that our method (called No Pairs Left Behind [NPLB]) improves upon the traditional and current state-of-the-art triplet objective formulations on standard benchmark datasets. To show the effectiveness and potentials of NPLB on real-world complex data, we evaluate our approach on a large-scale healthcare dataset (UK Biobank), demonstrating that the embeddings learned by our model significantly outperform all other current representations on tested downstream tasks. Additionally, we provide a new model-agnostic single-time health risk definition that, when used in tandem with the learned representations, achieves the most accurate prediction of a patient's future health complications. Our results indicate that NPLB is a simple, yet effective framework for improving existing deep metric learning models, showcasing the potential implications of deep metric learning in more complex applications, especially in the biological and healthcare domains.

Minimal Value-Equivalent Partial Models for Scalable and Robust Planning in Lifelong Reinforcement Learning

Safa Alver,Doina Precup

Learning models of the environment from pure interaction is often considered an essential component of building lifelong reinforcement learning agents. However, the common practice in model-based reinforcement learning is to learn models that model every aspect of the agent's environment, regardless of whether they are important in coming up with optimal decisions or not. In this paper, we argue that such models are not particularly well-suited for performing scalable and robust planning in lifelong reinforcement learning scenarios and we propose new kinds of models that only model the relevant aspects of the environment, which we call minimal value-equivalent partial models. After providing the formal definitions of these models, we provide theoretical results demonstrating the scalability advantages of performing planning with minimal value-equivalent partial models and then perform experiments to empirically illustrate our theoretical results. Finally, we provide some useful heuristics on how to learn such models with deep learning architectures and empirically demonstrate that models learned in such a way can allow for performing planning that is robust to distribution shifts and compounding model errors. Overall, both our theoretical and empirical results suggest that minimal value-equivalent partial models can provide significant benefits to performing scalable and robust planning in lifelong reinforcement learning scenarios.

Predictive Coding with Approximate Laplace Monte Carlo

Umais Zahid,Qinghai Guo,Karl Friston,Zafeirios Fountas

Predictive coding (PC) accounts of perception now form one of the dominant computational theories of the brain. Despite this, they have enjoyed little export to

the broader field of machine learning, where comparative generative models have flourished. In part, this has been due to the poor performance of models trained with standard implementations of PC when evaluated by both sample quality and marginal likelihood. By adopting the perspective of PC as a variational Bayes algorithm under the Laplace approximation, we identify the source of these deficits to lie in the exclusion of an associated Hessian term in the standard PC objective function. To remedy this, we make three primary contributions: we begin by suggesting a simple Monte Carlo estimated evidence lower bound which relies on sampling from the Hessian-parameterised variational posterior. We then derive a novel block diagonal approximation to the full Hessian matrix that has lower memory requirements and favourable mathematical properties. Lastly, we present an algorithm that combines our method with standard PC to reduce memory complexity further. We evaluate models trained with our approach against the standard PC framework on image benchmark datasets. Our approach produces higher log-likelihoods and qualitatively better samples that more closely capture the diversity of the data-generating distribution.

SIMPLE: A Gradient Estimator for k-Subset Sampling
kareem ahmed,Zhe Zeng,Mathias Niepert,Guy Van den Broeck

k-subset sampling is ubiquitous in machine learning, enabling regularization and interpretability through sparsity. The challenge lies in rendering k-subset sampling amenable to end-to-end learning. This has typically involved relaxing the reparameterized samples to allow for backpropagation, but introduces both bias and variance. In this work, we fall back to discrete k-subset sampling on the forward pass. This is coupled with using the gradient with respect to the exact marginals, computed efficiently, as a proxy for the true gradient. We show that our gradient estimator exhibits lower bias and variance compared to state-of-the-art estimators. Empirical results show improved performance on learning to explain and sparse models benchmarks. We provide an algorithm for computing the exact ELBO for the k-subset distribution, obtaining significantly lower loss compared to state-of-the-art discrete sparse VAEs. All of our algorithms are exact and efficient.

Transformers Implement First-Order Logic with Majority Quantifiers
William Merrill,Ashish Sabharwal

Characterizing the implicit structure of the computation within neural networks is a foundational problem in the area of deep learning interpretability. Can their inner decision process be captured symbolically in some familiar logic? We show that any transformer neural network can be translated into an equivalent fixed-size first-order logic formula which may also use majority quantifiers. The idea is to simulate transformers with highly uniform threshold circuits and leverage known theoretical connections between circuits and logic. Our findings also reveal the surprising fact that the entire transformer computation can be reduced merely to the division of two (large) integers. While our results are most pertinent for transformers, they apply equally to a broader class of neural network architectures, namely those with a fixed-depth uniform computation graph made up of standard neural net components, which includes feedforward and convolutional networks.

Robustness Evaluation Using Local Substitute Networks
Aleksei Kuvshinov,Crisitan Pavel,Stephan Günnemann

Robustness of a neural network against adversarial examples is an important topic when a deep classifier is applied in safety critical use cases like health care or autonomous driving. In order to assess the robustness, practitioners use a range of different tools ranging from the adversarial attacks to exact computation of the distance to the decision boundary. We use the fact that robustness of a neural network is a local property and empirically show that computing the same metrics for the smaller local substitute networks yields good estimates of the robustness for lower cost. To construct the substitute network we develop two pruning techniques that preserve the local properties of the initial network arou nd a given anchor point. Our experiments on CIFAR10 and MNIST datasets prove that this approach saves a significant amount of computing time and is especially beneficial for the larger models.

Learning Iterative Neural Optimizers for Image Steganography

Xiangyu Chen,Varsha Kishore,Kilian Q Weinberger

Image steganography is the process of concealing secret information in images through imperceptible changes.

Recent work has formulated this task as a classic constrained optimization problem. In this paper, we argue that image steganography is inherently performed on the (elusive) manifold of natural images, and propose an iterative neural network trained to perform the optimization steps. In contrast to classical optimization methods like L-BFGS or projected gradient descent, we train the neural network to also stay close to the manifold of natural images throughout the optimization. We show that our learned neural optimization is faster and more reliable than classical optimization approaches. In comparison to previous state-of-the-art encoder-decoder based steganography methods, it reduces the recovery error rate by multiple orders of magnitude and achieves zero error up to 3 bits per pixel (bpp) without the need for error-correcting codes.

Graph Neural Networks as Multi-View Learning

Haoyu Han,Xiaorui Liu,Haitao Mao,MohamadAli Torkamani,Feng Shi,Victor Lee,Jiliang Tang

Graph Neural Networks (GNNs) have demonstrated powerful representation capability in semi-supervised node classification. In this task, there are often three types of information -- graph structure, node features, and node labels. Existing GNNs usually leverage both node features and graph structure by feature transformation and aggregation, following end-to-end training via node labels. In this paper, we change our perspective by considering these three types of information as three views of nodes. This perspective motivates us to design a new GNN framework as multi-view learning which enables alternating optimization training instead of end-to-end training, resulting in significantly improved computation and memory efficiency. Extensive experiments with different settings demonstrate the effectiveness and efficiency of the proposed method.

Cramming: Training a language model on a single GPU in one day

Jonas Geiping,Tom Goldstein

Recent trends in language modeling have focused on increasing performance through scaling, and have resulted in an environment where training language models is out of reach for most researchers and practitioners. While most in the community are asking how to push the limits of extreme computation, we ask the opposite question:

How far can we get with a single GPU in just one day?

We investigate the downstream performance achievable with a transformer-based language model trained completely from scratch with masked language modeling for a single day on a single consumer GPU.

Aside from re-analyzing nearly all components of the pretraining pipeline for this scenario and providing a modified pipeline with performance close to BERT, we investigate why scaling down is hard, and which modifications actually improve performance in this scenario. We provide evidence that even in this constrained setting, performance closely follows scaling laws observed in large-compute settings. Through the lens of scaling laws, we categorize a range of recent improvements to training and architecture and discuss their merit and practical applicability (or lack thereof) for the limited compute setting.

BertNet: Harvesting Knowledge Graphs from Pretrained Language Models

Shibo Hao,Bowen Tan,Kaiwen Tang,Bin Ni,Hengzhe Zhang,Eric Xing,Zhiting Hu

Symbolic knowledge graphs (KGs) have been constructed either by expensive human crowdsourcing or with complex text mining pipelines. The emerging large pretrain ed language models (LMs), such as BERT, have shown to implicitly encode massive knowledge which can be queried with properly designed prompts. However, compared to the explicit KGs, the implict knowledge in the black-box LMs is often difficult to access or edit and lacks explainability. In this work, we aim at harvesting symbolic KGs from the LMs, and propose a new framework for automatic KG construction empowered by the neural LMs’ flexibility and scalability. Compared to prior works that often rely on large human annotated data or existing massive KGs, our approach requires only the minimal definition of relations as inputs, and hence is suitable for extracting knowledge of rich new relations that are instantly assigned and not available before. The framework automatically generates diverse prompts, and performs efficient knowledge search within a given LM for consistent outputs. The knowledge harvested with our approach shows competitive quality, diversity, and novelty. As a result, we derive from diverse LMs a family of new KGs (e.g., BERTNET and ROBERTANET) that contain a richer set of relations, including some complex ones (e.g., "A is capable of but not good at B") that cannot be extracted with previous methods. Besides, the resulting KGs also serve as a vehicle to interpret the respective source LMs, leading to new insights into the varying knowledge capability of different LMs.

How Hard is Trojan Detection in DNNs? Fooling Detectors With Evasive Trojans
Mantas Mazeika,Andy Zou,Akul Arora,Pavel Pleskov,Dawn Song,Dan Hendrycks,Bo Li,David Forsyth

As AI systems become more capable and widely used, a growing concern is the possibility for trojan attacks in which adversaries inject deep neural networks with hidden functionality. Recently, methods for detecting trojans have proven surprisingly effective against existing attacks. However, there is comparatively little work on whether trojans themselves could be rendered hard to detect. To fill this gap, we develop a general method for making trojans more evasive based on several novel techniques and observations. Our method combines distribution-matching, specificity, and randomization to eliminate distinguishing features of trojaned networks. Importantly, our method can be applied to various existing trojan attacks and is detector-agnostic. In experiments, we find that our evasive trojans reduce the efficacy of a wide range of detectors across numerous evaluation settings while maintaining high attack success rates. Moreover, we find that evasive trojans are also harder to reverse-engineer, underscoring the importance of developing more robust monitoring mechanisms for neural networks and clarifying the offence-defense balance of trojan detection.

Pix2Struct: Screenshot Parsing as Pretraining for Visual Language Understanding
Kenton Lee,Mandar Joshi,Iulia Raluca Turc,Hexiang Hu,Fangyu Liu,Julian Martin Eisenschlos,Urvashi Khandelwal,Peter Shaw,Ming-Wei Chang,Kristina Toutanova

Visually-situated language is ubiquitous---sources range from textbooks with diagrams to web pages with images and tables, to mobile apps with buttons and forms. Perhaps due to this diversity, previous work has typically relied on domain-specific recipes with limited sharing of the underlying data, model architectures, and objectives. We present Pix2Struct, a pretrained image-to-text model for purely visual language understanding, which can be finetuned on tasks containing visually-situated language. Pix2Struct is pretrained by learning to parse masked screenshots of web pages into simplified HTML. The web, with its richness of visual elements cleanly reflected in the HTML structure, provides a large source of pretraining data well suited to the diversity of downstream tasks. Intuitively, this objective subsumes common pretraining signals such as OCR, language modeling, image captioning. In addition to the novel pretraining strategy, we introduce a variable-resolution input representation and a more flexible integration of language and vision inputs, where language prompts such as questions are rendered directly on top of the input image. For the first time, we show that a single pretrained model can achieve state-of-the-art results in six out of nine tasks across four domains: documents, illustrations, user interfaces, and natural images.

Confidence-Conditioned Value Functions for Offline Reinforcement Learning

Joey Hong,Aviral Kumar,Sergey Levine

Offline reinforcement learning (RL) promises the ability to learn effective policies solely using existing, static datasets, without any costly online interaction. To do so, offline RL methods must handle distributional shift between the dataset and the learned policy. The most common approach is to learn conservative, or lower-bound, value functions, which underestimate the return of OOD actions. However, such methods exhibit one notable drawback: policies optimized on such value functions can only behave according to a fixed, possibly suboptimal, degree of conservatism. However, this can be alleviated if we instead are able to learn policies for varying degrees of conservatism at training time and devise a method to dynamically choose one of them during evaluation. To do so, in this work, we propose learning value functions that additionally condition on the degree of conservatism, which we dub confidence-conditioned value functions. We derive a new form of a Bellman backup that simultaneously learns Q-values for any degree of confidence with high probability. By conditioning on confidence, our value functions enable adaptive strategies during online evaluation by controlling for confidence level using the history of observations thus far. This approach can be implemented in practice by conditioning the Q-function from existing conservative algorithms on the confidence. We theoretically show that our learned value functions produce conservative estimates of the true value at any desired confidence. Finally, we empirically show that our algorithm outperforms existing conservative offline RL algorithms on multiple discrete control domains.

Current Anomaly Detectors are Anomalous: On Semantic Treatment of OOD Inputs

Ramneet Kaur,Xiayan Ji,Souradeep Dutta,Yahan Yang,Michele Caprio,Elena Bernardis,Oleg Sokolsky,Insup Lee

Machine learning models have achieved impressive performance across different modalities. It is well known that these models are prone to making mistakes on out-of-distribution inputs. OOD detection has, therefore, gained a lot of attention recently. We observe that most existing detectors use the distribution estimated by the training dataset for OOD detection. This can be a serious impediment since faulty OOD detectors can potentially restrict utility of the model. Such detectors, tied to the bias in data collection process, can be impermeable to inputs lying outside the training distribution but with the same semantic information (e.g., class labels) as the training data. We argue that in-distribution should not be tied to just the training distribution but to the distribution of the semantic information contained in the training data. To support our argument, we perform OOD detection on semantic information extracted from the training data of MNIST and COCO datasets, and show that it not only reduces false alarms but also significantly improves detection of OOD inputs with spurious features from training data.

****

FedX: Federated Learning for Compositional Pairwise Risk Optimization

Zhishuai Guo,Rong Jin,Jiebo Luo,Tianbao Yang

In this paper, we tackle a novel federated learning (FL) problem for optimizing a family of compositional pairwise risks, to which no existing FL algorithms are applicable. In particular, the objective has the form of $\E_{\z\sim \mathcal S_1} f(\E_{\z'\sim\mathcal S_2} \ell(\w; \z, \z'))$, where two sets of data $\mathcal S_1, \mathcal S_2$ are distributed over multiple machines, $\ell(\cdot; \cdot,\cdot)$ is a pairwise loss that only depends on the prediction outputs of the input data pairs $(\z, \z')$, and $f(\cdot)$ is possibly a non-linear non-convex function. This problem has important applications in machine learning, e.g., AUROC maximization with a pairwise loss, and partial AUROC maximization with a compositional loss, etc. The challenges for designing a FL algorithm lie at the non-decomposability of the objective over multiple machines and the interdependency between different machines. We propose two provable FL algorithms (FedX) for handling linear and nolinear f, respectively. To tackle the challenges, we decouple the gradient's components with two types namely active parts and lazy part

s, where the {\it active} parts depend on local data that can be computed with the local model and the {\it lazy} parts depend on other machines that are communicated/computed based on historical models. We develop a novel theoretical analysis to address the issue of latency of lazy parts and interdependency between the local gradient estimators and the involved data. We establish both iteration and communication complexities and exhibit that using the historical models for computing the lazy parts do not degrade the complexity results. We conduct empirical studies of FedX for AUROC and partial AUROC maximization, and demonstrate their performance compared with multiple baselines.

On the Sensitivity of Reward Inference to Misspecified Human Models
Joey Hong,Kush Bhatia,Anca Dragan
Inferring reward functions from human behavior is at the center of value alignment – aligning AI objectives with what we, humans, actually want. But doing so relies on models of how humans behave given their objectives. After decades of research in cognitive science, neuroscience, and behavioral economics, obtaining accurate human models remains an open research topic. This begs the question: how accurate do these models need to be in order for the reward inference to be accurate? On the one hand, if small errors in the model can lead to catastrophic error in inference, the entire framework of reward learning seems ill-fated, as we will never have perfect models of human behavior. On the other hand, if as our models improve, we can have a guarantee that reward accuracy also improves, this would show the benefit of more work on the modeling side. We study this question both theoretically and empirically. We do show that it is unfortunately possible to construct small adversarial biases in behavior that lead to arbitrarily large errors in the inferred reward. However, and arguably more importantly, we are also able to identify reasonable assumptions under which the reward inference error can be bounded linearly in the error in the human model. Finally, we verify our theoretical insights in discrete and continuous control tasks with simulated and human data.
****
DeepDFA: Dataflow Analysis-Guided Efficient Graph Learning for Vulnerability Detection
Benjamin Steenhoek,Wei Le,Hongyang Gao
Deep learning-based vulnerability detection models have recently been shown to be effective and, in some cases, outperform static analysis tools. However, the highest-performing approaches use token-based transformer models, which do not leverage domain knowledge. Classical program analysis techniques such as dataflow analysis can detect many types of bugs and are the most commonly used methods in practice. Motivated by the causal relationship between bugs and dataflow analysis, we present DeepDFA, a dataflow analysis-guided graph learning framework and embedding that use program semantic features for vulnerability detection. We show that DeepDFA is performant and efficient. DeepDFA ranked first in recall, first in generalizing over unseen projects, and second in F1 among all the state-of-the-art models we experimented with. It is also the smallest model in terms of the number of parameters, and was trained in 9 minutes, 69x faster than the highest-performing baseline. DeepDFA can be used with other models. By integrating LineVul and DeepDFA, we achieved the best vulnerability detection performance of 96.4 F1 score, 98.69 precision, and 94.22 recall.
****
Probability flow solution of the Fokker-Planck equation
Nicholas Matthew Boffi,Eric Vanden-Eijnden
The method of choice for integrating the time-dependent Fokker-Planck equation in high-dimension is to generate samples from the solution via integration of the associated stochastic differential equation. Here, we introduce an alternative scheme based on integrating an ordinary differential equation that describes the flow of probability. Acting as a transport map, this equation deterministically pushes samples from the initial density onto samples from the solution at any later time. Unlike integration of the stochastic dynamics, the method has the advantage of giving direct access to quantities that are challenging to estimate fr

om trajectories alone, such as the probability current, the density itself, and its entropy. The probability flow equation depends on the gradient of the logarithm of the solution (its "score"), and so is a-priori unknown. To resolve this dependence, we model the score with a deep neural network that is learned on-the-fly by propagating a set of samples according to the instantaneous probability current. We consider several high-dimensional examples from the physics of interacting particle systems to highlight the efficiency and precision of the approach; we find that the method accurately matches analytical solutions computed by hand and moments computed via Monte-Carlo.

Binding Language Models in Symbolic Languages

Zhoujun Cheng,Tianbao Xie,Peng Shi,Chengzu Li,Rahul Nadkarni,Yushi Hu,Caiming Xiong,Dragomir Radev,Mari Ostendorf,Luke Zettlemoyer,Noah A. Smith,Tao Yu

Though end-to-end neural approaches have recently been dominating NLP tasks in both performance and ease-of-use, they lack interpretability and robustness. We propose Binder, a training-free neural-symbolic framework that maps the task input to a program, which (1) allows binding a unified API of language model (LM) functionalities to a programming language (e.g., SQL, Python) to extend its grammar coverage and thus tackle more diverse questions, (2) adopts an LM as both the program parser and the underlying model called by the API during execution, and (3) requires only a few in-context exemplar annotations. Specifically, we employ GPT-3 Codex as the LM. In the parsing stage, with only a few in-context exemplars, Codex is able to identify the part of the task input that cannot be answerable by the original programming language, correctly generate API calls to prompt Codex to solve the unanswerable part, and identify where to place the API calls while being compatible with the original grammar. In the execution stage, Codex can perform versatile functionalities (e.g., commonsense QA, information extraction) given proper prompts in the API calls. Binder achieves state-of-the-art results on WikiTableQuestions and TabFact datasets, with explicit output programs that benefit human debugging. Note that previous best systems are all finetuned on tens of thousands of task-specific samples, while Binder only uses dozens of annotations as in-context exemplars without any training. Our code is available at anonymized.

Probabilistic Categorical Adversarial Attack and Adversarial Training

Pengfei He,Han Xu,Jie Ren,Yuxuan Wan,Zitao Liu,Jiliang Tang

The existence of adversarial examples brings huge concern for people to apply Deep Neural Networks (DNNs) in safety-critical tasks. However, how to generate adversarial examples with categorical data is an important problem but lacks extensive exploration. Previously established methods leverage greedy search methods, which can be very time-consuming to conduct a successful attack. This also limits the development of adversarial training and potential defenses for categorical data. To tackle this problem, we propose a Probabilistic Categorical Adversarial Attack (PCAA), which transfers the discrete optimization problem to a continuous problem that can be solved efficiently by Projected Gradient Descent. In our paper, we theoretically analyze its optimality and time complexity to demonstrate its significant advantage over current greedy-based attacks. Moreover, based on our attack, we propose an efficient adversarial training framework. Through a comprehensive empirical study, we justify the effectiveness of our proposed attack and defense algorithms.

Time Will Tell: New Outlooks and A Baseline for Temporal Multi-View 3D Object Detection

Jinhyung Park,Chenfeng Xu,Shijia Yang,Kurt Keutzer,Kris M. Kitani,Masayoshi Tomizuka,Wei Zhan

While recent camera-only 3D detection methods leverage multiple timesteps, the limited history they use significantly hampers the extent to which temporal fusion can improve object perception. Observing that existing works' fusion of multi-frame images are instances of temporal stereo matching, we find that performance is hindered by the interplay between 1) the low granularity of matching resolut ion and 2) the sub-optimal multi-view setup produced by limited history usage. Our theoretical and empirical analysis demonstrates that the optimal temporal difference between views varies significantly for different pixels and depths, making it necessary to fuse many timesteps over long-term history. Building on our investigation, we propose to generate a cost volume from a long history of image observations, compensating for the coarse but efficient matching resolution with a more optimal multi-view matching setup. Further, we augment the per-frame monocular depth predictions used for long-term, coarse matching with short-term, fine-grained matching and find that long and short term temporal fusion are highly complementary. While maintaining high efficiency, our framework sets new state-of-the-art on nuScenes, achieving first place on the test set and outperforming previous best art by 5.2% mAP and 3.7% NDS on the validation set. Code will be released here: https://github.com/Divadi/SOLOFusion.

Greedy Information Maximization for Online Feature Selection

Ian Connick Covert,Wei Qiu,MingYu Lu,Na Yoon Kim,Su-In Lee

Feature selection is commonly used to reduce feature acquisition costs, but the standard approach is to train models with static feature subsets. Here, we consider the online feature selection problem, where the model can adaptively query features based on the presently available information. Online feature selection has mainly been viewed as a reinforcement learning problem, but we propose a simpler approach of greedily selecting features that maximize mutual information with the response variable. This intuitive idea is difficult to implement without perfect knowledge of the joint data distribution, so we propose a deep learning approach that recovers the greedy procedure when perfectly optimized. We apply our approach to numerous datasets and observe better performance than both RL-based and offline feature selection methods

Towards Fair Classification against Poisoning Attacks

Han Xu,Xiaorui Liu,Yuxuan Wan,Jiliang Tang

Fair classification aims to stress the classification models to achieve the equality (treatment or prediction quality) among different sensitive groups. However, fair classification can be under the risk of poisoning attacks which deliberately insert malicious training samples to manipulate the trained classifiers' performance. In this work, we study the poisoning scenario where the attacker can insert a small fraction of samples into training data, with arbitrary sensitive attributes as well as other predictive features. We demonstrate that the fairly trained classifiers can be greatly vulnerable to such poisoning attacks, with much worse accuracy & fairness trade-off, even when we apply some of the most effective defenses (originally proposed to defend traditional classification tasks). As countermeasures to defend fair classification tasks, we propose a general and theoretically guaranteed framework which accommodates traditional defense methods to fair classification against poisoning attacks. Through extensive experiments, the results validate that the proposed defense framework obtains better robustness in terms of accuracy and fairness than baseline methods.

Unveiling Transformers with LEGO: A Synthetic Reasoning Task

Yi Zhang,Arturs Backurs,Sebastien Bubeck,Ronen Eldan,Suriya Gunasekar,Tal Wagner

We propose a synthetic reasoning task, LEGO (Learning Equality and Group Operations), that encapsulates the problem of following a chain of reasoning, and we study how the Transformer architectures learn this task. We pay special attention to data effects such as pretraining (on seemingly unrelated NLP tasks) and dataset composition (e.g., differing chain length at training and test time), as well as architectural variants such as weight-tied layers or adding convolutional components. We study how the trained models eventually succeed at the task, and in particular, we are able to understand (to some extent) some of the attention heads as well as how the information flows in the network. Based on these observations we propose a hypothesis that here pretraining helps for LEGO tasks due to certain structured attention patterns, and we experimentally verify this hypothesis. We also observe that in some data regimes the trained transformer finds ``sh ortcut" solutions to follow the chain of reasoning, which impedes the model's robustness, and moreover we propose ways to prevent it. Motivated by our findings on structured attention patterns, we propose to replace certain attention heads with hardcoded patterns. This architectural change significantly reduces Flops and maintains or even improves the model's performance at large-scale pretraining.

****

How Much Data Are Augmentations Worth? An Investigation into Scaling Laws, Invariance, and Implicit Regularization

Jonas Geiping,Micah Goldblum,Gowthami Somepalli,Ravid Shwartz-Ziv,Tom Goldstein,Andrew Gordon Wilson

Despite the clear performance benefits of data augmentations, little is known about why they are so effective. In this paper, we disentangle several key mechanisms through which data augmentations operate. Establishing an exchange rate between augmented and additional real data, we find that in out-of-distribution testing scenarios, augmentations which yield samples that are diverse, but inconsistent with the data distribution can be even more valuable than additional training data. Moreover, we find that data augmentations which encourage invariances can be more valuable than invariance alone, especially on small and medium sized training sets. Following this observation, we show that augmentations induce additional stochasticity during training, effectively flattening the loss landscape.

****

Spatial Reasoning Network for Zero-shot Constrained Scene Generation

Maxwell J Jacobson,Yexiang Xue

Constrained scene generation (CSG) generates images satisfying a given set of constraints. Zero-shot CSG generates images satisfying constraints not presented in the training set without retraining. Recent neural-based models generate images with excellent details, but largely cannot satisfy constraints, especially in complex scenes involving multiple objects. Such difficulty is due to the lack of effective approaches combining low-level visual element generation with high-level spatial reasoning. We introduce a Spatial Reasoning Network for constrained scene generation (SPREN). SPREN adds to the state-of-the-art image generation networks (for low-level visual element generation) a spatial reasoning module (for high-level spatial reasoning). The spatial reasoning module decides objects' positions following the output of a Recursive Neural Network (RNN), which is trained to learn implicit spatial knowledge (such as trees growing from the ground) from an image dataset. During inference, explicit constraints can be enforced by a forward-checking algorithm, which blocks invalid decisions from the RNN in a zero-shot manner. In experiments, we demonstrate SPREN is able to generate images with excellent detail while satisfying complex spatial constraints. SPREN also transfers good quality scene generation to unseen constraints without retraining.

Robust Graph Dictionary Learning

Weijie Liu,Jiahao Xie,Chao Zhang,Makoto Yamada,Nenggan Zheng,Hui Qian

Traditional Dictionary Learning (DL) aims to approximate data vectors as sparse linear combinations of basis elements (atoms) and is widely used in machine learning, computer vision, and signal processing. To extend DL to graphs, Vincent-Cuaz et al. 2021 propose a method, called GDL, which describes the topology of each graph with a pairwise relation matrix (PRM) and compares PRMs via the Gromov-Wasserstein Discrepancy (GWD). However, the lack of robustness often excludes GDL from a variety of real-world applications since GWD is sensitive to the structural noise in graphs. This paper proposes an improved graph dictionary learning algorithm based on a robust Gromov-Wasserstein discrepancy (RGWD) which has theoretically sound properties and an efficient numerical scheme. Based on such a discrepancy, our dictionary learning algorithm can learn atoms from noisy graph data. Experimental results demonstrate that our algorithm achieves good performance on both simulated and real-world datasets.

Matrix factorization under the constraint of connectivity between observed and s ource data ~ Muscle synergy analysis based on connectivity between muscle and brain activities ~

Takashi Isezaki,Michiaki Suzuki,Yukio Koike,Ryosuke Aoki,Yukio Nishimura

Matrix factorization is a popular method to investigate the hidden elements in observed data for tasks such as speech separation and muscle synergy analysis. The hidden elements may be closely related to the source phenomenon that cause the observed phenomenon.

However, conventional methods do not always factorize the observed phenomenon elements with the connectivity between the observed and source phenomena because they only use the observed phenomenon. This paper proposes a matrix decomposition method that constrains the connectivity between observed and source data by using the representations from a decoding model from source data to observed data. We applied our method to the corticomuscular system, which is made up of corticospinal pathways between the primary motor cortex and muscles in the body and creates muscle synergies that enable efficient connections between the brain and muscles. In this context, muscle activities are the observed phenomenon and brain activities are the source. Many previous studies have analyzed muscle synergies using only observed muscle activity, but there may be unrevealed muscle synergies under the constraint of the connectivity between brain and muscle activity. We therefore simultaneously recorded the brain activity from multiple regions of an extensive cortical area and the activity of multiple muscles of a monkey's forelimb while it performed a reach and grasp task throughout the course of recovery from a partial spinal cord injury (SCI). Analysis from a dataset of the monkey before SCI showed that some of the muscle synergies calculated from the proposed method using brain and muscle activities, did not exhibit a high degree of similarity to synergies obtained from the conventional method. The proposed method results obtained from the monkey after SCI showed an adaptive change in the number of muscle synergies associated with the degree of functional recovery. Specifically, the numbers of muscle synergies obtained by the proposed method initially increased immediately after SCI and then gradually decreased, while those obtained by a conventional method maintained the same number before and after SCI. These results suggest that our method is able to capture the unrevealed connectivity in the corticomuscular system that contributes to functional recovery: in other words, that it can factorize the observed data under the constraint of the connectivity between the observed and source data. Our work thus demonstrates the importance of using not only observed data but also source data to reveal unknown hidden elements.

****

Fundamental limits on the robustness of image classifiers

Zheng Dai,David Gifford

We prove that image classifiers are fundamentally sensitive to small perturbations in their inputs. Specifically, we show that given some image space of n-by-n images, all but a tiny fraction of images in any image class induced over that space can be moved outside that class by adding some perturbation whose p-norm is $O(n^{1/\max{(p,1)}})$, as long as that image class takes up at most half of the image space. We then show that $O(n^{1/\max{(p,1)}})$ is asymptotically optimal. Finally, we show that an increase in the bit depth of the image space leads to a loss in robustness. We supplement our results with a discussion of their implications for vision systems.

Stochastic Constrained DRO with a Complexity Independent of Sample Size

Qi Qi,Jiameng Lyu,Kung-sik Chan,Er-Wei Bai,Tianbao Yang

Distributionally Robust Optimization (DRO), as a popular method to train robust models against distribution shifts between training and test sets, has received tremendous attention in recent years. In this paper, we propose and analyze stochastic algorithms that apply to both non-convex and convex losses for solving Kullback–Leibler divergence constrained DRO problem. Compared with existing methods solving this problem, such as primal-dual methods and large mini-batch methods, our stochastic algorithms not only enjoy competitive if not better complexity independent of sample size but also just require a constant batch size at every iteration, which is more practical for broad applications. We establish a nearly optimal complexity bound for finding an ϵ-stationary solution for non-convex losses and an optimal complexity for finding an ϵ-optimal solution for convex losses. Empirical studies demonstrate the effectiveness of the proposed algorithms for solving non-convex and convex constrained DRO problems.

****

Evolve Smoothly, Fit Consistently: Learning Smooth Latent Dynamics For Advection-Dominated Systems

Zhong Yi Wan,Leonardo Zepeda-Nunez,Anudhyan Boral,Fei Sha

We present a data-driven, space-time continuous framework to learn surrogate models for complex physical systems described by advection-dominated partial differential equations. Those systems have slow-decaying Kolmogorov n-width that hinders standard methods, including reduced order modeling, from producing high-fidelity simulations at low cost. In this work, we construct hypernetwork-based latent dynamical models directly on the parameter space of a compact representation network. We leverage the expressive power of the network and a specially designed consistency-inducing regularization to obtain latent trajectories that are both low-dimensional and smooth. These properties render our surrogate models highly efficient at inference time. We show the efficacy of our framework by learning models that generate accurate multi-step rollout predictions at much faster inference speed compared to competitors, for several challenging examples.

Dissecting adaptive methods in GANs

Samy Jelassi,David Dobre,Arthur Mensch,Yuanzhi Li,Gauthier Gidel

Adaptive methods are a crucial component widely used for training generative adversarial networks (GANs). While there has been some work to pinpoint the “marginal value of adaptive methods” in standard tasks, it remains unclear why they are still critical for GAN training. In this paper, we formally study how adaptive methods help train GANs; inspired by the grafting method proposed in (Agarwal et al. 2021), we separate the magnitude and direction components of the Adam updates, and graft them to the direction and magnitude of SGDA updates respectively. By considering an update rule with the magnitude of the Adam update and the normalized direction of SGD, we empirically show that the adaptive magnitude of Adam is key for GAN training. This motivates us to have a closer look at the class of normalized stochastic gradient descent ascent (nSGDA) methods in the context of GAN training. We propose a synthetic theoretical framework to compare the performance of nSGDA and SGDA for GAN training with neural networks. We prove that in that setting, GANs trained with nSGDA recover all the modes of the true distribution, whereas the same networks trained with SGDA (and any learning rate configuration) suffer from mode collapse. The critical insight in our analysis is that normalizing the gradients forces the discriminator and generator to be updated at the same pace. We also experimentally show that for several datasets, Adam's performance can be recovered with nSGDA methods.

Recycling Scraps: Improving Private Learning by Leveraging Intermediate Checkpoints

Virat Shejwalkar,Arun Ganesh,Rajiv Mathews,Om Thakkar,Abhradeep Guha Thakurta

All state-of-the-art (SOTA) differentially private machine learning (DP ML) methods are iterative in nature, and their privacy analyses allow publicly releasing the intermediate training checkpoints. However, DP ML benchmarks, and even practical deployments, typically use only the final training checkpoint to make predictions. In this work, for the first time, we comprehensively explore various methods that aggregate intermediate checkpoints to improve the utility of DP training. Empirically, we demonstrate that checkpoint aggregations provide significant gains in the prediction accuracy over the existing SOTA for CIFAR10 and StackOverflow datasets, and that these gains get magnified in settings with periodically varying training data distributions. For instance, we improve SOTA StackOverflow accuracies to 22.7\% (+0.43\% absolute) for $\epsilon=8.2$, and 23.84\% (+0.43\%) for $\epsilon=18.9$. Theoretically, we show that uniform tail averaging of checkpoints improves the empirical risk minimization bound compared to the l ast checkpoint of DP-SGD. Lastly, we initiate an exploration into estimating the uncertainty that DP noise adds in the predictions of DP ML models. We prove that, under standard assumptions on the loss function, the sample variance from last few checkpoints provides a good approximation of the variance of the final model of a DP run. Empirically, we show that the last few checkpoints can provide a reasonable lower bound for the variance of a converged DP model.

Understanding Influence Functions and Datamodels via Harmonic Analysis
Nikunj Saunshi,Arushi Gupta,Mark Braverman,Sanjeev Arora

Influence functions estimate effect of individual data points on predictions of the model on test data and were adapted to deep learning in \cite{koh2017understanding}. They have been used for detecting data poisoning, detecting helpful and harmful examples, influence of groups of datapoints, etc. Recently, \cite{ilyas2022datamodels} introduced a linear regression method they termed {\em datamodels} to predict the effect of training points on outputs on test data. The current paper seeks to provide a better theoretical understanding of such interesting empirical phenomena. The primary tool is harmonic analysis and the idea of {\em noise stability}. Contributions include: (a) Exact characterization of the learnt datamodel in terms of Fourier coefficients. (b) An efficient method to estimate the residual error and quality of the optimum linear datamodel without having to train the datamodel. (c) New insights into when influences of groups of datapoints may or may not add up linearly.

BC-IRL: Learning Generalizable Reward Functions from Demonstrations
Andrew Szot,Amy Zhang,Dhruv Batra,Zsolt Kira,Franziska Meier

How well do reward functions learned with inverse reinforcement learning (IRL) generalize? We illustrate that state-of-the-art IRL algorithms, which maximize a maximum-entropy objective, learn rewards that overfit to the demonstrations. Such rewards struggle to provide meaningful rewards for states not covered by the demonstrations, a major detriment when using the reward to learn policies in new situations. We introduce BC-IRL a new inverse reinforcement learning method that learns reward functions that generalize better when compared to maximum-entropy IRL approaches. In contrast to the MaxEnt framework, which learns to maximize rewards around demonstrations, BC-IRL updates reward parameters such that the policy trained with the new reward matches the expert demonstrations better. We show that BC-IRL learns rewards that generalize better on an illustrative simple task and two continuous robotic control tasks, achieving over twice the success rate of baselines in challenging generalization settings.

TextGrad: Advancing Robustness Evaluation in NLP by Gradient-Driven Optimization
Bairu Hou,Jinghan Jia,Yihua Zhang,Guanhua Zhang,Yang Zhang,Sijia Liu,Shiyu Chang

Robustness evaluation against adversarial examples has become increasingly important to unveil the trustworthiness of the prevailing deep models in natural language processing (NLP). However, in contrast to the computer vision domain where the first-order projected gradient descent (PGD) is used as the benchmark approach to generate adversarial examples for robustness evaluation, there lacks a principled first-order gradient-based robustness evaluation framework in NLP. The emerging optimization challenges lie in 1) the discrete nature of textual inputs together with the strong coupling between the perturbation location and the actual content, and 2) the additional constraint that the perturbed text should be fluent and achieve a low perplexity under a language model. These challenges make the development of PGD-like NLP attacks difficult. To bridge the gap, we propose TextGrad, a new attack generator using gradient-driven optimization, supporting high-accuracy and high-quality assessment of adversarial robustness in NLP. Specifically, we address the aforementioned challenges in a unified optimization framework. And we develop an effective convex relaxation method to co-optimize the continuously-relaxed site selection and perturbation variables and leverage an effective sampling method to establish an accurate mapping from the continuous optimization variables to the discrete textual perturbations. Moreover, as a first-order attack generation method, TextGrad can be baked into adversarial traini ng to further improve the robustness of NLP models. Extensive experiments are provided to demonstrate the effectiveness of TextGrad not only in attack generation for robustness evaluation but also in adversarial defense. From the attack perspective, we show that TextGrad achieves remarkable improvements in both the attack success rate and the perplexity score over five state-of-the-art baselines. From the defense perspective, TextGrad-enabled adversarial training yields the most robust NLP model against a wide spectrum of NLP attacks.

****

Robustness for Free: Adversarially Robust Anomaly Detection Through Diffusion Model

Yuanpu Cao,Lu Lin,Jinghui Chen

Deep learning-based anomaly detection models have achieved remarkably high accuracy on commonly used benchmark datasets. However, the robustness of those models may not be satisfactory due to the existence of adversarial examples, which pose significant threats to the practical deployment of deep anomaly detectors. To tackle this issue, we propose an adversarially robust anomaly detector based on the diffusion model. There are two things that make diffusion models a perfect match for our task: 1) the diffusion model itself is a reconstruction-based modeling method whose reconstruction error can serve as a natural indicator of the anomaly score; 2) previous studies have shown that diffusion models can help purify the data for better adversarial robustness. In this work, we highlight that our diffusion model based method gains the adversarial robustness for free: the diffusion model will act both as an anomaly detector and an adversarial defender, thus no extra adversarial training or data purification is needed as in standard robust image classification tasks. We also extend our proposed method for certified robustness to l_2 norm bounded perturbations. Through extensive experiments, we show that our proposed method exhibits outstanding (certified) adversarial robustness while also maintaining equally strong anomaly detection performance on par with the state-of-the-art anomaly detectors on benchmark datasets.

****

ErrorAug: Making Errors to Find Errors in Semantic Segmentation

Devin Guillory,Dequan Wang,Shun Ishizaka,Kazuki Kozuka,Trevor Darrell

In order to develop trustworthy downstream applications for semantic segmentation models, it is important to not only understand the performance of a model on datasets, but to localize areas where the model may produce errors.
Pixel-wise error prediction of semantic segmentation maps is a challenging problem in which prior work relies on complicated image resynthesis pipelines.
We introduce \it{error augmentation}, a framework which enables us to learn robust error detectors by applying data transformations independently on the predicted segmentation maps.
This approach enables direct prediction of pixel-wise error in semantic segmentation maps, an approach explored as a naive baseline in prior works, to achieve state of the art performance.
As a proof-of-concept we propose a series of three simple transformations that generate challenging segmentation errors by swapping pixel predictions within a segmentation map.
Our approach outperforms previous methods of error detection for semantic segmentation across all metrics and improves performance by over 7.8% on AUPR-Error.
Additionally, we show that our approach not only generalizes to unseen test examples, but remains reliable despite significant shifts in the target domain.

Kernel Regression with Infinite-Width Neural Networks on Millions of Examples

Ben Adlam,Jaehoon Lee,Shreyas Padhy,Zachary Nado,Jasper Snoek

While kernel regression remains an important practical method, its connection to neural networks as their width becomes large has initiated fresh research. These neural kernels have drastically increased performance on diverse and nonstandard data modalities but require significantly more compute, which previously limited their application to smaller datasets. We address this by massively parallel izing their computation across many GPUs. We combine this with a distributed, preconditioned conjugate gradients algorithm to enable kernel regression at a large scale (i.e. up to 5 million examples). Using this approach, we study scaling laws of several neural kernels across many orders of magnitude for the CIFAR-5m dataset. Using data augmentation to expand the original CIFAR-10 training dataset by a factor of 20, we obtain a test accuracy of 91.2\% (SotA for a pure kernel method). Finally, we explore other data modalities, obtaining results on protein and small molecule prediction tasks that are competitive with SotA methods.

Information Plane Analysis for Dropout Neural Networks

Linara Adilova,Bernhard C Geiger,Asja Fischer

The information-theoretic framework promises to explain the predictive power of neural networks. In particular, the information plane analysis, which measures mutual information (MI) between input and representation as well as representation and output, should give rich insights into the training process. This approach, however, was shown to strongly depend on the choice of estimator of the MI. The problem is amplified for deterministic networks if the MI between input and representation is infinite. Thus, the estimated values are defined by the different approaches for estimation, but do not adequately represent the training process from an information-theoretic perspective. In this work, we show that dropout with continuously distributed noise ensures that MI is finite. We demonstrate in a range of experiments that this enables a meaningful information plane analysis for a class of dropout neural networks that is widely used in practice.

****

Fed-Cor: Federated Correlation Test with Secure Aggregation

Lun Wang,Qi Pang,Shuai Wang,Wenting Zheng,Dawn Song

In this paper, we propose the first federated correlation test framework compatible with secure aggregation, namely Fed-Cor. In Fed-Cor, correlation tests are recast as frequency moment estimation problems. To estimate the frequency moments, the clients collaboratively generate a shared projection matrix and then use stable projection to encode the local information in a compact vector. As such encodings can be linearly aggregated, secure aggregation can be applied to conceal the individual updates. We formally establish the security guarantee of Fed-Cor by proving that only the minimum necessary information (i.e., the correlation statistics) is revealed to the server. The evaluation results show that Fed-Cor achieves good accuracy with small client-side computation overhead and performs comparably to the centralized correlation test in several real-world case studies.

Feasible Adversarial Robust Reinforcement Learning for Underspecified Environments

John Banister Lanier,Stephen Marcus McAleer,Pierre Baldi,Roy Fox

Robust reinforcement learning (RL) considers the problem of learning policies that perform well in the worst case among a set of possible environment parameter values. In real-world environments, choosing the set of possible values for robust RL can be a difficult task. When that set is specified too narrowly, the agent will be left vulnerable to reasonable parameter values unaccounted for. When specified too broadly, the agent will be too cautious. In this paper, we propose Feasible Adversarial Robust RL (FARR), a novel problem formulation and objective for automatically determining the set of environment parameter values over which to be robust. FARR implicitly defines the set of feasible parameter values as those on which an agent could achieve a benchmark reward given enough training resources. By formulating this problem as a two-player zero-sum game, optimizing the FARR objective jointly produces an adversarial distribution over parameter values with feasible support and a policy robust over this feasible parameter set. We demonstrate that approximate Nash equilibria for this objective can be found using a variation of the PSRO algorithm. Furthermore, we show that an optimal agent trained with FARR is more robust to feasible adversarial parameter selection than with existing minimax, domain-randomization, and regret objectives in a parameterized gridworld and three MuJoCo control environments.

****

Phase2vec: dynamical systems embedding with a physics-informed convolutional network

Matt Ricci,Noa Moriel,Zoe Piran,Mor Nitzan

Dynamical systems are found in innumerable forms across the physical and biological sciences, yet all these systems fall naturally into equivalence classes: conservative or dissipative, stable or unstable, compressible or incompressible. Predicting these classes from data remains an essential open challenge in computational physics on which existing time-series classification methods struggle. Here, we propose, phase2vec, an embedding method that learns high-quality, physically-meaningful representations of low-dimensional dynamical systems without supervision. Our embeddings are produced by a convolutional backbone that extracts geometric features from flow data and minimizes a physically-informed vector field reconstruction loss. The trained architecture can not only predict the equations of unseen data, but also produces embeddings that encode meaningful physical properties of input data (e.g. stability of fixed points, conservation of energy, and the incompressibility of flows) more faithfully than standard blackbox classifiers and state-of-the-art time series classification techniques. We additionally apply our embeddings to the analysis of meteorological data, showing we can detect climatically meaningful features. Collectively, our results demonstrate the viability of embedding approaches for the discovery of dynamical features in physical systems.

Learning Harmonic Molecular Representations on Riemannian Manifold

Yiqun Wang,Yuning Shen,Shi Chen,Lihao Wang,Fei YE,Hao Zhou

Molecular representation learning plays a crucial role in AI-assisted drug discovery research. Encoding 3D molecular structures through Euclidean neural networks has become the prevailing method in the geometric deep learning community. However, the equivariance constraints and message passing in Euclidean space may limit the network expressive power. In this work, we propose a Harmonic Molecular Representation learning (HMR) framework, which represents a molecule using the Laplace-Beltrami eigenfunctions of the molecular surface. HMR offers a multi-resolution representation of molecular geometric and chemical properties on 2D Riemannian manifold. We also introduce a harmonic message passing method to realize efficient spectral message passing over the surface manifold for better molecular encoding. Our proposed method shows comparable predictive power to current models in small molecule property prediction, and outperforms the state-of-the-art deep learning models for the rigid protein docking challenge, demonstrating its versatility in molecular representation learning.

****

When is Offline Hyperparameter Selection Feasible for Reinforcement Learning?

Vincent Liu,Prabhat Nagarajan,Andrew Patterson,Martha White

Hyperparameter selection is a critical procedure before deploying reinforcement learning algorithms in real-world applications. However, hyperparameter selection prior to deployment requires selecting policies offline without online execution, which is a significant challenge known as offline policy selection. As yet, there is little understanding about the fundamental limitations of the offline policy selection problem. To contribute to our understanding of this problem, in this paper, we investigate when sample efficient offline policy selection is possible. As off-policy policy evaluation (OPE) is a natural approach for policy selection, the sample complexity of offline policy selection is therefore upper-bounded by the number of samples needed to perform OPE. In addition, we prove that the sample complexity of offline policy selection is also lower-bounded by the sample complexity of OPE. These results imply not only that offline policy selection is effective when OPE is effective, but also that sample efficient policy selection is not possible without additional assumptions that make OPE effective. Moreover, we theoretically study the conditions under which offline policy selection using Fitted Q evaluation (FQE) and the Bellman error is sample efficient. We conclude with an empirical study comparing FQE and Bellman errors for offlin e policy selection.

Plansformer: Generating Multi-Domain Symbolic Plans using Transformers

Vishal Pallagani,Bharath Chandra Muppasani,Keerthiram Murugesan,Francesca Rossi,Lior Horesh,Biplav Srivastava,Francesco Fabiano,Andrea Loreggia

Large Language Models (LLMs) have been the subject of active research, significantly advancing the field of Natural Language Processing (NLP). From BERT to BLOOM, LLMs have surpassed state-of-the-art results in various natural language tasks such as question answering, summarization, and text generation. Many ongoing efforts are focused on understanding LLMs' capabilities, including their knowledge of the world, syntax, and semantics. However, extending the textual prowess of LLMs to symbolic reasoning has been slow and predominantly focused on tackling problems related to the mathematical field. In this paper, we explore the use of LLMs for automated planning - a branch of AI concerned with the realization of action sequences (plans) to achieve a goal, typically for execution by intelligent agents, autonomous robots, and unmanned vehicles. We introduce Plansformer; an LLM fine-tuned on planning problems and capable of generating plans with favorable behavior in terms of correctness and length with minimal knowledge-engineering efforts. We also demonstrate the adaptability of Plansformer in solving different planning domains with varying complexities, owing to the transfer learning abilities of LLMs. For one configuration of Plansformer, we achieve ~97\% valid plans, out of which ~95\% are optimal for Towers of Hanoi - a puzzle-solving domain.

****

Greedy Actor-Critic: A New Conditional Cross-Entropy Method for Policy Improvement

Samuel Neumann,Sungsu Lim,Ajin George Joseph,Yangchen Pan,Adam White,Martha White

Many policy gradient methods are variants of Actor-Critic (AC), where a value function (critic) is learned to facilitate updating the parameterized policy (actor). The update to the actor involves a log-likelihood update weighted by the action-values, with the addition of entropy regularization for soft variants. In this work, we explore an alternative update for the actor, based on an extension of the cross entropy method (CEM) to condition on inputs (states). The idea is to start with a broader policy and slowly concentrate around maximal actions, using a maximum likelihood update towards actions in the top percentile per state. The speed of this concentration is controlled by a proposal policy, that concentrates at a slower rate than the actor. We first provide a policy improvement result in an idealized setting, and then prove that our conditional CEM (CCEM) strategy tracks a CEM update per state, even with changing action-values. We empirically show that our Greedy AC algorithm, that uses CCEM for the actor update, performs better than Soft Actor-Critic and is much less sensitive to entropy-regularization.

****

VISION TRANSFORMER FOR MULTIVARIATE TIME- SERIES CLASSIFICATION (VITMTSC)

Prem Shankar Kumar,Ashutosh Joshi,Srinivas Adavi

Multivariate Time-Series Classification (MTSC) is an important issue in many disciplines because of the proliferation of disparate data sources and sensors (economics, retail, health, etc.). Nonetheless, it remains difficult due to the high-dimensionality and richness of data that is regularly updated. We present a Vision Transformer for Multivariate Time-Series Classification (VitMTSC) model that learns latent features from raw time-series data for classification tasks and is applicable to large-scale time-series data with millions of data samples of variable lengths. According to our knowledge, this is the first implementation of the Vision Transformer (ViT) for MTSC. We demonstrate that our approach works on datasets ranging from a few thousand to millions of samples and achieves close to the state-of-the-art (SOTA) results on open datasets. Using click-stream data from a major retail website, we demonstrate that our model can scale to millions of samples and vastly outperform previous neural net-based MTSC models in real-world applications. Our source code is publicly accessible at https://github.co m/mtsc-research/vitmtsc to facilitate further research.

****

Multi-Environment Pretraining Enables Transfer to Action Limited Datasets

David Venuto,Sherry Yang,Pieter Abbeel,Doina Precup,Igor Mordatch,Ofir Nachum

Using massive datasets to train large-scale models has emerged as a dominant approach for broad generalization in natural language and vision applications. In reinforcement learning, however, a key challenge is that available data of sequential decision making is often not annotated with actions - for example, videos of game-play are much more available than sequences of frames paired with the logged game controls. We propose to circumvent this challenge by combining large but sparsely-annotated datasets from a \emph{target} environment of interest with fully-annotated datasets from various other \emph{source} environments. Our method, Action Limited PreTraining (ALPT), leverages the generalization capabilities of inverse dynamics modelling (IDM) to label missing action data in the target environment. We show that utilizing even one additional environment dataset of labelled data during IDM pretraining gives rise to substantial improvements in generating action labels for unannotated sequences. We evaluate our method on benchmark game-playing environments and show that we can significantly improve game performance and generalization capability compared to other approaches, even when using annotated datasets equivalent to only 12 minutes of gameplay.

****

Efficiently Controlling Multiple Risks with Pareto Testing

Bracha Laufer-Goldshtein,Adam Fisch,Regina Barzilay,Tommi S. Jaakkola

Machine learning applications frequently come with multiple diverse objectives and constraints that can change over time. Accordingly, trained models can be tuned with sets of hyper-parameters that affect their predictive behavior (e.g., their run-time efficiency versus error rate). As the number of constraints and hyper-parameter dimensions grow, naively selected settings may lead to sub-optimal and/or unreliable results. We develop an efficient method for calibrating models such that their predictions provably satisfy multiple explicit and simultaneous statistical guarantees (e.g., upper-bounded error rates), while also optimizing any number of additional, unconstrained objectives (e.g., total run-time cost). Building on recent results in distribution-free, finite-sample risk control for general losses, we propose Pareto Testing: a two-stage process which combines multi-objective optimization with multiple hypothesis testing. The optimization stage constructs a set of promising combinations on the Pareto frontier. We then apply statistical testing to this frontier only to identify configurations that have (a) high utility with respect to our objectives, and (b) guaranteed risk levels with respect to our constraints, with specifiably high probability. We demonstrate the effectiveness of our approach to reliably accelerate the execution of large-scale Transformer models in natural language processing (NLP) applications. In particular, we show how Pareto Testing can be used to dynamically configure multiple inter-dependent model attributes—including the number of layers computed before exiting, number of attention heads pruned, or number of text tokens considered—to simultaneously control and optimize various accuracy and cost metrics.

****

Graph Mixup with Soft Alignments

Hongyi Ling,Zhimeng Jiang,Meng Liu,Shuiwang Ji,Na Zou

We study graph data augmentation by mixup, which has been used successfully on images. A key operation of mixup is to compute a convex combination of a pair of inputs. This operation is straightforward for grid-like data, such as images, but challenging for graph data. The key difficulty lies in the fact that different graphs typically have different numbers of nodes, and thus there lacks a node-level correspondence between graphs. In this work, we propose a simple yet effective mixup method for graph classification by soft alignments. Specifically, given a pair of graphs, we explicitly obtain node-level correspondence via computing a soft assignment matrix to match the nodes between two graphs. Based on the so ft assignments, we transform the adjacency and node feature matrices of one graph, so that the transformed graph is aligned with the other graph. In this way, any pair of graphs can be mixed directly to generate an augmented graph. We conduct systematic experiments to show that our method can improve the performance and generalization of graph neural networks (GNNs) on various graph classification tasks. In addition, we show that our method can increase the robustness of GNNs against noisy labels.

****

CNN Compression and Search Using Set Transformations with Width Modifiers on Network Architectures

Bilal Siddiqui,Dakai Zhu

We propose a new approach, based on discrete filter pruning, to adapt off-the-shelf models into an embedded environment. Importantly, we circumvent the usually prohibitive costs of model compression. Our method, Structured Coarse Block Pruning (SCBP), prunes whole CNN kernels using width modifiers applied to a novel transformation of convlayers into superblocks. SCBP uses set representations to construct a rudimentary search to provide candidate networks. To test our approach, the original ResNet architectures serve as the baseline and also provide the 'seeds' for our candidate search. The search produces a configurable number of compressed (derived) models. These derived models are often ~20\% faster and ~50\% smaller than their unmodified counterparts. At the expense of accuracy, the size can become even smaller and the inference latency lowered even further. The unique SCBP transformations yield many new model variants, each with their own trade-offs, and does not require GPU clusters or expert humans for training and design.

****

Learning Interpretable Dynamics from Images of a Freely Rotating 3D Rigid Body

Justice Mason,Christine Allen-Blanchette,Nicholas F Zolman,Elizabeth Davison,Naomi Leonard

In many real-world settings, image observations of freely rotating 3D rigid bodies, such as satellites, may be available when low-dimensional measurements are not. However, the high-dimensionality of image data precludes the use of classical estimation techniques to learn the dynamics and a lack of interpretability reduces the usefulness of standard deep learning methods. In this work, we present a physics-informed neural network model to estimate and predict 3D rotational dynamics from image sequences. We achieve this using a multi-stage prediction pipeline that maps individual images to a latent representation homeomorphic to $\mathbf{SO}(3)$, computes angular velocities from latent pairs, and predicts future latent states using the Hamiltonian equations of motion with a learned representation of the Hamiltonian. We demonstrate the efficacy of our approach on a new rotating rigid-body dataset with sequences of rotating cubes and rectangular prisms with uniform and non-uniform density.

NOTELA: A Generalizable Method for Source Free Domain Adaptation

Malik Boudiaf,tom denton,Bart van Merrienboer,Vincent Dumoulin,Eleni Triantafillou

Source-free domain adaptation (SFDA) is a compelling problem as it allows to leverage any off-the-shelf model without requiring access to its original training set and adapts it using only unlabelled data. While several SFDA approaches have recently been proposed, their evaluation focuses on a narrow set of distribution shifts for vision tasks, and their generalizability outside of that scope has not yet been investigated. We put those recent approaches to the test by evaluating them on a new set of challenging---due to extreme covariate and label shift---and naturally-occurring distribution shifts in the audio domain. We study the task of adapting a bird species classifier trained on focalized recordings of bird songs to datasets of passive recordings for various geographical locations. I

nterestingly, we find that some recent SFDA methods underperform doing no adaptation at all. Drawing inspiration from those findings and insights, we propose a new method that improves on noisy student approaches by adjusting the teacher's pseudo-labels through Laplacian regularization. Our approach enjoys increased stability and significantly better performance on several of our proposed distribution shifts. We then look back at SFDA benchmarks in the vision domain and find that our approach is competitive with the state-of-the-art there as well.

Characteristic Neural Ordinary Differential Equation
Xingzi Xu,Ali Hasan,Khalil Elkhalil,Jie Ding,Vahid Tarokh

We propose Characteristic-Neural Ordinary Differential Equations (C-NODEs), a framework for extending Neural Ordinary Differential Equations (NODEs) beyond ODEs. While NODE models the evolution of latent variables as the solution to an ODE, C-NODE models the evolution of the latent variables as the solution of a family of first-order partial differential equations (PDEs) along curves on which the PDEs reduce to ODEs, referred to as characteristic curves. This reduction along characteristic curves allows for analyzing PDEs through standard techniques used for ODEs, in particular the adjoint sensitivity method. We also derive C-NODE-based continuous normalizing flows, which describe the density evolution of latent variables along multiple dimensions. Empirical results demonstrate the improvements provided by the proposed method for irregularly sampled time series prediction on MuJoCo, PhysioNet, and Human Activity datasets and classification and density estimation on CIFAR-10, SVHN, and MNIST datasets given a similar computational budget as the existing NODE methods.

The results also provide empirical evidence that the learned curves improve the system efficiency using a lower number of parameters and function evaluations compared with those of the baselines.

Fast Sampling of Diffusion Models with Exponential Integrator
Qinsheng Zhang,Yongxin Chen

The past few years have witnessed the great success of Diffusion models~(DMs) in generating high-fidelity samples in generative modeling tasks. A major limitation of the DM is its notoriously slow sampling procedure which normally requires hundreds to thousands of time discretization steps of the learned diffusion process to reach the desired accuracy. Our goal is to develop a fast sampling method for DMs with a much less number of steps while retaining high sample quality. To this end, we systematically analyze the sampling procedure in DMs and identify key factors that affect the sample quality, among which the method of discretization is most crucial. By carefully examining the learned diffusion process, we propose Diffusion Exponential Integrator Sampler~(DEIS). It is based on the Exponential Integrator designed for discretizing ordinary differential equations (ODEs) and leverages a semilinear structure of the learned diffusion process to reduce the discretization error. The proposed method can be applied to any DMs and can generate high-fidelity samples in as few as 10 steps. Moreover, by directly using pre-trained DMs, we achieve state-of-art sampling performance when the number of score function evaluation~(NFE) is limited, e.g., 4.17 FID with 10 NFEs, 2.86 FID with only 20 NFEs on CIFAR10.

STay-On-the-Ridge (STON'R): Guaranteed Convergence to Local Minimax Equilibrium in Nonconvex-Nonconcave Games
Constantinos Costis Daskalakis,Noah Golowich,EFSTRATIOS PANTELEIMON SKOULAKIS,Emmanouil Zampetakis

Min-max optimization problems involving nonconvex-nonconcave objectives have found important applications in adversarial training and other multi-agent learning settings. Yet, no known gradient descent-based method is guaranteed to converge to (even local notions of) min-max equilibrium in the nonconvex-nonconcave setting. For all known methods, there exist relatively simple objectives for which they cycle or exhibit other undesirable behavior different from converging to a point, let alone to some game-theoretically meaningful one [Flokas et al. '19, Hsieh et al. '21]. The only known convergence guarantees hold under the strong ass umption that the initialization is very close to a local min-max equilibrium [Wang et al. '19]. Moreover, the afore-described challenges are not just theoretical curiosities. All known methods are unstable in practice, even in simple settings.

We propose the first method that is guaranteed to converge to a local min-max equilibrium for smooth nonconvex-nonconcave objectives. Our method is second-order and provably escapes limit cycles as long as it is initialized at an easy-to-find initial point. Both the definition of our method and its convergence analysis are motivated by the topological nature of the problem. In particular, our method is not designed to decrease some potential function, such as the distance of its iterate from the set of local min-max equilibria or the projected gradient of the objective, but is designed to satisfy a topological property that guarantees the avoidance of cycles and implies its convergence.

Federated Representation Learning via Maximal Coding Rate Reduction

Juan Cervino,Navid Naderializadeh,Alejandro Ribeiro

We propose a federated methodology to learn low-dimensional representations from a dataset that is distributed among several clients. In particular, we move away from the commonly-used cross-entropy loss in federated learning, and seek to learn shared low-dimensional representations of the data in a decentralized manner via the principle of maximal coding rate reduction (MCR2). Our proposed method, which we refer to as FLOW, utilizes MCR2 as the objective of choice, hence resulting in representations that are both between-class discriminative and within-class compressible. We theoretically show that our distributed algorithm achieves a first-order stationary point. Moreover, we demonstrate, via numerical experiments, the utility of the learned low-dimensional representations.

3D Surface Reconstruction in the Wild by Deforming Shape Priors from Synthetic Data

Nicolai Haeni,Jun-Jee Chao,Volkan Isler

We present a new method for category-specific 3D reconstruction from a single image. A limitation of current color image-based 3D reconstruction models is that they do not generalize across datasets, due to domain shift. In contrast, we show that one can learn to reconstruct objects across datasets by shape priors learned from synthetic 3D data and a point cloud pose canonicalization method. Given a single depth image at test time, we first place this partial point cloud in a canonical pose. Then, we use a neural deformation field in the canonical coordinate frame to reconstruct the 3D surface of the object. Finally, we jointly optimize object pose and 3D shape to fit the partial depth observation. Our approach achieves state-of-the-art reconstruction performance across several real-world datasets, even when trained without ground truth camera poses (which are required by some of the state-of-the-art methods). We further show that our method generalizes to different input modalities, from dense depth images to sparse and noisy LIDAR scans.
****

gDDIM: Generalized denoising diffusion implicit models

Qinsheng Zhang,Molei Tao,Yongxin Chen

Our goal is to extend the denoising diffusion implicit model (DDIM) to general diffusion models~(DMs) besides isotropic diffusions. Instead of constructing a non-Markov noising process as in the original DDIM, we examine the mechanism of DDIM from a numerical perspective. We discover that the DDIM can be obtained by using some specific approximations of the score when solving the corresponding stochastic differential equation. We present an interpretation of the accelerating effects of DDIM that also explains the advantages of a deterministic sampling scheme over the stochastic one for fast sampling. Building on this insight, we extend DDIM to general DMs, coined generalized DDIM (gDDIM), with a small but delicate modification in parameterizing the score network. We validate gDDIM in two non-isotropic DMs: Blurring diffusion model (BDM) and Critically-damped Langevin diffusion model (CLD). We observe more than 20 times acceleration in BDM. In th e CLD, a diffusion model by augmenting the diffusion process with velocity, our algorithm achieves an FID score of 2.26, on CIFAR10, with only 50 number of score function evaluations~(NFEs) and an FID score of 2.86 with only 27 NFEs.

Panning for Gold in Federated Learning: Targeted Text Extraction under Arbitrarily Large-Scale Aggregation

Hong-Min Chu,Jonas Geiping,Liam H Fowl,Micah Goldblum,Tom Goldstein

As federated learning (FL) matures, privacy attacks against FL systems in turn become more numerous and complex. Attacks on language models have progressed from recovering single sentences in simple classification tasks to recovering larger parts of user data. Current attacks against federated language models are sequence-agnostic and aim to extract as much data as possible from an FL update - often at the expense of fidelity for any particular sequence. Because of this, current attacks fail to extract any meaningful data under large-scale aggregation. In realistic settings, an attacker cares most about a small portion of user data that contains sensitive personal information, for example sequences containing the phrase "my credit card number is ...". In this work, we propose the first attack on FL that achieves targeted extraction of sequences that contain privacy-critical phrases, whereby we employ maliciously modified parameters to allow the transformer itself to filter relevant sequences from aggregated user data and encode them in the gradient update. Our attack can effectively extract sequences of interest even against extremely large-scale aggregation.

Artificial Neuronal Ensembles with Learned Context Dependent Gating

Matthew James Tilley,Michelle Miller,David Freedman

Biological neural networks are capable of recruiting different sets of neurons to encode different memories. However, when training artificial neural networks on a set of tasks, typically, no mechanism is employed for selectively producing anything analogous to these neuronal ensembles. Further, artificial neural networks suffer from catastrophic forgetting, where the network's performance rapidly deteriorates as tasks are learned sequentially. By contrast, sequential learning is possible for a range of biological organisms. We introduce Learned Context Dependent Gating (LXDG), a method to flexibly allocate and recall `artificial neuronal ensembles', using a particular network structure and a new set of regularization terms. Activities in the hidden layers of the network are modulated by gates, which are dynamically produced during training. The gates are outputs of networks themselves, trained with a sigmoid output activation. The regularization terms we have introduced correspond to properties exhibited by biological neuronal ensembles. The first term penalizes low gate sparsity, ensuring that only a specified fraction of the network is used. The second term ensures that previously learned gates are recalled when the network is presented with input from previously learned tasks. Finally, there is a regularization term responsible for ensuring that new tasks are encoded in gates that are as orthogonal as possible from previously used ones. We demonstrate the ability of this method to alleviate catastrophic forgetting on continual learning benchmarks. When the new regularization terms are included in the model along with Elastic Weight Consolidation (EWC) it achieves better performance on the benchmark `permuted MNIST' than with EWC alone. The benchmark `rotated MNIST' demonstrates how similar tasks recruit similar neurons to the artificial neuronal ensemble.

Linkless Link Prediction via Relational Distillation

Zhichun Guo,William Shiao,Shichang Zhang,Yozen Liu,Nitesh Chawla,Neil Shah,Tong Zhao

Graph Neural Networks (GNNs) have been widely used on graph data and have shown exceptional performance in the task of link prediction. Despite their effectiveness, GNNs often suffer from high latency due to non-trivial neighborhood data dependency in practical deployments. To address this issue, researchers have proposed methods based on knowledge distillation (KD) to transfer the knowledge from teacher GNNs to student MLPs, which are known to be efficient even with industrial scale data, and have shown promising results on node classification. Nonethel ess, using KD to accelerate link prediction is still unexplored. In this work, we start with exploring two direct analogs of traditional KD for link prediction, i.e., predicted logit-based matching and node representation-based matching. Upon observing direct KD analogs do not perform well for link prediction, we propose a relational KD framework, Linkless Link Prediction (LLP). Unlike simple KD methods that match independent link logits or node representations, LLP distills relational knowledge that is centered around each (anchor) node to the student MLP. Specifically, we propose two matching strategies that complement each other: rank-based matching and distribution-based matching. Extensive experiments demonstrate that LLP boosts the link prediction performance of MLPs with significant margins, and even outperforms the teacher GNNs on 6 out of 9 benchmarks. LLP also achieves a 776.37x speedup in link prediction inference compared to GNNs on the large scale Citation2 dataset.

A Differentiable Loss Function for Learning Heuristics in A*

Leah Chrestien,Tomáš Pevný,Antonin Komenda,Stefan Edelkamp

Optimization of heuristic functions for the A* algorithm, realized by deep neural networks, is usually done by minimizing square root loss of estimate of the cost to goal values. This paper argues that this does not necessarily lead to a faster search of A* algorithm since its execution relies on relative values instead of absolute ones. As a mitigation, we propose a L* loss, which upper-bounds the number of excessively expanded states inside the A* search. The L* loss, when used in the optimization of state-of-the-art deep neural networks for automated planning in maze domains like Sokoban and maze with teleports, significantly improves the fraction of solved problems, the quality of founded plans, and reduces the number of expanded states to approximately 50%

Understanding Multi-Task Scaling in Machine Translation

Patrick Fernandes,Behrooz Ghorbani,Xavier Garcia,Markus Freitag,Orhan Firat

In this work, we provide a large-scale empirical study of the scaling properties of multilingual (multitask) neural machine translation models. We examine how increases in the model size affect the model performance and investigate the role of the individual task weights on the scaling behavior. We find that these weights only affect the multiplicative factor of the scaling law and in particular, the scaling exponent is unaffected by them. Through a novel joint scaling law formulation, we compute the effective number of parameters allocated to each task and examine the role of language similarity in the scaling behavior of our models. We find minimal evidence that language similarity has any impact. In contrast, ``direction'' of the multilinguality plays a big role, with models translating from multiple languages into English having a larger number of effective parameters per task than their reversed counterparts. Finally, we leverage our observations to predict the performance of multilingual models trained with any language weighting at any scale, greatly reducing efforts required for task balancing in large multitask models. Our findings apply to both in-domain and out-of-domain test sets and to multiple evaluation metrics, such as ChrF and BLEURT.

Learning Language Representations with Logical Inductive Bias

Jianshu Chen

Transformer architectures have achieved great success in solving natural language tasks, which learn strong language representations from large-scale unlabeled texts. In this paper, we seek to go further beyond and explore a new logical inductive bias for better language representation learning. Logic reasoning is known as a formal methodology to reach answers from given knowledge and facts. Inspired by such a view, we develop a novel neural architecture named FOLNet (First-Order Logic Network), to encode this new inductive bias. We construct a set of neural logic operators as learnable Horn clauses, which are further forward-chained into a fully differentiable neural architecture (FOLNet). Interestingly, we find that the self-attention module in transformers can be composed by two of our neural logic operators, which probably explains their strong reasoning performance. Our proposed FOLNet has the same input and output interfaces as other pretra

ined models and thus could be pretrained/finetuned by using similar losses. It also allows FOLNet to be used in a plug-and-play manner when replacing other pretrained models. With our logical inductive bias, the same set of ``logic deduction skills'' learned through pretraining are expected to be equally capable of solving diverse downstream tasks. For this reason, FOLNet learns language representations that have much stronger transfer capabilities. Experimental results on several language understanding tasks show that our pretrained FOLNet model outperforms the existing strong transformer-based approaches.

AsymQ: Asymmetric Q-loss to mitigate overestimation bias in off-policy reinforcement learning
Qinsheng Zhang,Arjun Krishna,Sehoon Ha,Yongxin Chen
It is well-known that off-policy deep reinforcement learning algorithms suffer from overestimation bias in value function approximation. Existing methods to reduce overestimation bias often utilize multiple value function estimators. Consequently, these methods have a larger time and memory consumption. In this work, we propose a new class of policy evaluation algorithms dubbed, \textbf{AsymQ}, that use asymmetric loss functions to train the Q-value network. Departing from the symmetric loss functions such as mean squared error~(MSE) and Huber loss on the Temporal difference~(TD) error, we adopt asymmetric loss functions of the TD-error to impose a higher penalty on overestimation error. We present one such AsymQ loss called \textbf{Softmax MSE~(SMSE)} that can be implemented with minimal modifications to the standard policy evaluation. Empirically, we show that using SMSE loss helps reduce estimation bias, and subsequently improves policy performance when combined with standard reinforcement learning algorithms. With SMSE, even the Deep Deterministic Policy Gradients~(DDPG) algorithm can achieve performance comparable to that of state-of-the-art methods such as the Twin-Delayed DDPG (TD3) and Soft Actor Critic~(SAC) on challenging environments in the OpenAI Gym MuJoCo benchmark. We additionally demonstrate that the proposed SMSE loss can also boost the performance of Deep Q learning (DQN) in Atari games with discrete action spaces.

Movement-to-Action Transformer Networks for Temporal Action Proposal Generation
Xiaodan Hu,Narendra Ahuja
The task of generating temporal action proposals is aimed at identifying temporal intervals containing human actions in untrimmed videos. For arbitrary actions, this requires learning long-range interactions. We propose an end-to-end Movement-and-Action Transformer Network (MatNet) that uses results of human movement studies to encode actions ranging from localized, atomic, body part movements, to longer-range, semantic ones, involving movements of subsets of body parts. In particular, we make direct use of the results of Laban Movement Analysis (LMA). We use LMA-based measures of movements as computational definitions of actions. We input RGB + Flow (I3D) features and 3D pose, compute LMA based low-to-high-level movement features from it, and learn the action proposals by applying two heads on the boundary Transformer and three heads on the proposal Transformer, and using five losses with different weights. We visualize and explain relations between the movement descriptors and attention map of the action proposals. We report results from extensive experiments on the Thumos14, ActivityNet and PKU-MMD datasets, showing that MatNet achieves SOTA or better performance on the temporal action proposal generation task.

INSPIRE: A Framework for Integrating Individual User Preferences in Recourse
Prateek Yadav,Peter Hase,Mohit Bansal
Most recourse generation approaches optimize for indirect distance-based metrics like diversity, proximity, and sparsity, or a shared cost function across all users to generate recourse. The latter is an unrealistic assumption because users can have diverse feature preferences which they might be willing to act upon and any changes to any undesirable feature might lead to an impractical recourse. In this work, we propose a novel framework to incorporate the individuality of users in both recourse generation and evaluation procedure by focusing on the cos

t incurred by a user when opting for a recourse. To achieve this, we first propose an objective function, Expected Minimum Cost (EMC) that is based on two key ideas: (1) the user should be comfortable adopting at least one solution when presented with multiple options, and (2) we can approximately optimize for users' satisfaction even when their true cost functions (i.e., costs associated with feature changes) are unknown. EMC samples multiple plausible cost functions based on diverse feature preferences in the population and then finds a recourse set with one good solution for each category of user preferences. We optimize EMC with a novel discrete optimization algorithm, Cost-Optimized Local Search (COLS), that is guaranteed to improve the quality of the recourse set over iterations. Our evaluation framework computes the fraction of satisfied users by simulating each user's cost function and then computing the incurred cost for the provided recourse set. Experimental evaluation on popular real-world datasets demonstrates that our method satisfies up to 25.9% more users compared to strong baselines. Moreover, the human evaluation shows that our recourses are preferred more than twice as often as the strongest baseline.

How Does Semi-supervised Learning with Pseudo-labelers Work? A Case Study

Yiwen Kou,Zixiang Chen,Yuan Cao,Quanquan Gu

Semi-supervised learning is a popular machine learning paradigm that utilizes a large amount of unlabeled data as well as a small amount of labeled data to facilitate learning tasks. While semi-supervised learning has achieved great success in training neural networks, its theoretical understanding remains largely open. In this paper, we aim to theoretically understand a semi-supervised learning approach based on pre-training and linear probing. In particular, the semi-supervised learning approach we consider first trains a two-layer neural network based on the unlabeled data with the help of pseudo-labelers. Then it linearly probes the pre-trained network on a small amount of labeled data. We prove that, under a certain toy data generation model and two-layer convolutional neural network, the semisupervised learning approach can achieve nearly zero test loss, while a neural network directly trained by supervised learning on the same amount of labeled data can only achieve constant test loss. Through this case study, we demonstrate a separation between semi-supervised learning and supervised learning in terms of test loss provided the same amount of labeled data.

Empowering Graph Representation Learning with Test-Time Graph Transformation

Wei Jin,Tong Zhao,Jiayuan Ding,Yozen Liu,Jiliang Tang,Neil Shah

As powerful tools for representation learning on graphs, graph neural networks (GNNs) have facilitated various applications from drug discovery to recommender systems. Nevertheless, the effectiveness of GNNs is immensely challenged by issues related to data quality, such as distribution shift, abnormal features and adversarial attacks. Recent efforts have been made on tackling these issues from a modeling perspective which requires additional cost of changing model architectures or re-training model parameters. In this work, we provide a data-centric view to tackle these issues and propose a graph transformation framework named GTrans which adapts and refines graph data at test time to achieve better performance. We provide theoretical analysis on the design of the framework and discuss why adapting graph data works better than adapting the model. Extensive experiments have demonstrated the effectiveness of GTrans on three distinct scenarios for eight benchmark datasets where suboptimal data is presented. Remarkably, GTrans performs the best in most cases with improvements up to 2.8%, 8.2% and 3.8% over the best baselines on three experimental settings.

Provable Robustness against Wasserstein Distribution Shifts via Input Randomization

Aounon Kumar,Alexander Levine,Tom Goldstein,Soheil Feizi

Certified robustness in machine learning has primarily focused on adversarial perturbations with a fixed attack budget for each sample in the input distribution. In this work, we present provable robustness guarantees on the accuracy of a model under bounded Wasserstein shifts of the data distribution. We show that a s

imple procedure that randomizes the input of the model within a transformation space is provably robust to distributional shifts under that transformation. Our framework allows the datum-specific perturbation size to vary across different points in the input distribution and is general enough to include fixed-sized perturbations as well. Our certificates produce guaranteed lower bounds on the performance of the model for any shift (natural or adversarial) of the input distribution within a Wasserstein ball around the original distribution. We apply our technique to certify robustness against natural (non-adversarial) transformations of images such as color shifts, hue shifts, and changes in brightness and saturation. We obtain strong performance guarantees for the robust model under clearly visible shifts in the input images. Our experiments establish the non-vacuousness of our certificates by showing that the certified lower bound on a robust model's accuracy is higher than the empirical accuracy of an undefended model under a distribution shift. Moreover, our results also imply guaranteed lower bounds (hardness result) on the performance of models trained on so-called "unlearnable" datasets that have been poisoned to interfere with model training. We show that the performance of a robust model is guaranteed to remain above a certain threshold on the test distribution even when the base model is trained on the poisoned dataset.
****
GROOT: Corrective Reward Optimization for Generative Sequential Labeling
Kazuma Hashimoto,Karthik Raman
Sequential labeling is a fundamental NLP task, forming the backbone of many applications.
Supervised learning of Seq2Seq models (like T5) has shown great success on these problems.
However there remains a significant disconnect between the training objectives of these models vs the metrics and desiderata we care about in practical applications.
For example, a practical sequence tagging application may want to optimize for a certain precision-recall trade-off (of the top-k predictions) which is quite different from the standard objective of maximizing the likelihood of the gold labeled sequence.
Thus to bridge this gap, we propose GROOT -- a simple yet effective framework for Generative Reward Optimization Of Text sequences.
GROOT works by training a generative sequential labeling model to match the decoder output distribution with that of the (black-box) reward function.
Using an iterative training regime, we first generate prediction candidates, then correct errors in them, and finally contrast those candidates (based on their reward values).
As demonstrated via extensive experiments on four public benchmarks, GROOT significantly improves all reward metrics.
Furthermore, GROOT also leads to improvements of the overall decoder distribution as evidenced by the quality gains of the top-k candidates.
****
Interpretations of Domain Adaptations via Layer Variational Analysis
Huan-Hsin Tseng,Hsin-Yi Lin,Kuo-Hsuan Hung,Yu Tsao
Transfer learning is known to perform efficiently in many applications empirically, yet limited literature reports the mechanism behind the scene. This study establishes both formal derivations and heuristic analysis to formulate the theory of transfer learning in deep learning. Our framework utilizing layer variational analysis proves that the success of transfer learning can be guaranteed with corresponding data conditions. Moreover, our theoretical calculation yields intuitive interpretations towards the knowledge transfer process. Subsequently, an alternative method for network-based transfer learning is derived. The method shows an increase in efficiency and accuracy for domain adaptation. It is particularly advantageous when new domain data is sufficiently sparse during adaptation. Numerical experiments over diverse tasks validated our theory and verified that our analytic expression achieved better performance in domain adaptation than the gradient descent method.

****

Forget Unlearning: Towards True Data-Deletion in Machine Learning

Rishav Chourasia,Neil Shah,Reza Shokri

Unlearning has emerged as a technique to efficiently erase information of deleted records from learned models. We show, however, that the influence created by the original presence of a data point in the training set can still be detected after running certified unlearning algorithms (which can result in its reconstruction by an adversary). Thus, under realistic assumptions about the dynamics of model releases over time and in the presence of adaptive adversaries, we show that unlearning is not equivalent to data deletion and does not guarantee the "right to be forgotten." We then propose a more robust data-deletion guarantee and show that it is necessary to satisfy differential privacy to ensure true data deletion. Under our notion, we propose an accurate, computationally efficient, and secure data-deletion machine learning algorithm in the online setting based on noisy gradient descent algorithm.

Evaluating Unsupervised Denoising Requires Unsupervised Metrics

Adria Marcos Morales,Matan Leibovich,Sreyas Mohan,Joshua Lawrence Vincent,Piyush Haluai,MAI TAN,Peter Crozier,Carlos Fernandez-Granda

Unsupervised denoising is a crucial challenge in real-world imaging applications. Unsupervised deep-learning methods have demonstrated impressive performance on benchmarks based on synthetic noise. However, no metrics are available to evaluate these methods in an unsupervised fashion. This is highly problematic for the many practical applications where ground-truth clean images are not available. In this work, we propose two novel metrics: the unsupervised mean squared error (MSE) and the unsupervised peak signal-to-noise ratio (PSNR), which are computed using only noisy data. We provide a theoretical analysis of these metrics, showing that they are asymptotically consistent estimators of the supervised MSE and PSNR. Controlled numerical experiments with synthetic noise confirm that they provide accurate approximations in practice. We validate our approach on real-world data from two imaging modalities: videos in raw format and transmission electron microscopy. Our results demonstrate that the proposed metrics enable unsupervised evaluation of denoising methods based exclusively on noisy data.

****

Denoising Diffusion Samplers

Francisco Vargas,Will Sussman Grathwohl,Arnaud Doucet

Denoising diffusion models are a popular class of generative models providing state-of-the-art results in many domains. One adds gradually noise to data using a diffusion to transform the data distribution into a Gaussian distribution. Samples from the generative model are then obtained by simulating an approximation of the time-reversal of this diffusion initialized by Gaussian samples. Practically, the intractable score terms appearing in the time-reversed process are approximated using score matching techniques. We explore here a similar idea to sample approximately from unnormalized probability density functions and estimate their normalizing constants. We consider a process where the target density diffuses towards a Gaussian. Denoising Diffusion Samplers (DDS) are obtained by approximating the corresponding time-reversal. While score matching is not applicable in this context, we can leverage many of the ideas introduced in generative modeling for Monte Carlo sampling. Existing theoretical results from denoising diffusion models also provide theoretical guarantees for DDS. We discuss the connections between DDS, optimal control and Schr\"odinger bridges and finally demonstrate DDS experimentally on a variety of challenging sampling tasks.

How I Learned to Stop Worrying and Love Retraining

Max Zimmer,Christoph Spiegel,Sebastian Pokutta

Many Neural Network Pruning approaches consist of several iterative training and pruning steps, seemingly losing a significant amount of their performance after pruning and then recovering it in the subsequent retraining phase. Recent works of Renda et al. (2020) and Le & Hua (2021) demonstrate the significance of the learning rate schedule during the retraining phase and propose specific heuristi cs for choosing such a schedule for IMP (Han et al., 2015). We place these findings in the context of the results of Li et al. (2020) regarding the training of models within a fixed training budget and demonstrate that, consequently, the retraining phase can be massively shortened using a simple linear learning rate schedule. Improving on existing retraining approaches, we additionally propose a method to adaptively select the initial value of the linear schedule. Going a step further, we propose similarly imposing a budget on the initial dense training phase and show that the resulting simple and efficient method is capable of outperforming significantly more complex or heavily parameterized state-of-the-art approaches that attempt to sparsify the network during training. These findings not only advance our understanding of the retraining phase, but more broadly question the belief that one should aim to avoid the need for retraining and reduce the negative effects of ‘hard’ pruning by incorporating the sparsification process into the standard training.

****

The Value of Out-of-distribution Data

Ashwin De Silva,Rahul Ramesh,Carey Priebe,Pratik Chaudhari,Joshua T Vogelstein

More data is expected to help us generalize to a task. But real datasets can contain out-of-distribution (OOD) data; this can come in the form of heterogeneity such as intra-class variability but also in the form of temporal shifts or concept drifts. We demonstrate a counter-intuitive phenomenon for such problems: generalization error of the task can be a non-monotonic function of the number of OOD samples; a small number of OOD samples can improve generalization but if the number of OOD samples is beyond a threshold, then the generalization error can deteriorate. We also show that if we know which samples are OOD, then using a weighted objective between the target and OOD samples ensures that the generalization error decreases monotonically. We demonstrate and analyze this phenomenon using linear classifiers on synthetic datasets and medium-sized neural networks on vision benchmarks such as MNIST, CIFAR-10, CINIC-10, PACS, and DomainNet, and observe the effect data augmentation, hyperparameter optimization, and pre-training have on this behavior.

Factors Influencing Generalization in Chaotic Dynamical Systems

Luã Streit,Vikram Voleti,Tegan Maharaj

Many real-world systems exhibit chaotic behaviour, for example: weather, fluid dynamics, stock markets, natural ecosystems, and disease transmission. While chaotic systems are often thought to be completely unpredictable, in fact there are patterns within and across that experts frequently describe and contrast qualitatively. We hypothesize that given the right supervision / task definition, representation learning systems will be able to pick up on these patterns, and successfully generalize both in- and out-of-distribution (OOD).

Thus, this work explores and identifies key factors which lead to good generalization. We observe a variety of interesting phenomena, including: learned representations transfer much better when fine-tuned vs. frozen; forecasting appears to be the best pre-training task; OOD robustness falls off very quickly outside the training distribution; recurrent architectures generally outperform others on OOD generalization.

Our findings are of interest to any domain of prediction where chaotic dynamics play a role.

Interpretable Geometric Deep Learning via Learnable Randomness Injection

Siqi Miao,Yunan Luo,Mia Liu,Pan Li

Point cloud data is ubiquitous in scientific fields. Recently, geometric deep learning (GDL) has been widely applied to solve prediction tasks with such data. However, GDL models are often complicated and hardly interpretable, which poses concerns to scientists who are to deploy these models in scientific analysis and experiments. This work proposes a general mechanism, learnable randomness injection (LRI), which allows building inherently interpretable models based on general GDL backbones. LRI-induced models, once trained, can detect the points in the point cloud data that carry information indicative of the prediction label. We a lso propose four datasets from real scientific applications that cover the domains of high-energy physics and biochemistry to evaluate the LRI mechanism. Compared with previous post-hoc interpretation methods, the points detected by LRI align much better and stabler with the ground-truth patterns that have actual scientific meanings. LRI is grounded by the information bottleneck principle, and thus LRI-induced models are also more robust to distribution shifts between training and test scenarios. Our code and datasets are available at https://github.com/Graph-COM/LRI.

Koopman Operator Learning for Accelerating Quantum Optimization and Machine Learning

Di Luo,Jiayu Shen,Rumen Dangovski,Marin Soljacic

Finding efficient optimization methods plays an important role for quantum optimization and quantum machine learning on near-term quantum computers. While backpropagation on classical computers is computationally efficient, obtaining gradients on quantum computers is not, because the computational complexity scales linearly with the number of parameters and measurements. In this paper, we connect Koopman operator theory, which has been successful in predicting nonlinear dynamics, with natural gradient methods in quantum optimization. We propose a data-driven approach using Koopman operator learning to accelerate quantum optimization and quantum machine learning. We develop two new families of methods: the sliding window dynamic mode decomposition (DMD) and the neural DMD for efficiently updating parameters on quantum computers. We show that our methods can predict gradient dynamics on quantum computers and accelerate the quantum variational eigensolver used in quantum optimization, as well as quantum machine learning. We further implement the learning algorithms on a real quantum computer and demonstrate their practical effectiveness.

****

GOGGLE: Generative Modelling for Tabular Data by Learning Relational Structure

Tennison Liu,Zhaozhi Qian,Jeroen Berrevoets,Mihaela van der Schaar

Deep generative models learn highly complex and non-linear representations to generate realistic synthetic data. While they have achieved notable success in computer vision and natural language processing, similar advances have been less demonstrable in the tabular domain. This is partially because generative modelling of tabular data entails a particular set of challenges, including heterogeneous relationships, limited number of samples, and difficulties in incorporating prior knowledge. Additionally, unlike their counterparts in image and sequence domain, deep generative models for tabular data almost exclusively employ fully-connected layers, which encode weak inductive biases about relationships between inputs. Real-world data generating processes can often be represented using relational structures, which encode sparse, heterogeneous relationships between variables. In this work, we learn and exploit relational structure underlying tabular data to better model variable dependence, and as a natural means to introduce regularization on relationships and include prior knowledge. Specifically, we introduce GOGGLE, an end-to-end message passing scheme that jointly learns the relational structure and corresponding functional relationships as the basis of generating synthetic samples. Using real-world datasets, we provide empirical evidence that the proposed method is effective in generating realistic synthetic data and exploiting domain knowledge for downstream tasks.

A Reproducible and Realistic Evaluation of Partial Domain Adaptation Methods

Tiago Salvador,Kilian FATRAS,Ioannis Mitliagkas,Adam M Oberman

Unsupervised Domain Adaptation (UDA) aims at classifying unlabeled target images leveraging source labeled ones. In this work, we consider the Partial Domain Adaptation (PDA) variant, where we have extra source classes not present in the target domain. Most successful algorithms use model selection strategies that rely on target labels to find the best hyper-parameters and/or models along training. However, these strategies violate the main assumption in PDA: only unlabeled target domain samples are available. Moreover, there are also inconsistencies in the experimental settings - architecture, hyper-parameter tuning, number of runs

- yielding unfair comparisons. The main goal of this work is to provide a realistic evaluation of PDA methods with the different model selection strategies under a consistent evaluation protocol. We evaluate 7 representative PDA algorithms on 2 different real-world datasets using 7 different model selection strategies. Our two main findings are: (i) without target labels for model selection, the accuracy of the methods decreases up to 30 percentage points; (ii) only one method and model selection pair performs well on both datasets. Experiments were performed with our PyTorch framework, BenchmarkPDA, which we open source.

Progressive Prompts: Continual Learning for Language Models

Anastasia Razdaibiedina,Yuning Mao,Rui Hou,Madian Khabsa,Mike Lewis,Amjad Almahairi

We introduce Progressive Prompts – a simple and efficient approach for continual learning in language models. Our method allows forward transfer and resists catastrophic forgetting, without relying on data replay or a large number of task-specific parameters. Progressive Prompts learns a new soft prompt for each task and sequentially concatenates it with the previously learned prompts, while keeping the base model frozen. Experiments on standard continual learning benchmarks show that our approach outperforms state-of-the-art methods, with an improvement >20% in average test accuracy over the previous best-preforming method on T5 model. We also explore a more challenging continual learning setup with longer sequences of tasks and show that Progressive Prompts significantly outperforms prior methods.

Differentiable Rendering with Reparameterized Volume Sampling

Kirill Struminsky,Oleg Desheulin

We propose an alternative rendering algorithm for neural radiance fields based on importance sampling. In view synthesis, a neural radiance field approximates underlying density and radiance fields based on a sparse set of views of a scene. To generate a pixel of a novel view, it marches a ray through the pixel and computes a weighted sum of radiance emitted from a dense set of ray points. This rendering algorithm is fully differentiable and facilitates gradient-based optimization of the fields. However, in practice, only a tiny opaque portion of the ray contributes most of the radiance to the sum. Therefore, we can avoid computing radiance in the rest part. In this work, we use importance sampling to pick non-transparent points on the ray. Specifically, we generate samples according to the probability distribution induced by the density field. Our main contribution is the reparameterization of the sampling algorithm. It allows end-to-end learning with gradient descent as in the original rendering algorithm. With our approach, we can optimize a neural radiance field with just a few radiance field evaluations per ray. As a result, we alleviate the costs associated with the color component of the neural radiance field.

****

Deep Learning From Crowdsourced Labels: Coupled Cross-Entropy Minimization, Identifiability, and Regularization

Shahana Ibrahim,Tri Nguyen,Xiao Fu

Using noisy crowdsourced labels from multiple annotators, a deep learning-based end-to-end (E2E) system aims to learn the label correction mechanism and the neural classifier simultaneously. To this end, many E2E systems concatenate the neural classifier with multiple annotator-specific label confusion layers and co-train the two parts in a parameter-coupled manner. The formulated coupled cross-entropy minimization (CCEM)-type criteria are intuitive and work well in practice. Nonetheless, theoretical understanding of the CCEM criterion has been limited. The contribution of this work is twofold: First, performance guarantees of the CCEM criterion are presented. Our analysis reveals for the first time that the CCEM can indeed correctly identify the annotators' confusion characteristics and the desired ``ground-truth'' neural classifier under realistic conditions, e.g., when only incomplete annotator labeling and finite samples are available. Second, based on the insights learned from our analysis, two regularized variants of the CCEM are proposed. The regularization terms provably enhance the identifiabi lity of the target model parameters in various more challenging cases. A series of synthetic and real data experiments are presented to showcase the effectiveness of our approach.

Maximum Likelihood Learning of Energy-Based Models for Simulation-Based Inference

Pierre Glaser,Michael Arbel,Arnaud Doucet,Arthur Gretton

We introduce two Synthetic Likelihood methods for Simulation-Based Inference (SBI), to conduct either amortized or targeted inference from experimental observations when a high-fidelity simulator is available. Both methods learn a Conditional Energy-Based Model (EBM) of the likelihood using synthetic data generated by the simulator, conditioned on parameters drawn from a proposal distribution. The learned likelihood can then be combined with any prior to obtain a posterior estimate, from which samples can be drawn using MCMC.

Our methods uniquely combine a flexible Energy-Based Model and the minimization of a KL loss: this is in contrast to other synthetic likelihood methods, which either rely on normalizing flows, or minimize score-based objectives; choices that come with known pitfalls. Our first method, Amortized Unnormalized Neural Likelihood Estimation (AUNLE), introduces a tilting trick during training that allows to perform inference using efficient MCMC techniques. Our second method, Sequential UNLE (SUNLE), employs a doubly intractable approach in order to re-use simulation data and improve posterior accuracy for a specific observation.

We demonstrate the properties of both methods on a range of synthetic datasets, and apply it to a neuroscience model of the pyloric network in the crab, matching the performance of other synthetic likelihood methods at a fraction of the simulation budget.

Just Avoid Robust Inaccuracy: Boosting Robustness Without Sacrificing Accuracy

Yannick Merkli,Pavol Bielik,PETAR TSANKOV,Martin Vechev

While current methods for training robust deep learning models optimize robust accuracy, they significantly reduce natural accuracy, hindering their adoption in practice. Further, the resulting models are often both robust and inaccurate on numerous samples, providing a false sense of safety for those. In this work, we extend prior works in three main directions. First, we explicitly train the models to jointly maximize robust accuracy and minimize robust inaccuracy. Second, since the resulting models are trained to be robust only if they are accurate, we leverage robustness as a principled abstain mechanism. Finally, this abstain mechanism allows us to combine models in a compositional architecture that significantly boosts overall robustness without sacrificing accuracy. We demonstrate the effectiveness of our approach for empirical and certified robustness on six recent state-of-the-art models and four datasets. For example, on CIFAR-10 with $\epsilon_\infty = 1/255$, we successfully enhanced the robust accuracy of a pre-trained model from 26.2% to 87.8% while even slightly increasing its natural accuracy from 97.8% to 98.0%.

****

Projective Proximal Gradient Descent for Nonconvex Nonsmooth Optimization: Fast Convergence Without Kurdyka-Lojasiewicz (KL) Property

Yingzhen Yang,Ping Li

Nonconvex and nonsmooth optimization problems are important and challenging for statistics and machine learning. In this paper, we propose Projected Proximal Gradient Descent (PPGD) which solves a class of nonconvex and nonsmooth optimization problems, where the nonconvexity and nonsmoothness come from a nonsmooth regularization term which is nonconvex but piecewise convex. In contrast with existing convergence analysis of accelerated PGD methods for nonconvex and nonsmooth problems based on the Kurdyka-\L{}ojasiewicz (K\L{}) property, we provide a new theoretical analysis showing local fast convergence of PPGD. It is proved that PPGD achieves a fast convergence rate of $O(1/k^2)$ when the iteration number $k \ge k_0$ for a finite k_0 on a class of nonconvex and nonsmooth problems under mild assumptions, which is locally the Nesterov's optimal convergence rate of first-order methods on smooth and convex objective function with Lipschitz continu ous gradient. Experimental results demonstrate the effectiveness of PPGD.

First Steps Toward Understanding the Extrapolation of Nonlinear Models to Unseen Domains

Kefan Dong,Tengyu Ma

Real-world machine learning applications often involve deploying neural networks to domains that are not seen in the training time. Hence, we need to understand the extrapolation of \textit{nonlinear} models---under what conditions on the distributions and function class, models can be guaranteed to extrapolate to new test distributions. The question is very challenging because even two-layer neural networks cannot be guaranteed to extrapolate outside the support of the training distribution without further assumptions on the domain shift. This paper makes some initial steps towards analyzing the extrapolation of nonlinear models for structured domain shift. We primarily consider settings where the \textit{marginal} distribution of each coordinate of the data (or subset of coordinates) do not shift significantly across the training and test distributions, but the joint distribution may have a much bigger shift. We prove that the family of nonlinear models of the form $f(x)=\sum f_i(x_i)$, where f_i is an \emph{arbitrary} function on the subset of features x_i, can extrapolate to unseen distributions, if the covariance of the features is well-conditioned. To the best of our knowledge, this is the first result that goes beyond linear models and the bounded density ratio assumption, even though the assumptions on the distribution shift and function class are stylized.

****

A Kernel-Based View of Language Model Fine-Tuning

Sadhika Malladi,Alexander Wettig,Dingli Yu,Danqi Chen,Sanjeev Arora

It has become standard to solve NLP tasks by fine-tuning pre-trained language models (LMs), especially in low-data settings. There is minimal theoretical understanding of empirical success, e.g., why fine-tuning a model with 10^8 or more parameters on a couple dozen training points does not result in overfitting. We investigate whether the Neural Tangent Kernel (NTK)--which originated as a model to study the gradient descent dynamics of infinitely wide networks with suitable random initialization--describes fine-tuning of pre-trained LMs. This study was inspired by the decent performance of NTK for computer vision tasks (Wei et al., 2022). We also extend the NTK formalism to fine-tuning with Adam. We present extensive experiments that suggest that once the task is formulated as a masked language modeling problem through prompting, the NTK lens can often reasonably describe the model updates during fine-tuning with both SGD and Adam.
This kernel view also suggests an explanation for success of parameter-efficient subspace-based fine-tuning methods. Finally, we suggest a path toward a formal explanation for our findings via Tensor Programs (Yang, 2020).

Compositionality with Variation Reliably Emerges in Neural Networks

Henry Conklin,Kenny Smith

Human languages enable robust generalization, letting us leverage our prior experience to communicate about novel meanings. This is partly due to language being compositional, where the meaning of a whole expression is a function of its parts. Natural languages also exhibit extensive variation, encoding meaning predictably enough to enable generalization without limiting speakers to one and only one way of expressing something. Previous work looking at the languages that emerge between neural networks in a communicative task has shown languages that enable robust communication and generalization reliably emerge. Despite this those languages score poorly on existing measures of compositionality leading to claims that a language's degree of compositionality has little bearing on how well it can generalise. We argue that the languages that emerge between networks are in fact straightforwardly compositional, but with a degree of natural language-like variation that can obscure their compositionality from existing measures. We introduce 4 measures of linguistic variation and show that early in training measures of variation correlate with generalization performance, but that this effect goes away over time as the languages that emerge become regular enough to gener alize robustly. Like natural languages, emergent languages appear able to support a high degree of variation while retaining the generalizability we expect from compositionality. In an effort to decrease the variability of emergent languages we show how reducing a model's capacity results in greater regularity, in line with claims about factors shaping the emergence of regularity in human language.

****

Systematic Rectification of Language Models via Dead-end Analysis

Meng Cao,Mehdi Fatemi,Jackie CK Cheung,Samira Shabanian

With adversarial or otherwise normal prompts, existing large language models (LLM) can be pushed to generate toxic discourses. One way to reduce the risk of LLMs generating undesired discourses is to alter the training of the LLM. This can be very restrictive due to demanding computation requirements. Other methods rely on rule-based or prompt-based token elimination, which are limited as they dismiss future tokens and the overall meaning of the complete discourse. Here, we center detoxification on the probability that the finished discourse is ultimately considered toxic. That is, at each point, we advise against token selections proportional to how likely a finished text from this point will be toxic. To this end, we formally extend the dead-end theory from the recent reinforcement learning (RL) literature to also cover uncertain outcomes. Our approach, called rectification, utilizes a separate but significantly smaller model for detoxification, which can be applied to diverse LLMs as long as they share the same vocabulary. Importantly, our method does not require access to the internal representations of the LLM, but only the token probability distribution at each decoding step. We believe this is important since many LLMs today are hosted in servers and only accessible through APIs. When applied to various LLMs, including GPT-3, our approach generates notably better results compared to the base LLMs and other techniques in terms of the overall language and detoxification performance.

Model-free Reinforcement Learning that Transfers Using Random Reward Features

Boyuan Chen,Chuning Zhu,Pulkit Agrawal,Kaiqing Zhang,Abhishek Gupta

Favorable reinforcement learning (RL) algorithms should not only be able to synthesize controller for complex tasks, but also transfer across various such tasks. Classical model-free RL algorithms like Q-learning can be made stable, and has the potential to solve complicated tasks individually. However, rewards are key supervision signals in model-free approaches, making it challenging in general to transfer across multiple tasks with different reward functions. On the other hand, model-based RL algorithms, naturally transfers to various reward functions if the transition dynamics are learned well. Unfortunately, model-learning usually suffers from high dimensional observations and/or long horizons due to the challenges of compounding error. In this work, we propose a new way to transfer behaviors across problems with different reward functions that enjoy the best of both worlds. Specifically, we develop a model-free approach that implicitly learns the model without constructing the transition dynamics. This is achieved by using random features to generate reward functions in training, and incorporating model predictive control with open-loop policies in online planning. We show that the approach enables fast adaptation to problems with completely new reward functions, while scaling to high dimensional observations and long horizons. Moreover, our method can easily be trained on large offline datasets, and be quickly deployed on new tasks with good performance, making it more widely applicable than typical model-free and model-based RL methods. We evaluate the superior performance of our algorithm in a variety of RL and robotics domains.

Multiple sequence alignment as a sequence-to-sequence learning problem

Edo Dotan,Yonatan Belinkov,Oren Avram,Elya Wygoda,Noa Ecker,Michael Alburquerque,Omri Keren,Gil Loewenthal,Tal Pupko

The sequence alignment problem is one of the most fundamental problems in bioinformatics and a plethora of methods were devised to tackle it. Here we introduce BetaAlign, a methodology for aligning sequences using an NLP approach. BetaAlign accounts for the possible variability of the evolutionary process among differe nt datasets by using an ensemble of transformers, each trained on millions of samples generated from a different evolutionary model. Our approach leads to alignment accuracy that is similar and often better than commonly used methods, such as MAFFT, DIALIGN, ClustalW, T-Coffee, PRANK, and MUSCLE.

Fair Graph Message Passing with Transparency
Zhimeng Jiang,Xiaotian Han,Chao Fan,Zirui Liu,Na Zou,Ali Mostafavi,Xia Hu

Recent advanced works achieve fair representations and predictions through regularization, adversarial debiasing, and contrastive learning in graph neural networks (GNNs). These methods \textit{implicitly} encode the sensitive attribute information in the well-trained model weight via \textit{backward propagation}. In practice, we not only pursue a fair machine learning model but also lend such fairness perception to the public. For current fairness methods,
how the sensitive attribute information usage makes the model achieve fair prediction still remains a black box. In this work, we first propose the concept \textit{transparency} to describe \textit{whether} the model embraces the ability of lending fairness perception to the public \textit{or not}. Motivated by the fact that current fairness models lack of transparency, we aim to pursue a fair machine learning model with transparency via \textit{explicitly} rendering sensitive attribute usage for fair prediction in \textit{forward propagation} . Specifically, we develop an effective and transparent \textsf{F}air \textsf{M}essage \textsf{P}assing (FMP) scheme adopting sensitive attribute information in forward propagation. In this way, FMP explicitly uncovers how sensitive attributes influence final prediction. Additionally, FMP scheme can aggregate useful information from neighbors and mitigate bias in a unified framework to simultaneously achieve graph smoothness and fairness objectives. An acceleration approach is also adopted to improve the efficiency of FMP. Experiments on node classification tasks demonstrate that the proposed FMP outperforms the state-of-the-art baselines in terms of fairness and accuracy on three real-world datasets. The code is available in {\color{blue}\url{https://anonymous.4open.science/r/FMP-AD84}}.

FedExP: Speeding Up Federated Averaging via Extrapolation
Divyansh Jhunjhunwala,Shiqiang Wang,Gauri Joshi

Federated Averaging (FedAvg) remains the most popular algorithm for Federated Learning (FL) optimization due to its simple implementation, stateless nature, and privacy guarantees combined with secure aggregation. Recent work has sought to generalize the vanilla averaging in FedAvg to a generalized gradient descent step by treating client updates as pseudo-gradients and using a server step size. While the use of a server step size has been shown to provide performance improvement theoretically, the practical benefit of the server step size has not been seen in most existing works. In this work, we present FedExP, a method to adaptively determine the server step size in FL based on dynamically varying pseudo-gradients throughout the FL process. We begin by considering the overparameterized convex regime, where we reveal an interesting similarity between FedAvg and the Projection Onto Convex Sets (POCS) algorithm. We then show how FedExP can be motivated as a novel extension to the extrapolation mechanism that is used to speed up POCS. Our theoretical analysis later also discusses the implications of FedExP in underparameterized and non-convex settings. Experimental results show that FedExP consistently converges faster than FedAvg and competing baselines on a range of realistic FL datasets.

Graph Neural Networks Are More Powerful Than we Think
Charilaos Kanatsoulis,Alejandro Ribeiro

Graph Neural Networks (GNNs) are powerful convolutional architectures that have shown remarkable performance in various node-level and graph-level tasks. Despite their success, the common belief is that the expressive power of standard GNNs is limited and that they are at most as discriminative as the Weisfeiler-Lehman (WL) algorithm. In this paper we argue the opposite and show that the WL algorithm is the upper bound only when the input to the GNN is the vector of all ones. In this direction, we derive an alternative analysis that employs linear algebr aic tools and characterize the representational power of GNNs with respect to the eigenvalue decomposition of the graph operators. We show that GNNs can distinguish between any graphs that differ in at least one eigenvalue and design simple GNN architectures that are provably more expressive than the WL algorithm. Thorough experimental analysis on graph isomorphism and graph classification datasets corroborates our theoretical results and demonstrates the effectiveness of the proposed architectures.

A Mixture-of-Expert Approach to RL-based Dialogue Management

Yinlam Chow,Azamat Tulepbergenov,Ofir Nachum,Dhawal Gupta,Moonkyung Ryu,Mohammad Ghavamzadeh,Craig Boutilier

Despite recent advancements in language models (LMs), their application to dialogue management (DM) problems and ability to carry on rich conversations remain a challenge. We use reinforcement learning (RL) to develop a dialogue agent that avoids being short-sighted (outputting generic utterances) and maximizes overall user satisfaction. Most existing RL approaches to DM train the agent at the word-level, and thus, have to deal with a combinatorially complex action space even for a medium-size vocabulary. As a result, they struggle to produce a successful and engaging dialogue even if they are warm-started with a pre-trained LM. To address this issue, we develop a RL-based DM using a novel mixture of expert language model (MoE-LM) that consists of (i) a LM capable of learning diverse semantics for conversation histories, (ii) a number of specialized LMs (or experts) capable of generating utterances corresponding to a particular attribute or personality, and (iii) a RL-based DM that performs dialogue planning with the utterances generated by the experts. Our MoE approach provides greater flexibility to generate sensible utterances with different intents and allows RL to focus on conversational-level DM. We compare it with SOTA baselines on open-domain dialogues and demonstrate its effectiveness both in terms of the diversity and sensibility of the generated utterances and the overall DM performance.

f-DM: A Multi-stage Diffusion Model via Progressive Signal Transformation

Jiatao Gu,Shuangfei Zhai,Yizhe Zhang,Miguel Ángel Bautista,Joshua M. Susskind

Diffusion models (DMs) have recently emerged as SoTA tools for generative modeling in various domains. Standard DMs can be viewed as an instantiation of hierarchical variational autoencoders (VAEs) where the latent variables are inferred from input-centered Gaussian distributions with fixed scales and variances. Unlike VAEs, this formulation constrains DMs from changing the latent spaces and learning abstract representations. In this work, we propose f-DM, a generalized family of DMs which allows progressive signal transformation. More precisely, we extend DMs to incorporate a set of (hand-designed or learned) transformations, where the transformed input is the mean of each diffusion step. We propose a generalized formulation and derive the corresponding de-noising objective with a modified sampling algorithm. As a demonstration, we apply f-DM in image generation tasks with a range of functions, including down-sampling, blurring, and learned transformations based on the encoder of pretrained VAEs. In addition, we identify the importance of adjusting the noise levels whenever the signal is sub-sampled and propose a simple rescaling recipe. f-DM can produce high-quality samples on standard image generation benchmarks like FFHQ, AFHQ, LSUN, and ImageNet with better efficiency and semantic interpretation.

An Empirical Study of the Neural Contextual Bandit Algorithms

Bowen Wei,Yiling Jia,Hongning Wang

Recent advances in representation learning have made significant influences on solutions of contextual bandit problems. Neural bandit algorithms have been actively developed and reported to gain extraordinary performance improvement against classical bandit algorithms in numerous papers. However, there lacks a comprehensive comparison among the existing neural bandit algorithms, and it is still not clear whether or when they can succeed in complex real-world problems. In this work, we present an inclusive empirical study on three different categories of existing neural bandit algorithms on several real-world datasets. The results sh ow that such algorithms are highly competitive against their classical counterparts in most cases, however the advantage is not consistent. The results also reveal crucial challenges for future research in neural bandit algorithms.

Backpropagation at the Infinitesimal Inference Limit of Energy-Based Models: Unifying Predictive Coding, Equilibrium Propagation, and Contrastive Hebbian Learning

Beren Millidge,Yuhang Song,Tommaso Salvatori,Thomas Lukasiewicz,Rafal Bogacz

How the brain performs credit assignment is a fundamental unsolved problem in neuroscience. Many `biologically plausible' algorithms have been proposed, which compute gradients that approximate those computed by backpropagation (BP), and which operate in ways that more closely satisfy the constraints imposed by neural circuitry. Many such algorithms utilize the framework of energy-based models (EBMs), in which all free variables in the model are optimized to minimize a global energy function. However, in the literature, these algorithms exist in isolation and no unified theory exists linking them together. Here, we provide a comprehensive theory of the conditions under which EBMs can approximate BP, which lets us unify many of the BP approximation results in the literature (namely, predictive coding, equilibrium propagation, and contrastive Hebbian learning) and demonstrate that their approximation to BP arises from a simple and general mathematical property of EBMs at free-phase equilibrium. This property can then be exploited in different ways with different energy functions, and these specific choices yield a family of BP-approximating algorithms, which both includes the known results in the literature and can be used to derive new ones.

****

A Theoretical Framework for Inference and Learning in Predictive Coding Networks

Beren Millidge,Yuhang Song,Tommaso Salvatori,Thomas Lukasiewicz,Rafal Bogacz

Predictive coding (PC) is an influential theory in computational neuroscience, which argues that the cortex forms unsupervised world models by implementing a hierarchical process of prediction error minimization. PC networks (PCNs) are trained in two phases. First, neural activities are updated to optimize the network's response to external stimuli. Second, synaptic weights are updated to consolidate this change in activity --- an algorithm called \emph{prospective configuration}. While previous work has shown how in various limits, PCNs can be found to approximate backpropagation (BP), recent work has demonstrated that PCNs operating in this standard regime, which does not approximate BP, nevertheless obtain competitive training and generalization performance to BP-trained networks while outperforming them on various tasks. However, little is understood theoretically about the properties and dynamics of PCNs in this regime. In this paper, we provide a comprehensive theoretical analysis of the properties of PCNs trained with prospective configuration. We first derive analytical results concerning the inference equilibrium for PCNs and a previously unknown close connection relationship to target propagation (TP). Secondly, we provide a theoretical analysis of learning in PCNs as a variant of generalized expectation-maximization and use that to prove the convergence of PCNs to critical points of the BP loss function, thus showing that deep PCNs can, in theory, achieve the same generalization performance as BP, while maintaining their unique advantages.

Causally-guided Regularization of Graph Attention improves Generalizability

Alexander P Wu,Thomas Markovich,Bonnie Berger,Nils Yannick Hammerla,Rohit Singh

Graph attention networks estimate the relational importance of node neighbors to aggregate relevant information over local neighborhoods for a prediction task. However, the inferred attentions are vulnerable to spurious correlations and connectivity in the training data, hampering the generalizability of the model. We introduce CAR, a general-purpose regularization framework for graph attention networks. Embodying a causal inference approach, CAR aligns the attention mechanism with the causal effects of active interventions on graph connectivity in a scalable manner. CAR is compatible with a variety of graph attention architectures, and we show that it systematically improves generalizability on various node classification tasks. Our ablation studies indicate that CAR hones in on the aspec ts of graph structure most pertinent to the prediction (e.g., homophily), and does so more effectively than alternative approaches. Finally, we also show that CAR enhances interpretability of attention weights by accentuating node-neighbor relations that point to causal hypotheses. For social media network-sized graphs, a CAR-guided graph rewiring approach could allow us to combine the scalability of graph convolutional methods with the higher performance of graph attention.

On a Benefit of Masked Language Model Pretraining: Robustness to Simplicity Bias
Ting-Rui Chiang

Despite the success of pretrained masked language models (MLM), why MLM pretraining is useful is still a question not fully answered. In this work we theoretically and empirically show that MLM pretraining makes models robust to lexicon-level spurious features, partly answering the question. Our explanation is that MLM pretraining may alleviate problems brought by simplicity bias (Shahet al., 2020), which refers to the phenomenon that a deep model tends to rely excessively on simple features. In NLP tasks, those simple features could be token-level features whose spurious association with the label can be learned easily. We show that MLM pretraining makes learning from the context easier. Thus, pretrained models are less likely to rely excessively on a single token. We also explore the theoretical explanations of MLM’s efficacy in causal settings. Compared with Wei et al. (2021), we achieve similar results with milder assumptions. Finally, we close the gap between our theories and real-world practices by conducting experiments on real-world tasks.

FLGAME: A Game-theoretic Defense against Backdoor Attacks In Federated Learning
Jinyuan Jia,Zhuowen Yuan,Dinuka Sahabandu,Luyao Niu,Arezoo Rajabi,Bhaskar Ramasubramanian,Bo Li,Radha Poovendran

Federated learning enables the distributed training paradigm, where multiple local clients jointly train a global model without needing to share their local training data. However, recent studies have shown that federated learning provides an additional surface for backdoor attacks. For instance, an attacker can compromise a subset of clients and thus corrupt the global model to incorrectly predict an attacker-chosen target class given any input embedded with the backdoor trigger. Existing defenses for federated learning against backdoor attacks usually detect and exclude the corrupted information from the compromised clients based on a $\textit{static}$ attacker model. Such defenses, however, are less effective when faced with $\textit{dynamic}$ attackers who can strategically adapt their attack strategies. In this work, we model the strategic interaction between the (global) defender and attacker as a minimax game. Based on the analysis of our model, we design an interactive defense mechanism that we call FLGAME. Theoretically, we prove that under mild assumptions, the global model trained with FLGAME under backdoor attacks is close to that trained without attacks. Empirically, we perform extensive evaluations on benchmark datasets and compare FLGAME with multiple state-of-the-art baselines. Our experimental results show that FLGAME can effectively defend against strategic attackers and achieves significantly higher robustness than baselines.

The Onset of Variance-Limited Behavior for Networks in the Lazy and Rich Regimes
Alexander Atanasov,Blake Bordelon,Sabarish Sainathan,Cengiz Pehlevan

For small training set sizes P, the generalization error of wide neural networks is well-approximated by the error of an infinite width neural network (NN), either in the kernel or mean-field/feature-learning regime. However, after a critical sample size P^*, we empirically find the finite-width network generalization becomes worse than that of the infinite width network. In this work, we empirically study the transition from infinite-width behavior to this \textit{variance-limited} regime as a function of sample size P and network width N. We find that finite-size effects can become relevant for very small dataset sizes on the order of $P^* \sim \sqrt{N}$ for polynomial regression with ReLU networks. We discuss the source of these effects using an argument based on the variance of the NN's final neural tangent kernel (NTK). This transition can be pushed to l arger P by enhancing feature learning or by ensemble averaging the networks. We find that the learning curve for regression with the final NTK is an accurate approximation of the NN learning curve. Using this, we provide a toy model which also exhibits $P^* \sim \sqrt{N}$ scaling and has P-dependent benefits from feature learning.

A Simple Approach for Visual Room Rearrangement: 3D Mapping and Semantic Search

Brandon Trabucco,Gunnar A Sigurdsson,Robinson Piramuthu,Gaurav S. Sukhatme,Ruslan Salakhutdinov

Physically rearranging objects is an important capability for embodied agents. Visual room rearrangement evaluates an agent's ability to rearrange objects in a room to a desired goal based solely on visual input. We propose a simple yet effective method for this problem: (1) search for and map which objects need to be rearranged, and (2) rearrange each object until the task is complete. Our approach consists of an off-the-shelf semantic segmentation model, voxel-based semantic map, and semantic search policy to efficiently find objects that need to be rearranged. Our method was the winning submission to the AI2-THOR Rearrangement Challenge in the 2022 Embodied AI Workshop at CVPR 2022, and improves on current state-of-the-art end-to-end reinforcement learning-based methods that learn visual room rearrangement policies from 0.53% correct rearrangement to 16.56%, using only 2.7% as many samples from the environment.

****

Memory Efficient Dynamic Sparse Training

Mike Heddes,Narayan Srinivasa

The excessive memory and energy consumption of modern Artificial Neural Networks (ANNs) is posing limitations on the machines that can run these models. Sparsification of ANNs is often motivated by time, memory and energy savings only during model inference, yielding no benefits during training. A growing body of work is now focusing on providing the benefits of model sparsification also during training. While these methods improve the energy efficiency during training, the algorithms yielding the most accurate models still have a peak memory usage on the same order as the dense model. We propose a Dynamic Sparse Training (DST) algorithm that reduces the peak memory usage during training while preserving the energy advantages of sparsely trained models. We evaluate our algorithm on CIFAR-10/100 using ResNet-56 and VGG-16 and compare it against a range of sparsification methods. The benefits of our method are twofold: first, it allows for a given model to be trained to an accuracy on par with the dense model while requiring significantly less memory and energy; second, the savings in memory and energy can be allocated towards training an even larger sparse model on the same machine, generally improving the accuracy of the model.

****

Accelerated Training via Principled Methods for Incrementally Growing Neural Networks

Xin Yuan,Pedro Henrique Pamplona Savarese,Michael Maire

We develop an approach to efficiently grow neural networks, within which parameterization and optimization strategies are designed by considering their effects on the training dynamics. Unlike existing growing methods, which follow simple replication heuristics or utilize auxiliary gradient-based local optimization, we craft a parameterization scheme which dynamically stabilizes weight, activation, and gradient scaling as the architecture evolves, and maintains the inference functionality of the network. To address the optimization difficulty resulting from imbalanced training effort distributed to subnetworks fading in at different growth phases, we propose a learning rate adaption mechanism that rebalances the gradient contribution of these separate subcomponents. Experimental results show that our method achieves comparable or better accuracy than training large fixed-size models, while saving a substantial portion of the original computation budget for training. We demonstrate that these gains translate into real wall-clock training speedups.

Progressive Mix-Up for Few-Shot Supervised Multi-Source Domain Transfer

Ronghang Zhu,Ronghang Zhu,Xiang Yu,Sheng Li

This paper targets at a new and challenging setting of knowledge transfer from multiple source domains to a single target domain, where target data is few shot or even one shot with label. Traditional domain generalization or adaptation methods cannot directly work since there is no sufficient target domain distribution serving as the transfer object. The multi-source setting further prevents the transfer task as excessive domain gap introduced from all the source domains. To tackle this problem, we newly propose a progressive mix-up (P-Mixup) mechanism to introduce an intermediate mix-up domain, pushing both the source domains and the few-shot target domain aligned to this mix-up domain. Further by enforcing the mix-up domain to progressively move towards the source domains, we achieve the domain transfer from multi-source domains to the single one-shot target domain. Our P-Mixup is different from traditional mix-up that ours is with a progressive and adaptive mix-up ratio, following the curriculum learning spirit to better align the source and target domains. Moreover, our P-Mixup combines both pixel-level and feature-level mix-up to better enrich the data diversity. Experiments on two benchmarks show that our P-Mixup significantly outperforms the state-of-the-art methods, i.e., 6.0\% and 6.8\% improvements on Office-Home and DomainNet.

Mitigating Propagation Failures in PINNs using Evolutionary Sampling

Arka Daw,Jie Bu,Sifan Wang,Paris Perdikaris,Anuj Karpatne

Despite the success of physics-informed neural networks (PINNs) in approximating partial differential equations (PDEs), it is known that PINNs can sometimes fail to converge to the correct solution in problems involving complicated PDEs. This is reflected in several recent studies on characterizing and mitigating the ``failure modes'' of PINNs. While most of these studies have focused on balancing loss functions or adaptively tuning PDE coefficients, what is missing is a thorough understanding of the connection between failure modes of PINNs and sampling strategies used for training PINNs. In this paper, we provide a novel perspective of failure modes of PINNs by hypothesizing that the training of PINNs rely on successful ``propagation'' of solution from initial and/or boundary condition points to interior points. We show that PINNs with poor sampling strategies can get stuck at trivial solutions if there are propagation failures. We additionally demonstrate that propagation failures are characterized by highly imbalanced PDE residual fields where very high residuals are observed over very narrow regions. To mitigate propagation failures, we propose a novel evolutionary sampling (Evo) method that can incrementally accumulate collocation points in regions of high PDE residuals with little to no computational overhead. We provide an extension of Evo to respect the principle of causality while solving time-dependent PDEs. We theoretically analyze the behavior of Evo and empirically demonstrate its efficacy and efficiency in comparison with baselines on a variety of PDE problems.

Revisiting Information-Based Clustering with Pseudo-Posterior Models

Zhongwen Zhang,Yuri Boykov

Maximization of mutual information (MI) between the network's input and output motivates standard losses for unsupervised discriminative clustering enforcing "decisiveness" and "fairness". In the context of common softmax models, we clarify several general properties of such discriminative losses that were previously not well understood: the relation to K-means, or lack thereof, and "margin-maximization". In particular, we show that "desiciveness" without the extra regularization term can lead to poor classification margins. Also, non-convexity of information-based losses motivates us to focus on self-supervised approaches introducing effective higher-order optimization algorithms with auxiliary variables. Addressing limitations of existing formulations, we propose a new self-supervised loss with soft auxiliary variables, or "pseudo-confidence" estimates. In particular, we introduce "strong" fairness and motivate the "reverse" cross-entropy as a robust loss for network training from noisy pseudo-confidence estimates. The latter is efficiently computed using variational inference - we derive a new EM algorithm with closed-form solutions for E and M steps. Empirically, our algorithm improves the performance of earlier methods for information-based clustering.

Neural Compositional Rule Learning for Knowledge Graph Reasoning

Kewei Cheng,Nesreen Ahmed,Yizhou Sun

Learning logical rules is critical to improving reasoning in KGs. This is due to their ability to provide logical and interpretable explanations when used for predictions, as well as their ability to generalize to other tasks, domains, and data. While recent methods have been proposed to learn logical rules, the majority of these methods are either restricted by their computational complexity and can not handle the large search space of large-scale KGs, or show poor generalization when exposed to data outside the training set. In this paper, we propose an end-to-end neural model for learning compositional logical rules called NCRL. NCRL detects the best compositional structure of a rule body, and breaks it into small compositions in order to infer the rule head. By recurrently merging compositions in the rule body with a recurrent attention unit, NCRL finally predicts a single rule head. Experimental results show that NCRL learns high-quality rules, as well as being generalizable. Specifically, we show that NCRL is scalable, efficient, and yields state-of-the-art results for knowledge graph completion on large-scale KGs. Moreover, we test NCRL for systematic generalization by learning to reason on small-scale observed graphs and evaluating on larger unseen ones.

Temporal Change Sensitive Representation for Reinforcement Learing

Qi Gao,Wei Xu

Image-based deep reinforcement learning has made a great improvement recently by combining state-of-the-art reinforcement learning algorithms with self-supervised representation learning algorithms. However, these self-supervised representation learning algorithms are designed to preserve global visual information, which may miss changes in visual information that are important for performing the task. To resolve this problem, self-supervised representation learning specifically designed for better preserving task relevant information is necessary. Following this idea, we introduce Temporal Change Sensitive Representation (TCSR), which is designed for reinforcement learning algorithms that have a latent dynamic model. TCSR enforces the latent state representation of the reinforcement agent to put more emphasis on the part of observation that could potentially change in the future. Our method achieves SoTA performance in Atari100K benchmark.

Provably Efficient Reinforcement Learning for Online Adaptive Influence Maximization

Kaixuan Huang,Yu Wu,Xuezhou Zhang,Shenyinying Tu,Qingyun Wu,Mengdi Wang,Huazheng Wang

Online influence maximization aims to maximize the influence spread of a content in a social network with an unknown network model by selecting a few seed nodes. Recent studies followed a non-adaptive setting, where the seed nodes are selected before the start of the diffusion process and network parameters are updated when the diffusion stops. We consider an adaptive version of content-dependent online influence maximization problem where the seed nodes are sequentially activated based on real-time feedback. In this paper, we formulate the problem as an infinite-horizon discounted MDP under a linear diffusion process and present a model-based reinforcement learning solution. Our algorithm maintains a network model estimate and selects seed users adaptively, exploring the social network while improving the optimal policy optimistically. We establish $\widetilde O(\sqrt{T})$ regret bound for our algorithm. Empirical evaluations on synthetic and real-world networks demonstrate the efficiency of our algorithm.

****

Efficient approximation of neural population structure and correlations with probabilistic circuits

Koosha Khalvati,Samantha Johnson,Stefan Mihalas,Michael A Buice

We present a computationally efficient framework to model a wide range of population structures with high order correlations and a large number of neurons. Our method is based on a special type of Bayesian network that has linear inference time and is founded upon the concept of contextual independence. Moreover, we use an efficient architecture learning method for network selection to model large neural populations even with a small amount of data. Our framework is both fast and accurate in approximating neural population structures. Furthermore, our approach enables us to reliably quantify higher order neural correlations. We test our method on simulated neural populations commonly used to generate higher order correlations, as well as on publicly available large-scale neural recordings from the Allen Brain Observatory. Our approach significantly outperforms other models both in terms of statistical measures and alignment with experimental evidence.

Exploring perceptual straightness in learned visual representations

Anne Harrington,Vasha DuTell,Ayush Tewari,Mark Hamilton,Simon Stent,Ruth Rosenholtz,William T. Freeman

Humans have been shown to use a ''straightened'' encoding to represent the natural visual world as it evolves in time (Henaff et al. 2019). In the context of discrete video sequences, ''straightened'' means that changes between frames follow a more linear path in representation space at progressively deeper levels of processing. While deep convolutional networks are often proposed as models of human visual processing, many do not straighten natural videos. In this paper, we explore the relationship between network architecture, differing types of robustness, biologically-inspired filtering mechanisms, and representational straightness in response to time-varying input; we identify strengths and limitations of straightness as a useful way of evaluating neural network representations. We find that (1) adversarial training leads to straighter representations in both CNN and transformer-based architectures but (2) this effect is task-dependent, not generalizing to tasks such as segmentation and frame-prediction, where straight representations are not favorable for predictions; and nor to other types of robustness. In addition, (3) straighter representations impart temporal stability to class predictions, even for out-of-distribution data. Finally, (4) biologically-inspired elements increase straightness in the early stages of a network, but do not guarantee increased straightness in downstream layers of CNNs. We show that straightness is an easily computed measure of representational robustness and stability, as well as a hallmark of human representations with benefits for computer vision models.

Improving Subgraph Representation Learning via Multi-View Augmentation

Yili Shen,Cheng-Wei Ju,Jiaxu Yan,Jun Yi,Zhou Lin,Hui Guan

Subgraph representation learning based on Graph Neural Network (GNN) has exhibited broad applications in scientific advancements, such as predictions of molecular structure-property relationships and collective cellular function. In particular, graph augmentation techniques have shown promising results in improving graph-based and node-based classification tasks. Still, they have rarely been explored in the existing GNN-based subgraph representation learning studies. In this study, we develop a novel multi-view augmentation mechanism to improve subgraph representation learning models and thus the accuracy of downstream prediction tasks. Our augmentation technique creates multiple variants of subgraphs and embeds these variants into the original graph to achieve highly improved training efficiency, scalability, and accuracy. Benchmark experiments on several real-world biological and physiological datasets demonstrate the superiority of our proposed multi-view augmentation techniques in subgraph representation learning.

System identification of neural systems: If we got it right, would we know?

Yena Han,Tomaso Poggio,Brian Cheung

Various artificial neural networks developed by engineers are now proposed as models of parts of the brain, such as the ventral stream in the primate visual cortex. The network activations are compared to recordings of biological neurons, and good performance in reproducing neural responses is considered to support the model's validity. This system identification approach, however, is only part of the traditional ways to develop and test models in the natural sciences. A key question is how much the ability to predict neural responses tells us. In particular, do these functional tests about neuron activation allow us to distinguish between different model architectures? We benchmark existing techniques to correctly identify a model by replacing brain recordings with known ground truth models. We evaluate the most commonly used identification approaches, such as a linear encoding model and centered kernel alignment. Even in the setting where the correct model is among the candidates, system identification performance is quite variable; it also depends significantly on factors independent of the ground truth architecture, such as stimuli images. In addition, we show the limitations of using functional similarity scores in identifying higher-level architectural motifs.

Is Forgetting Less a Good Inductive Bias for Forward Transfer?
Jiefeng Chen,Timothy Nguyen,Dilan Gorur,Arslan Chaudhry

One of the main motivations of studying continual learning is that the problem setting allows a model to accrue knowledge from past tasks to learn new tasks more efficiently. However, recent studies suggest that the key metric that continual learning algorithms optimize, reduction in catastrophic forgetting, does not correlate well with the forward transfer of knowledge. We believe that the conclusion previous works reached is due to the way they measure forward transfer. We argue that the measure of forward transfer to a task should not be affected by the restrictions placed on the continual learner in order to preserve knowledge of previous tasks. Instead, forward transfer should be measured by how easy it is to learn a new task given a set of representations produced by continual learning on previous tasks. Under this notion of forward transfer, we evaluate different continual learning algorithms on a variety of image classification benchmarks. Our results indicate that less forgetful representations lead to a better forward transfer suggesting a strong correlation between retaining past information and learning efficiency on new tasks. Further, we found less forgetful representations to be more diverse and discriminative compared to their forgetful counterparts.

High-Precision Regressors for Particle Physics
Fady Bishara,Ayan Paul,Jennifer Dy

Monte Carlo simulations of physics processes at particle colliders like the Large Hadron Collider at CERN take up a major fraction of the computational budget. For some simulations, a single data point takes seconds, minutes, or even hours to compute from first principles. Since the necessary number of data points per simulation is on the order of 10^9 -- 10^{12}, machine learning regressors can be used in place of physics simulators to significantly reduce this computational burden. However, this task requires high precision regressors that can deliver data with relative errors less than 1\% or even 0.1\% over the entire domain of the function. In this paper, we develop optimal training strategies and tune various machine learning regressors to satisfy the high-precision requirement. We leverage symmetry arguments from particle physics to optimize the performance of the regressors. Inspired by ResNets, we design a Deep Neural Network with skip connections that outperform fully connected Deep Neural Networks. We find that at lower dimensions, boosted decision trees far outperform neural networks while at higher dimensions neural networks perform better. We show that these regressors can speed up simulations by a factor of 10^3 -- 10^6 over the first-principles computations currently used in Monte Carlo simulations. Additionally, using symmetry arguments derived from particle physics, we reduce the number of regressors necessary for each simulation by an order of magnitude. Our work can significantly reduce the training and storage burden of Monte Carlo simulations at current and future collider experiments.

Learning Structured Representations by Embedding Class Hierarchy
Siqi Zeng,Remi Tachet des Combes,Han Zhao

Existing models for learning representations in supervised classification problems are permutation invariant with respect to class labels. However, structured knowledge about the classes, such as hierarchical label structures, widely exists in many real-world datasets, e.g., the ImageNet and CIFAR benchmarks. How to learn representations that can preserve such structures among the classes remains an open problem. To approach this problem, given a tree of class hierarchy, we first define a tree metric between any pair of nodes in the tree to be the length of the shortest path connecting them. We then provide a method to learn the hierarchical relationship of class labels by approximately embedding the tree metric in the Euclidean space of features. More concretely, during supervised training, we propose to use the Cophenetic Correlation Coefficient (CPCC) as a regularizer for the cross-entropy loss to correlate the tree metric of classes and the Euclidean distance in the class-conditioned representations. Our proposed regularizer is computationally lightweight and easy to implement. Empirically, we demonstrate that this approach can help to learn more interpretable representations due to the preservation of the tree metric, and leads to better in-distribution generalization as well as under sub-population shifts over six real-world datasets.

Promptagator: Few-shot Dense Retrieval From 8 Examples

Zhuyun Dai,Vincent Y Zhao,Ji Ma,Yi Luan,Jianmo Ni,Jing Lu,Anton Bakalov,Kelvin Guu,Keith Hall,Ming-Wei Chang

Much recent research on information retrieval has focused on how to transfer from one task (typically with abundant supervised data) to various other retrieval tasks where supervision is limited, with the implicit assumption that it is possible to generalize from one task to all the rest. However, this overlooks the fact that there are many diverse and unique retrieval problems, each targeting different search intents, queries, and search domains. In this paper, we suggest to work on Few-shot Dense Retrieval, a setting where each task comes with a short description and a few examples. To address this, we introduce Prompt-based Query Generation forRetrieval (Promptagator): for each task, we feed the few-shot examples to a large language model (LLM) and prompt it to behave as a task-specific query generator. Using this, we can synthetically generate a large number of relevant queries for any document, yielding abundant data for training task-specific retrievers --- with no reliance on traditional resources such as Natural Questions (Kwiatkowskiet al., 2019) or MS MARCO (Nguyen et al., 2016). Surprisingly, Promptagator with only 8 annotated examples enables efficient dual encoder retrievers to outperform computationally more expensive models trained on MS MARCO such as ColBERT v2 (Santhanam et al., 2022) by more than 1.2 points nDCG@10 on average on 11 retrieval sets. Further training standard-size re-rankers using the same generated data yields another 5.0 points nDCG@10 improvement. Our studies show that synthetic query generation can be far more effective than previously observed, especially when a small amount of task-specific knowledge is given.

Brain-like representational straightening of natural movies in robust feedforward neural networks

Tahereh Toosi,Elias Issa

Representational straightening refers to a decrease in curvature of visual feature representations of a sequence of frames taken from natural movies. Prior work established straightening in neural representations of the primate primary visual cortex (V1) and perceptual straightening in human behavior as a hallmark of biological vision in contrast to artificial feedforward neural networks which did not demonstrate this phenomenon as they were not explicitly optimized to produce temporally predictable movie representations. Here, we show robustness to noise in the input image can produce representational straightening in feedforward neural networks. Both adversarial training (AT) and base classifiers for Random Smoothing (RS) induced remarkably straightened feature codes. Demonstrating their utility within the domain of natural movies, these codes could be inverted to generate intervening movie frames by linear interpolation in the feature space even though they were not trained on these trajectories. Demonstrating their biolo gical utility, we found that AT and RS training improved predictions of neural data in primate V1 over baseline models providing a parsimonious, bio-plausible mechanism -- noise in the sensory input stages -- for generating representations in early visual cortex. Finally, we compared the geometric properties of frame representations in these networks to better understand how they produced representations that mimicked the straightening phenomenon from biology. Overall, this work elucidating emergent properties of robust neural networks demonstrates that it is not necessary to utilize predictive objectives or train directly on natural movie statistics to achieve models supporting straightened movie representations similar to human perception that also predict V1 neural responses.

FunkNN: Neural Interpolation for Functional Generation

AmirEhsan Khorashadizadeh,Anadi Chaman,Valentin Debarnot,Ivan Dokmani■

Can we build continuous generative models which generalize across scales, can be evaluated at any coordinate, admit calculation of exact derivatives, and are conceptually simple? Existing MLP-based architectures generate worse samples than the grid-based generators with favorable convolutional inductive biases. Models that focus on generating images at different scales do better, but employ complex architectures not designed for continuous evaluation of images and derivatives.

We take a signal-processing perspective and treat continuous signal generation as interpolation from samples. Indeed, correctly sampled discrete images contain all information about the low spatial frequencies. The question is then how to extrapolate the spectrum in a data-driven way while meeting the above design criteria. Our answer is FunkNN---a novel convolutional network which learns how to reconstruct continuous images at arbitrary coordinates and can be applied to any image dataset. Combined with a discrete generative model it becomes a functional generator which can act as a prior in continuous ill-posed inverse problems. We show that FunkNN generates high-quality continuous images and exhibits strong out-of-distribution performance thanks to its patch-based design. We further showcase its performance in several stylized inverse problems with exact spatial derivatives.

A Framework for Comprehensive Evaluations of Graph Neural Network based Community Detection using Node Clustering

Will Leeney,Ryan McConville

Graph Neural Networks (GNNs) have shown promising performance across a number of tasks in recent years. Unsupervised community detection using GNNs involves the clustering of nodes of a graph given both the features of nodes as well as the structure of the graph, and has many applications to real world tasks from social networks to genomics. Unfortunately, there has been relatively little research using GNNs for commOunity detection, and even less that evaluates the systems rigorously and fairly. A comprehensive evaluation of the performance of GNNs requires an suitable environment within which they are evaluated. This is exacerbated by the fact that community detection is primarily an unsupervised task, and that (graph) neural networks are used which contain many hyperparameters, discovered by inconsistent procedures. We argue that there is currently a gap in the literature that establishes a sufficient benchmarking environment for the consistent evaluation of GNN based community detection, thereby impeding progress in this nascent field. In this work we propose and evaluate an environment for the consistent evaluation of neural community detection. With this we show the strong dependence of the performance to the experimental settings , thereby motivating the use of this framework to facilitate research into GNN based community detection.

CrystalBox: Efficient Model-Agnostic Explanations for Deep RL Controllers

Sagar Patel,Sangeetha Abdu Jyothi,Nina Narodytska

Practical adoption of Reinforcement Learning (RL) controllers is hindered by a lack of explainability. Particularly, in input-driven environments such as comput er systems where the state dynamics are affected by external processes, explainability can serve as a key towards increased real-world deployment of RL controllers. In this work, we propose a novel framework, CrystalBox, for generating black-box post-hoc explanations for RL controllers in input-driven environments. CrystalBox is built on the principle of separation between policy learning and explanation computation. As the explanations are generated completely outside the training loop, CrystalBox is generalizable to a large family of input-driven RL controllers.To generate explanations, CrystalBox combines the natural decomposability of reward functions in systems environments with the explanatory power of decomposed returns. CrystalBox predicts these decomposed future returns using on policy Q-function approximations. Our design leverages two complementary approaches for this computation: sampling- and learning-based methods. We evaluate CrystalBox with RL controllers in real-world settings and demonstrate that it generates high-fidelity explanations.

Label Propagation with Weak Supervision

Rattana Pukdee,Dylan Sam,Pradeep Kumar Ravikumar,Nina Balcan

Semi-supervised learning and weakly supervised learning are important paradigms that aim to reduce the growing demand for labeled data in current machine learning applications. In this paper, we introduce a novel analysis of the classical label propagation algorithm (LPA) (Zhu & Ghahramani, 2002) that moreover takes advantage of useful prior information, specifically probabilistic hypothesized labels on the unlabeled data. We provide an error bound that exploits both the local geometric properties of the underlying graph and the quality of the prior information. We also propose a framework to incorporate multiple sources of noisy information. In particular, we consider the setting of weak supervision, where our sources of information are weak labelers. We demonstrate the ability of our approach on multiple benchmark weakly supervised classification tasks, showing improvements upon existing semi-supervised and weakly supervised methods.

****

TypeT5: Seq2seq Type Inference using Static Analysis

Jiayi Wei,Greg Durrett,Isil Dillig

There has been growing interest in automatically predicting missing type annotations in programs written in Python and JavaScript. While prior methods have achieved impressive accuracy when predicting the most common types, they often perform poorly on rare or complex types. In this paper, we present a new type inference method that treats type prediction as a code infilling task by leveraging CodeT5, a state-of-the-art seq2seq pre-trained language model for code. Our method uses static analysis to construct dynamic contexts for each code element whose type signature is to be predicted by the model. We also propose an iterative decoding scheme that incorporates previous type predictions in the model's input context, allowing information exchange between related code elements. Our evaluation shows that the proposed approach, TypeT5, not only achieves a higher overall accuracy (particularly on rare and complex types) but also produces more coherent results with fewer type errors---while enabling easy user intervention.

Approximating any Function via Coreset for Radial Basis Functions: Towards Provable Data Subset Selection For Efficient Neural Networks training

Murad Tukan,Samson Zhou,Alaa Maalouf,Vladimir Braverman,Dan Feldman

Radial basis function neural networks (\emph{RBFNN}) are notoriously known for their capability to approximate any continuous function on a closed bounded set with arbitrary precision given enough hidden neurons. Coreset is a small weighted subset of an input set of items, that provably approximates their loss function for a given set of queries (models, classifiers, etc.). In this paper, we suggest the first coreset construction algorithm for \emph{RBFNNs}, i.e., a small weighted subset which approximates the loss of the input data on any radial basis function network and thus approximates any function defined by an \emph{RBFNN} on the big input data. This is done by constructing coresets for radial basis and Laplacian loss functions. We use our coreset to suggest a provable data subset s election algorithm for training deep neural networks, since our coreset approximates every function, it should approximate the gradient of each weight in a neural network as it is defined as a function on the input. Experimental results on function approximation and dataset subset selection on popular network architectures and data sets are presented, demonstrating the efficacy and accuracy of our coreset construction.

Axiomatic Explainer Locality With Optimal Transport

Joshua Bone,Aria Masoomi,Jennifer Dy

Explainability methods have been notoriously difficult to evaluate and compare. Because of this, practitioners are often left guessing as to which explainer they should use for their task. Locality is one critical property of explainers which grants insight into the diversity of produced explanations. In this paper, we define a set of axioms which align with natural intuition regarding globalness, the inverse of locality. We then introduce a novel measure of globalness, Wasserstein Globalness, which uses optimal transport to quantify how local or global a given explainer is. Finally, we provide theoretical results describing the sample complexity of Wasserstein Globalness, and experimentally demonstrate how globalness can be used to effectively compare explainers. These results illustrate connections between both explainer fidelity and explainer robustness.

****

Fine-Tuning Offline Policies With Optimistic Action Selection

Max Sobol Mark,Ali Ghadirzadeh,Xi Chen,Chelsea Finn

Offline reinforcement learning algorithms can train performant policies for hard tasks using previously-collected datasets. However, the quality of the offline dataset often limits the levels of performance possible. We consider the problem of improving offline policies through online fine-tuning. Offline RL requires a pessimistic training objective to mitigate distributional shift between the trained policy and the offline behavior policy, which will make the trained policy averse to picking novel actions. In contrast, online RL requires exploration, or optimism. Thus, fine-tuning online policies with the offline training objective is not ideal. Additionally, loosening the fine-tuning objective to allow for more exploration can potentially destroy the behaviors learned in the offline phase because of the sudden and significant change in the optimization objective. To mitigate this challenge, we propose a method to facilitate exploration during online fine-tuning that maintains the same training objective throughout both offline and online phases, while encouraging exploration. We accomplish this by changing the action-selection method to be more optimistic with respect to the Q-function. By choosing to take actions in the environment with higher expected Q-values, our method is able to explore and improve behaviors more efficiently, obtaining 56% more returns on average than the alternative approaches on several locomotion, navigation, and manipulation tasks.

Improving the Strength of Human-Like Models in Chess

Saumik Narayanan,Kassa Korley,Chien-Ju Ho,Siddhartha Sen

Designing AI systems that capture human-like behavior has attracted growing attention in applications where humans may want to learn from, or need to collaborate with, these AI systems. Many existing works in designing human-like AI have taken a supervised learning approach that learns from data of human behavior, with the goal of creating models that can accurately predict human behavior. While this approach has shown success in capturing human behavior at different skill levels and even identifying individual behavioral styles, it also suffers from the drawback of mimicking human mistakes. Moreover, existing models only capture a snapshot of human behavior, leaving the question of how to improve them---e.g., from one human skill level to a stronger one---largely unanswered. Using chess as an experimental domain, we investigate the question of teaching an existing human-like model to be stronger using a data-efficient curriculum, while maintaining the model's human similarity. To achieve this goal, we extend the concept of curriculum learning to settings with multiple labeling strategies, allowing us to vary both the curriculum (dataset) and the teacher (labeling strategy). We fi nd that the choice of teacher has a strong impact on both playing strength and human similarity; for example, a teacher that is too strong can be less effective at improving playing strength and degrade human similarity more rapidly. We also find that the choice of curriculum can impact these metrics, but to a smaller extent; for example, training on a curriculum of human mistakes provides only a marginal benefit over training on a random curriculum. Finally, we show that our strengthened models achieve human similarity on datasets corresponding to their strengthened level of play, suggesting that our curriculum training methodology is improving them in human-like steps.

AGRO: Adversarial discovery of error-prone Groups for Robust Optimization

Bhargavi Paranjape,Pradeep Dasigi,Vivek Srikumar,Luke Zettlemoyer,Hannaneh Hajishirzi

Models trained via empirical risk minimization (ERM) are known to rely on spurious correlations between labels and task-independent input features, resulting in poor generalization to distributional shifts. Group distributionally robust optimization (G-DRO) can alleviate this problem by minimizing the worst-case loss over a set of pre-defined groups over training data. G-DRO successfully improves performance of the worst group, where the correlation does not hold. However, G-DRO assumes that the spurious correlations and associated worst groups are known in advance, making it challenging to apply them to new tasks with potentially multiple unknown correlations. We propose AGRO---Adversarial Group discovery for Distributionally Robust Optimization---an end-to-end approach that jointly identifies error-prone groups and improves accuracy on them. AGRO equips G-DRO with an adversarial slicing model to find a group assignment for training examples which maximizes worst-case loss over the discovered groups. On the WILDS benchmark, AGRO results in 8\% higher model performance on average on known worst-groups, compared to prior group discovery approaches used with G-DRO. AGRO also improves out-of-distribution performance on SST2, QQP, and MS-COCO---datasets where potential spurious correlations are as yet uncharacterized. Human evaluation of ARGO groups shows that they contain well-defined, yet previously unstudied spurious correlations that lead to model errors.

Learning Multiobjective Program Through Online Learning

Chaosheng Dong,Yijia Wang,Bo Zeng

We investigate the problem of learning the parameters (i.e., objective functions or constraints) of a multiobjective decision making model, based on a set of sequentially arrived decisions. In particular, these decisions might not be exact and possibly carry measurement noise or are generated with the bounded rationality of decision makers. In this paper, we propose a general online learning framework to deal with this learning problem using inverse multiobjective optimization, and prove that this framework converges at a rate of $\mathcal{O}(1/\sqrt{T})$ under certain regularity conditions. More precisely, we develop two online learning algorithms with implicit update rules which can handle noisy data. Numerical results with both synthetic and real world datasets show that both algorithms can learn the parameters of a multiobjective program with great accuracy and are robust to noise.

****

Dichotomy of Control: Separating What You Can Control from What You Cannot

Sherry Yang,Dale Schuurmans,Pieter Abbeel,Ofir Nachum

Future- or return-conditioned supervised learning is an emerging paradigm for offline reinforcement learning (RL), in which the future outcome (i.e., return) associated with a sequence of actions in an offline dataset is used as input to a policy trained to imitate those same actions. While return-conditioning is at the heart of popular algorithms such as decision transformer (DT), these methods tend to perform poorly in highly stochastic environments, where an occasional high return associated with a sequence of actions may be due more to the randomness of the environment than to the actions themselves. Such situations can lead to a learned policy that is inconsistent with its conditioning inputs; i.e., using the policy – while conditioned on a specific desired return – to act in the envi ronment can lead to a distribution of real returns that is wildly different than desired. In this work, we propose the dichotomy of control (DoC), a future-conditioned supervised learning framework that separates mechanisms within a policy’s control (actions) from those outside of a policy’s control (environment stochasticity). We achieve this by conditioning the policy on a latent variable representation of the future and designing a mutual information constraint that removes any future information from the latent variable that is only due to randomness of the environment. Theoretically, we show that DoC yields policies that are consistent with their conditioning inputs, ensuring that conditioning a learned policy on a desired high-return future outcome will correctly induce high-return behavior. Empirically, we show that DoC is able to achieve significantly better performance than DT on environments with highly stochastic rewards (e.g., Bandit) and transitions (e.g., FrozenLake).

Progressive Knowledge Distillation: Constructing Ensembles for Efficient Inference

Don Dennis,Abhishek Shetty,Anish Prasad Sevekari,Kazuhito Koishida,Virginia Smith

Knowledge distillation is commonly used to compress an ensemble of models into a single model. In this work we study the problem of progressive distillation: Given a large, pretrained teacher model g, we seek to decompose the model into an ensemble of smaller, low-inference cost student models f_i. The resulting ensemble allows for flexibly tuning accuracy vs. inference cost, which can be useful for a multitude of applications in efficient inference. Our method, B-DISTIL, uses a boosting procedure that allows function composition based aggregation rules to construct expressive ensembles with similar performance as g using much smaller student models. We demonstrate the effectiveness of B-DISTIL by decomposing pretrained models across a variety of image, speech, and sensor datasets. Our method comes with strong theoretical guarantees in terms of convergence as well as generalization.

Efficient Approximations of Complete Interatomic Potentials for Crystal Property Prediction

Yuchao Lin,Keqiang Yan,Youzhi Luo,Yi Liu,Xiaoning Qian,Shuiwang Ji

We study the problem of crystal material property prediction. A crystal structure consists of a minimal unit cell that is repeated infinitely in 3D space. How to accurately represent such repetitive structures in machine learning models remains unresolved. Current methods construct graphs by establishing edges only between nearby nodes, thereby failing to faithfully capture infinite repeating patterns and distant interatomic interactions. In this work, we propose several innovations to overcome these limitations. First, we propose to model physics-principled interatomic potentials directly instead of only using distances as in existing methods. These potentials include the Coulomb potential, London dispersion potential, and Pauli repulsion potential. Second, we propose to model the complete set of potentials among all atoms, instead of only between nearby atoms as in prior methods. This is enabled by our approximations of infinite potential summations with provable error bounds. We further develop efficient algorithms to compute the approximations. Finally, we propose to incorporate our computations of complete interatomic potentials into message passing neural networks for representation learning. We perform experiments on the JARVIS and Materials Project benchmarks for evaluation. Results show that the use of complete interatomic potentials leads to consistent performance improvements with reasonable computational costs.

LogicDP: Creating Labels for Graph Data via Inductive Logic Programming

Yuan Yang,Faramarz Fekri,James Clayton Kerce,Ali Payani

Graph data, such as scene graphs and knowledge graphs, see wide use in AI systems. In real-world and large applications graph data are usually incomplete, motivating graph reasoning models for missing-fact or missing-relationship inference. While these models can achieve state-of-the-art performance, they require a lar ge amount of training data.

Recent years have witnessed the rising interest in label creation with data programming (DP) methods, which aim to generate training labels from heuristic labeling functions. However, existing methods typically focus on unstructured data and are not optimized for graphs. In this work, we propose LogicDP, a data programming framework for graph data. Unlike existing DP methods, (1) LogicDP utilizes the inductive logic programming (ILP) technique and automatically discovers the labeling functions from the graph data; (2) LogicDP employs a budget-aware framework to iteratively refine the functions by querying an oracle, which significantly reduces the human efforts in function creations. Experiments show that LogicDP achieves better data efficiency in both scene graph and knowledge graph reasoning tasks.

Simulating Environments for Evaluating Scarce Resource Allocation Policies
Jeroen Berrevoets,Alex Chan,Daniel Jarrett,Mihaela van der Schaar
Consider the sequential decision problem of allocating a limited supply of resources to a pool of potential recipients: This scarce resource allocation problem arises in a variety of settings characterized by "hard-to-make" tradeoffs– such as assigning organs to transplant patients, or rationing ventilators in overstretched ICUs. Assisting human judgement in these choices are dynamic allocation policies that prescribe how to match available assets to an evolving pool of beneficiaries– such as clinical guidelines that stipulate selection criteria on the basis of recipient and organ attributes. However, while such policies have received increasing attention in recent years, a key challenge lies in pre-deployment evaluation: How might allocation policies behave in the real world? In particular, in addition to conventional backtesting, it is crucial that policies be evaluated on a variety of possible scenarios and sensitivities– such as distributions of recipients and organs that may diverge from historic patterns. In this work, we present AllSim, an open-source framework for performing data-driven simulation of scarce resource allocation policies for pre-deployment evaluation. Simulation environments are modular (i.e. parameterized componentwise), learnable (i.e. on historical data), and customizable (i.e. to unseen conditions), and– upon interaction with a policy –outputs a dataset of simulated outcomes for analysis and benchmarking. Compared to existing work, we believe this approach takes a step towards more methodical evaluation of scarce resource allocation policies.

Learning to reason with relational abstractions
Andrew Joo Hun Nam,Mengye Ren,Chelsea Finn,James Lloyd McClelland
Large language models have recently shown promising progress in mathematical reasoning when fine-tuned with human-generated sequences walking through a sequence of solution steps. However, the solution sequences are not formally structured and the resulting model-generated sequences may not reflect the kind of systematic reasoning we might expect an expert human to produce.

In this paper, we study how to build stronger reasoning capability in language models using the idea of relational abstractions. We introduce new types of sequences that more explicitly provide an abstract characterization of the transitions through intermediate solution steps to the goal state. We found that models that are supplied with such sequences as prompts can solve tasks with a significantly higher accuracy, and models that are trained to produce such sequences solve problems better than those that are trained with previously used human-generated sequences and other baselines. Our work thus takes several steps toward elucidating and improving how language models perform on tasks requiring multi-step mathematical reasoning.

A Simple Approach for State-Action Abstraction using a Learned MDP Homomorphism
Augustine N. Mavor-Parker,Matthew James Sargent,Andrea Banino,Lewis Griffin,Caswell Barry
Animals are able to rapidly infer from limited experience when sets of state action pairs have equivalent reward and transition dynamics. On the other hand, mod

ern reinforcement learning systems must painstakingly learn through trial and error that sets of state action pairs are value equivalent---requiring an often prohibitively large amount of samples from their environment. MDP homomorphisms have been proposed that reduce the observed MDP of an environment to an abstract MDP, which can enable more sample efficient policy learning. Consequently, impressive improvements in sample efficiency have been achieved when a suitable MDP homomorphism can be constructed a priori---usually by exploiting a practioner's knowledge of environment symmetries. We propose a novel approach to constructing a homomorphism in discrete action spaces, which uses a partial model of environment dynamics to infer which state action pairs lead to the same state---reducing the size of the state-action space by a factor equal to the cardinality of the action space. We call this method equivalent effect abstraction. We demonstrate empirically that equivalent effect abstraction can improve sample efficiency in a model-free setting and planning efficiency for model based approaches.

RankMe: Assessing the Downstream Performance of Pretrained Self-Supervised Representations by Their Rank

Quentin Garrido,Randall Balestriero,Laurent Najman,Yann LeCun

Joint-Embedding Self Supervised Learning (JE-SSL) has seen a rapid development, with the emergence of many method variations and few principled guidelines that would help practitioners to successfully deploy those methods. The main reason for that pitfall actually comes from JE-SSL's core principle of not employing any input reconstruction. Without any visual clue, it becomes extremely cryptic to judge the quality of a learned representation without having access to a labelled dataset. We hope to correct those limitations by providing a single --theoretically motivated-- criterion that reflects the quality of learned JE-SSL representations: their effective rank. Albeit simple and computationally friendly, this method ---coined {\em RankMe}--- allows one to assess the performance of JE-SSL representations, even on different downstream datasets, without requiring any labels, training or parameters to tune. Through thorough empirical experiments involving hundreds of repeated training episodes, we demonstrate how RankMe can be used for hyperparameter selection with nearly no loss in final performance compared to the current selection method that involve dataset labels. We hope that RankMe will facilitate the use of JE-SSL in domains with little or no labeled data.

Revisiting Intrinsic Reward for Exploration in Procedurally Generated Environments

Kaixin Wang,Kuangqi Zhou,Bingyi Kang,Jiashi Feng,Shuicheng YAN

Exploration under sparse rewards remains a key challenge in deep reinforcement learning. Recently, studying exploration in procedurally-generated environments has drawn increasing attention. Existing works generally combine lifelong intrinsic rewards and episodic intrinsic rewards to encourage exploration. Though various lifelong and episodic intrinsic rewards have been proposed, the individual contributions of the two kinds of intrinsic rewards to improving exploration are barely investigated. To bridge this gap, we disentangle these two parts and conduct ablative experiments. We consider lifelong and episodic intrinsic rewards used in prior works, and compare the performance of all lifelong-episodic combinations on the commonly used MiniGrid benchmark. Experimental results show that only using episodic intrinsic rewards can match or surpass prior state-of-the-art methods. On the other hand, only using lifelong intrinsic rewards hardly makes progress in exploration. This demonstrates that episodic intrinsic reward is more crucial than lifelong one in boosting exploration. Moreover, we find through experimental analysis that the lifelong intrinsic reward does not accurately reflect the novelty of states, which explains why it does not help much in improving exploration.

Online Learning for Obstacle Avoidance

David Snyder,Wenhan Xia,Daniel Suo,Anirudha Majumdar,Elad Hazan

We approach the fundamental problem of obstacle avoidance for robotic systems vi a the lens of online learning. In contrast to prior work that either assumes worst-case realization of uncertainty in the environment or a given stochastic model of uncertainty, we propose a method that is efficient to implement and provably grants instance-optimality to perturbations of trajectories generated from an open-loop planner in the sense of minimizing worst-case regret. The resulting policy thus adapts online to realizations of uncertainty and provably compares well with the best obstacle avoidance policy in hindsight from a rich class of policies. The method is validated in simulation on a dynamical system environment and compared to baseline open-loop planning and robust Hamilton-Jacobi reachability techniques.

Transformer-based World Models Are Happy With 100k Interactions

Jan Robine,Marc Höftmann,Tobias Uelwer,Stefan Harmeling

Deep neural networks have been successful in many reinforcement learning settings. However, compared to human learners they are overly data hungry. To build a sample-efficient world model, we apply a transformer to real-world episodes in an autoregressive manner: not only the compact latent states and the taken actions but also the experienced or predicted rewards are fed into the transformer, so that it can attend flexibly to all three modalities at different time steps. The transformer allows our world model to access previous states directly, instead of viewing them through a compressed recurrent state. By utilizing the Transformer-XL architecture, it is able to learn long-term dependencies while staying computationally efficient. Our transformer-based world model (TWM) generates meaningful, new experience, which is used to train a policy that outperforms previous model-free and model-based reinforcement learning algorithms on the Atari 100k benchmark. Our code is available at https://github.com/jrobine/twm.

Can Neural Networks Learn Implicit Logic from Physical Reasoning?

Aaron Traylor,Roman Feiman,Ellie Pavlick

Despite the success of neural network models in a range of domains, it remains an open question whether they can learn to represent abstract logical operators such as negation and disjunction. We test the hypothesis that neural networks without inherent inductive biases for logical reasoning can acquire an implicit representation of negation and disjunction. Here, implicit refers to limited, domain-specific forms of these operators, and work in psychology suggests these operators may be a precursor (developmentally and evolutionarily) to the type of abstract, domain-general logic that is characteristic of adult humans. To test neural networks, we adapt a test designed to diagnose the presence of negation and disjunction in animals and pre-verbal children, which requires inferring the location of a hidden object using constraints of the physical environment as well as implicit logic: if a ball is hidden in A or B, and shown not to be in A, can the subject infer that it is in B? Our results show that, despite the neural networks learning to track objects behind occlusion, they are unable to generalize to a task that requires implicit logic. We further show that models are unable to generalize to the test task even when they are trained directly on a logically identical (though visually dissimilar) task. However, experiments using transfer learning reveal that the models do recognize structural similarity between tasks which invoke the same logical reasoning pattern, suggesting that some desirable abstractions are learned, even if they are not yet sufficient to pass established tests of logical reasoning.

Blockwise self-supervised learning with Barlow Twins

Shoaib Ahmed Siddiqui,David Krueger,Yann LeCun,Stephane Deny

Current state-of-the-art deep networks are all powered by backpropagation. In this paper, we explore alternatives to full backpropagation in the form of blockwise learning rules, leveraging the latest developments in self-supervised learning. Notably, we show that a blockwise pretraining procedure consisting of training independently the 4 main blocks of layers of a ResNet-50 with Barlow Twins loss function at each block performs almost as well as end-to-end backpropagation on ImageNet: a linear probe trained on top of our blockwise pretrained model obta ins a top-1 classification accuracy of 70.48\%, only 1.1\% below the accuracy of an end-to-end pretrained network (71.57\% accuracy). We perform extensive experiments to understand the impact of different components within our method and explore a variety of adaptations of self-supervised learning to the blockwise paradigm, building an exhaustive understanding of the critical avenues for scaling local learning rules to large networks, with implications ranging from hardware design to neuroscience.

DIGEST: FAST AND COMMUNICATION EFFICIENT DECENTRALIZED LEARNING WITH LOCAL UPDATES

Peyman Gholami,Hulya Seferoglu

Decentralized learning advocates the elimination of centralized parameter servers (aggregation points) for potentially better utilization of underlying resources, delay reduction, and resiliency against parameter server unavailability and catastrophic failures. Gossip based decentralized algorithms, where each node in a network has its own locally kept model on which it effectuates the learning by talking to its neighbors, received a lot of attention recently. Despite their potential, Gossip algorithms introduce huge communication costs. In this work, we show that nodes do not need to communicate as frequently as in Gossip for fast convergence; in fact, a sporadic exchange of a digest of a trained model is sufficient. Thus, we design a fast and communication-efficient decentralized learning mechanism; DIGEST by particularly focusing on stochastic gradient descent (SGD). DIGEST is a decentralized algorithm building on local-SGD algorithms, which are originally designed for communication efficient centralized learning. We show through analysis and experiments that DIGEST significantly reduces the communication cost without hurting convergence time for both iid and non-iid data.

Learning to Improve Code Efficiency

Binghong Chen,Daniel Tarlow,Kevin Swersky,Martin Maas,Pablo Heiber,Ashish V Naik,Milad Hashemi,Parthasarathy Ranganathan

Improvements in the performance of computing systems, driven by Moore’s Law, have transformed society. As such hardware-driven gains slow down, it becomes even more important for software developers to focus on performance and efficiency during development. While several studies have demonstrated the potential from such improved code efficiency (e.g., 2x better generational improvements compared to hardware), unlocking these gains in practice has been challenging. Reasoning about algorithmic complexity and the interaction of coding patterns on hardware can be challenging for the average programmer, especially when combined with pragmatic constraints around development velocity and multi-person development.

This paper seeks to address this problem. We analyze a large competitive programming dataset from the Google Code Jam competition and find that efficient code is indeed rare, with a 2x runtime difference between the median and the 90th percentile of solutions. We propose using machine learning to automatically provide prescriptive feedback in the form of hints, to guide programmers towards writing high-performance code. To automatically learn these hints from the dataset, we propose a novel discrete variational auto-encoder, where each discrete latent variable represents a different learned category of code-edit that increases performance. We show that this method represents the multi-modal space of code efficiency edits better than a sequence-to-sequence baseline and generates a distribution of more efficient solutions.

ESCHER: Eschewing Importance Sampling in Games by Computing a History Value Function to Estimate Regret

Stephen Marcus McAleer,Gabriele Farina,Marc Lanctot,Tuomas Sandholm

Recent techniques for approximating Nash equilibria in very large games leverage neural networks to learn approximately optimal policies (strategies). One promis- ing line of research uses neural networks to approximate counterfactual regret minimization (CFR) or its modern variants. DREAM, the only current CFR-based neural method that is model free and therefore scalable to very large games, trains a neural network on an estimated regret target that can have extremely high variance due to an importance sampling term inherited from Monte Carlo CFR (MCCFR). In this paper we propose an unbiased model-free method that does not require any importance sampling. Our method, ESCHER, is principled and is guaranteed to converge to an approximate Nash equilibrium with high probability. We show that the variance of the estimated regret of ESCHER is orders of magnitude lower than DREAM and other baselines. We then show that ESCHER outperforms the prior state of the art—DREAM and neural fictitious self play (NFSP)—on a number of games and the difference becomes dramatic as game size increases. In the very large game of dark chess, ESCHER is able to beat DREAM and NFSP in a head-to-head competition over 90% of the time.

****

On Achieving Optimal Adversarial Test Error

Justin D. Li,Matus Telgarsky

We first elucidate various fundamental properties of optimal adversarial predictors: the structure of optimal adversarial convex predictors in terms of optimal adversarial zero-one predictors, bounds relating the adversarial convex loss to the adversarial zero-one loss, and the fact that continuous predictors can get arbitrarily close to the optimal adversarial error for both convex and zero-one losses. Applying these results along with new Rademacher complexity bounds for adversarial training near initialization, we prove that for general data distributions and perturbation sets, adversarial training on shallow networks with early stopping and an idealized optimal adversary is able to achieve optimal adversarial test error. By contrast, prior theoretical work either considered specialized data distributions or only provided training error guarantees.

General Policy Evaluation and Improvement by Learning to Identify Few But Crucial States

Francesco Faccio,Aditya Ramesh,Vincent Herrmann,Jean Harb,Jürgen Schmidhuber

Learning to evaluate and improve policies is a core problem of Reinforcement Learning (RL). Traditional RL algorithms learn a value function defined for a single policy. A recently explored competitive alternative is to learn a single value function for many policies. Here we combine the actor-critic architecture of Parameter-Based Value Functions and the policy embedding of Policy Evaluation Networks to learn a single value function for evaluating (and thus helping to improve) any policy represented by a deep neural network (NN). The method yields competitive experimental results. In continuous control problems with infinitely many states, our value function minimizes its prediction error by simultaneously learning a small set of `probing states' and a mapping from actions produced in probing states to the policy's return. The method extracts crucial abstract knowledge about the environment in form of very few states sufficient to fully specify the behavior of many policies. A policy improves solely by changing actions in probing states, following the gradient of the value function's predictions. Surprisingly, it is possible to clone the behavior of a near-optimal policy in Swimmer-v3 and Hopper-v3 environments only by knowing how to act in 3 and 5 such learned states, respectively. Remarkably, our value function trained to evaluate NN policies is also invariant to changes of the policy architecture: we show that it allows for zero-shot learning of linear policies competitive with the best policy seen during training.

Serving Graph Compression for Graph Neural Networks

Si Si,Felix Yu,Ankit Singh Rawat,Cho-Jui Hsieh,Sanjiv Kumar

Serving a GNN model online is challenging --- in many applications when testing nodes are connected to training nodes, one has to propagate information from training nodes to testing nodes to achieve the best performance, and storing the wh ole training set (including training graph and node features) during inference stage is prohibitive for large-scale problems. In this paper, we study graph compression to reduce the storage requirement for GNN in serving. Given a GNN model to be served, we propose to construct a compressed graph with a smaller number of nodes. In serving time, one just needs to replace the original training set graph by this compressed graph, without the need of changing the actual GNN model and the forward pass. We carefully analyze the error in the forward pass and derive simple ways to construct the compressed graph to minimize the approximation error. Experimental results on semi-supervised node classification demonstrate that the proposed method can significantly reduce the serving space requirement for GNN inference.

Optimal Data Sampling for Training Neural Surrogates of Programs

Alex Renda,Yi Ding,Michael Carbin

Programmers and researchers are increasingly developing surrogates of programs, models of a subset of the observable behavior of a given program, to solve a variety of software development challenges. Programmers train surrogates from measurements of the behavior of a program on a dataset of input examples.

We present a methodology for optimally sampling datasets to train neural network based surrogates of programs. We first characterize the optimal proportion of data to sample from each path in a program based on the complexity of learning the path. We next provide a program analysis to determine the complexity of different paths in a program. We evaluate these results on a large-scale graphics program, demonstrating that theoretically optimal sampling results in empirical improvements in accuracy.

Towards Understanding GD with Hard and Conjugate Pseudo-labels for Test-Time Adaptation

Jun-Kun Wang,Andre Wibisono

We consider a setting that a model needs to adapt to a new domain under distribution shifts, given that only unlabeled test samples from the new domain are accessible at test time. A common idea in most of the related works is constructing pseudo-labels for the unlabeled test samples and applying gradient descent (GD) to a loss function with the pseudo-labels. Recently, Goyal et al. (2022) propose conjugate labels, which is a new kind of pseudo-labels for self-training at test time. They empirically show that the conjugate label outperforms other ways of pseudo-labeling on many domain adaptation benchmarks. However, provably showing that GD with conjugate labels learns a good classifier for test-time adaptation remains open. In this work, we aim at theoretically understanding GD with hard and conjugate labels for a binary classification problem. We show that for square loss, GD with conjugate labels converges to an ϵ-optimal predictor under a Gaussian model for any arbitrarily small ϵ, while GD with hard pseudo-labels fails in this task. We also analyze them under different loss functions for the update. Our results shed lights on understanding when and why GD with hard labels or conjugate labels works in test-time adaptation.

Achieving Communication-Efficient Policy Evaluation for Multi-Agent Reinforcement Learning: Local TD-Steps or Batching?

FNU Hairi,Zifan Zhang,Jia Liu

In many consensus-based actor-critic multi-agent reinforcement learning (MARL) strategies, one of the key components is the MARL policy evaluation (PE) problem, where a set of N agents work cooperatively to evaluate the value function of the global states under a given policy only through communicating with their neighbors.

In MARL-PE, a critical challenge is how to lower the communication complexity, which is defined as the rounds of communication between neighboring nodes in order to converge to some ϵ-stationary point.

To lower communication complexity in MARL-PE, there exist two ``natural'' ideas: i) using batching to reduce the variance of TD (temporal difference) errors, wh

ich in turn improves the convergence rate of MARL-PE; and ii) performing multiple local TD update steps between each consecutive rounds of communication, so as to reduce the communication frequency.
While the effectiveness of the batching approach has been verified and relatively well-understood, the validity of the local TD-steps approach remains unclear due to the potential ``agent-drift'' phenomenon resulted from various heterogeneity factors across agents.
This leads to an interesting open question in MARL-PE: *Does the local TD-steps approach really work and how does it perform in comparison to the batching approach?*
In this paper, we take the first attempt to answer this interesting and fundamental question.
Our theoretical analysis and experimental results confirm that allowing multiple local TD steps is indeed a valid approach in lowering the communication complexity of MARL-PE compared to vanilla consensus-based MARL-PE algorithms.
Specifically, the local TD steps between two consecutive communication rounds can be as large as
$\mathcal{O}(\sqrt{1/\epsilon}\log{(1/\epsilon)})$ in order to converge to an ϵ-stationary point of MARL-PE.
Theoretically, we show that in order to reach the optimal sample complexity up to a log factor, the communication complexity is $\mathcal{O}(\sqrt{1/\epsilon}\log{(1/\epsilon)})$, which is *considerably worse* than TD learning with batching, whose communication complexity is $\mathcal{O}(\log (1/\epsilon))$. However, the experimental results show that the allowing multiple steps can be as good as the batch approach.

Learning where and when to reason in neuro-symbolic inference
Cristina Cornelio,Jan Stuehmer,Shell Xu Hu,Timothy Hospedales
The integration of hard constraints on neural network outputs is a very desirable capability. This allows to instill trust in AI by guaranteeing the sanity of that neural network predictions with respect to domain knowledge. Recently, this topic has received a lot of attention. However, all the existing methods usually either impose the constraints in a "weak" form at training time, with no guarantees at inference, or fail to provide a general framework that supports different tasks and constraint types. We tackle this open problem from a neuro-symbolic perspective. Our pipeline enhances a conventional neural predictor with (1) a symbolic reasoning module capable of correcting structured prediction errors and (2) a neural attention module that learns to direct the reasoning effort to focus on potential prediction errors, while keeping other outputs unchanged. This framework provides an appealing trade-off between the efficiency of constraint-free neural inference and the prohibitive cost of exhaustive reasoning at inference time. We show that our method outperforms the state of the art on visual-Sudoku, and can also benefit visual scene graph prediction. Furthermore, it can improve the performance of existing neuro-symbolic systems that lack our explicit reasoning during inference.
****
Aging with GRACE: Lifelong Model Editing with Key-Value Adaptors
Thomas Hartvigsen,Swami Sankaranarayanan,Hamid Palangi,Yoon Kim,Marzyeh Ghassemi
Large language models often err during deployment, either due to non-representative training data or distribution shift in the test set. Recently, model editors have been proposed to fix errors by adjusting a pre-trained model's weights. So far, however, existing model editors fail when making sequential edits by quickly decaying a model's performance on its upstream data. Further, when editing deployed online models, they quickly forget how to fix previously-seen mistakes. We advance beyond these existing methods by proposing and studying a novel Lifelong Model Editing setting, where errors stream into a deployed model and we update the model to correct its predictions without influencing its predictions for unrelated inputs. Towards effective methods in this challenging setting, we propose with General Retrieval Adaptors for Continual Editing, or GRACE. GRACE is a new Key-Value framework that casts model editing as a codebook update problem. Th

e proposed approach edits selected model layers by caching activations that are queried using embeddings from the previous layer. The cached activations are trained to correct a model's predictions, treating future layers as a decoder. As edits stream in, the keys and values of a GRACE layer are updated while the model weights remain frozen, ensuring similar edits are treated similarly without altering the model's performance on unrelated instances. Experimentally, we show that \method substantially improves over recent model editors.

A VAE for Transformers with Nonparametric Variational Information Bottleneck
James Henderson,Fabio James Fehr
We propose a Variational AutoEncoder (VAE) for Transformers by developing a Variational Information Bottleneck (VIB) regulariser for Transformer embeddings. We formalise such attention-based representations as mixture distributions, and use Bayesian nonparametrics to develop a Nonparametric VIB (NVIB) for them. The variable number of mixture components supported by nonparametrics captures the variable number of vectors supported by attention, and exchangeable distributions from nonparametrics capture the permutation invariance of attention. Our Transformer VAE (NVAE) uses NVIB to regularise the information passing from the Transformer encoder to the Transformer decoder. Evaluations of a NVAE, trained on natural language text, demonstrate that NVIB can regularise the number of mixture components in the induced embedding whilst maintaining generation quality and reconstruction capacity.

Learning MLPs on Graphs: A Unified View of Effectiveness, Robustness, and Efficiency
Yijun Tian,Chuxu Zhang,Zhichun Guo,Xiangliang Zhang,Nitesh Chawla
While Graph Neural Networks (GNNs) have demonstrated their efficacy in dealing with non-Euclidean structural data, they are difficult to be deployed in real applications due to the scalability constraint imposed by the multi-hop data dependency. Existing methods attempt to address this scalability issue by training student multi-layer perceptrons (MLPs) exclusively on node content features using labels derived from the teacher GNNs. However, the trained MLPs are neither effective nor robust. In this paper, we ascribe the lack of effectiveness and robustness to three significant challenges: 1) the misalignment between content feature and label spaces, 2) the strict hard matching to teacher's output, and 3) the sensitivity to node feature noises. To address the challenges, we propose NOSMOG, a novel method to learn NOise-robust Structure-aware MLPs On Graphs, with remarkable effectiveness, robustness, and efficiency. Specifically, we first address the misalignment by complementing node content with position features to capture the graph structural information. We then design an innovative representational similarity distillation strategy to inject soft node similarities into MLPs. Finally, we introduce adversarial feature augmentation to ensure stable learning against feature noises. Extensive experiments and theoretical analyses demonstrate the superiority of NOSMOG by comparing it to GNNs and the state-of-the-art method in both transductive and inductive settings across seven datasets. Codes are available at https://github.com/meettyj/NOSMOG.

On The Specialization of Neural Modules
Devon Jarvis,Richard Klein,Benjamin Rosman,Andrew M Saxe
A number of machine learning models have been proposed with the goal of achieving systematic generalization: the ability to reason about new situations by combining aspects of previous experiences. These models leverage compositional architectures which aim to learn specialized modules dedicated to structures in a task that can be composed to solve novel problems with similar structures. While the compositionality of these architectures is guaranteed by design, the modules specializing is not. Here we theoretically study the ability of network modules to specialize to useful structures in a dataset and achieve systematic generalization. To this end we introduce a minimal space of datasets motivated by practical systematic generalization benchmarks. From this space of datasets we present a mathematical definition of systematicity and study the learning dynamics of line

ar neural modules when solving components of the task. Our results shed light on the difficulty of module specialization, what is required for modules to successfully specialize, and the necessity of modular architectures to achieve systematicity. Finally, we confirm that the theoretical results in our tractable setting generalize to more complex datasets and non-linear architectures.

HomoDistil: Homotopic Task-Agnostic Distillation of Pre-trained Transformers

Chen Liang,Haoming Jiang,Zheng Li,Xianfeng Tang,Bing Yin,Tuo Zhao

Knowledge distillation has been shown to be a powerful model compression approach to facilitate the deployment of pre-trained language models in practice. This paper focuses on task-agnostic distillation. It produces a compact pre-trained model that can be easily fine-tuned on various tasks with small computational costs and memory footprints. Despite the practical benefits, task-agnostic distillation is challenging. Since the teacher model has a significantly larger capacity and stronger representation power than the student model, it is very difficult for the student to produce predictions that match the teacher's over a massive amount of open-domain training data. Such a large prediction discrepancy often diminishes the benefits of knowledge distillation. To address this challenge, we propose Homotopic Distillation (HomoDistil), a novel task-agnostic distillation approach equipped with iterative pruning. Specifically, we initialize the student model from the teacher model, and iteratively prune the student's neurons until the target width is reached. Such an approach maintains a small discrepancy between the teacher's and student's predictions throughout the distillation process, which ensures the effectiveness of knowledge transfer. Extensive experiments demonstrate that HomoDistil achieves significant improvements on existing baselines. Our codes will be released.

Information-Theoretic Underpinnings of Generalization and Translation in Emergent Communication

Mycal Tucker,Julie Shah,Roger P. Levy,Noga Zaslavsky

Traditional emergent communication (EC) methods often fail to generalize to novel settings or align with representations of natural language. While these limitations may at first appear unrelated, in this work, we show how controlling the Information Bottleneck (IB) tradeoff between complexity and informativeness (a principle thought to guide human languages) helps to address both of these problems in EC. Specifically, we build on VQ-VIB, a recently proposed method for training EC agents while controlling the IB tradeoff, in addition to maximizing agents' utility. We find that increasing informativeness, which is a task-agnostic measure of how well a listener can reconstruct a speaker's meaning, allows EC agents to better generalize to novel settings and more challenging tasks. At the same time, in translation experiments between EC and English, we find that increasing EC informativeness only improves team performance up to a certain threshold, corresponding to the English informativeness-complexity tradeoff. Jointly, our results indicate the importance of training EC systems while controlling the informativeness-complexity tradeoff to simultaneously support improved self-play performance and human-agent interaction.

Optimal Transport-Based Supervised Graph Summarization

Sepideh Neshatfar,Abram Magner,Salimeh Yasaei Sekeh

Graph summarization is the problem of producing smaller graph representations of an input graph dataset, in such a way that
  the smaller ``compressed'' graphs capture relevant structural information for downstream tasks. One graph summarization
  method, recently proposed in Garg & Jaakkola (2019), formulates an optimal transport-based framework that allows prior information
  about node, edge, and attribute importance to be incorporated into the graph summarization process. We extend the optimal transport framework to a supervised graph summarization setting, wherein we seek to preserve relevant information about a class label. We first formulate the problem in terms of maximizing the mutual information between the summarized graph and the class label. We then prop

ose a method that incorporates mutual information estimates between random variables associated with sample graphs and class labels into the optimal transport compression framework from Garg & Jaakkola (2019). We empirically show performance improvements over the previous work by Garg & Jaakkola (2019), in terms of classification and compression on synthetic and real datasets. We then theoretically show limitations of the optimal transport approach: e.g., that it fails to satisfy a certain desirable information monotonicity property.

****

Contrastive Vision Transformer for Self-supervised Out-of-distribution Detection

Hengding Wang,Yuchen Lu,Xi Chen

Out-of-distribution (OOD) detection is a type of technique that aims to detect abnormal samples that don't belong to the distribution of training data (or in-distribution (ID) data). The technique has been applied to various image classification tasks to identify abnormal image samples for which the abnormality is caused by semantic shift (from different classes) or covariate shift (from different domains). However, disentangling OOD samples caused by different shifts remains a challenge in image OOD detection. This paper proposes Contrastive Vision Transformer (CVT), an attention-based contrastive learning model, for self-supervised OOD detection in image classification tasks. Specifically, vision transformer architecture is integrated as a feature extracting module under a contrastive learning framework. An empirical ensemble module is developed to extract representative ensemble features, from which a balance can be achieved between semantic and covariate OOD samples. The proposed CVT model is tested in various self-supervised OOD detection tasks, and our approach outperforms state-of-the-art methods by 5.5% AUROC on CIFAR-10 (ID) vs. CIFAR-100 (OOD), and by 10.7% AUROC on CIFAR-100 (ID) vs. CIFAR-10 (OOD).

Does the Half Adversarial Robustness Represent the Whole? It Depends... A Theoretical Perspective of Subnetwork Robustness

Jovon Craig,Joshua Andle,Theodore Stein Nowak,Salimeh Yasaei Sekeh

Adversarial robustness of deep neural networks has been studied extensively and can bring security against adversarial attacks/examples. However, adversarially robust training approaches require a training mechanism on the entire deep network which can come at the cost of efficiency and computational complexity such as runtime. As a pilot study, we develop in this paper a novel theoretical framework that aims to answer the question of how can we make a whole model robust to adversarial examples by making part of a model robust? Toward promoting subnetwork robustness, we propose for the first time a new concept of semirobustness, which indicates adversarial robustness of a part of the network. We provide a theoretical analysis to show that if a subnetwork is robust and highly correlated with the rest of the network, then the remaining layers are also guaranteed to be robust. To guide the empirical investigation of our theoretical findings, we implemented our method at multiple layer depths and across multiple common image classification datasets. Experiments demonstrate that our method, with sufficient dependency between subnetworks, successfully utilizes subnetwork robustness to match fully-robust models' performance across AlexNet, VGG16, and ResNet50 benchmarks, for attack types FGSM, I-FGSM, PGD, and C&W.

Using Both Demonstrations and Language Instructions to Efficiently Learn Robotic Tasks

Albert Yu,Ray Mooney

Demonstrations and natural language instructions are two common ways to specify and teach robots novel tasks. However, for many complex tasks, a demonstration or language instruction alone contains ambiguities, preventing tasks from being specified clearly. In such cases, a combination of both a demonstration and an instruction more concisely and effectively conveys the task to the robot than either modality alone. To instantiate this problem setting, we train a single multi-task policy on a few hundred challenging robotic pick-and-place tasks and propose DeL-TaCo (Joint Demo-Language Task Conditioning), a method for conditioning a robotic policy on task embeddings comprised of two components: a visual demonstration and a language instruction. By allowing these two modalities to mutually disambiguate and clarify each other during novel task specification, DeL-TaCo (1) substantially decreases the teacher effort needed to specify a new task and (2) achieves better generalization performance on novel objects and instructions over previous task-conditioning methods. To our knowledge, this is the first work to show that simultaneously conditioning a multi-task robotic manipulation policy on both demonstration and language embeddings improves sample efficiency and generalization over conditioning on either modality alone.

On the duality between contrastive and non-contrastive self-supervised learning

Quentin Garrido,Yubei Chen,Adrien Bardes,Laurent Najman,Yann LeCun

Recent approaches in self-supervised learning of image representations can be categorized into different families of methods and, in particular, can be divided into contrastive and non-contrastive approaches. While differences between the two families have been thoroughly discussed to motivate new approaches, we focus more on the theoretical similarities between them. By designing contrastive and covariance based non-contrastive criteria that can be related algebraically and shown to be equivalent under limited assumptions, we show how close those families can be. We further study popular methods and introduce variations of them, allowing us to relate this theoretical result to current practices and show the influence (or lack thereof) of design choices on downstream performance. Motivated by our equivalence result, we investigate the low performance of SimCLR and show how it can match VICReg's with careful hyperparameter tuning, improving significantly over known baselines. We also challenge the popular assumption that non-contrastive methods need large output dimensions. Our theoretical and quantitative results suggest that the numerical gaps between contrastive and non-contrastive methods in certain regimes can be closed given better network design choices and hyperparameter tuning. The evidence shows that unifying different SOTA methods is an important direction to build a better understanding of self-supervised learning.

Few-Shot Incremental Learning Using HyperTransformers

Max Vladymyrov,Andrey Zhmoginov,Mark Sandler

Incremental few-shot learning methods make it possible to learn without forgetting from multiple few-shot tasks arriving sequentially. In this work we approach this problem using the recently published HyperTransformer (HT): a hypernetwork that generates task-specific CNN weights directly from the support set. We propose to re-use these generated weights as an input to the HT for the next task of the continual-learning sequence. Thus, the HT uses the weights themselves as the representation of the previously learned tasks. This approach is different from most continual learning algorithms that typically rely on using replay buffers, weight regularization or task-dependent architectural changes. Instead, we show that the HT works akin to a recurrent model, relying on the weights from the previous task and a support set from a new task. We demonstrate that a single HT equipped with a prototypical loss is capable of learning and retaining knowledge about past tasks for two continual learning scenarios: incremental-task learning and incremental-class learning.

The Brainy Student: Scalable Unlearning by Selectively Disobeying the Teacher

Meghdad Kurmanji,Peter Triantafillou,Eleni Triantafillou

Deep machine unlearning is the problem of removing the influence of a cohort of data from the weights of a trained deep model. This challenge has enjoyed increasing attention recently, motivated to the widespread use of neural networks in applications involving user data: allowing users to exercise their `right to be forgotten' necessitates an effective unlearning algorithm. Deleting data from models is also of interest in practice for removing out-of-date examples, outliers or noisy labels. However, most previous unlearning methods consider simple scenarios where a theoretical treatment is possible. Consequently, not only do their guarantees not apply to deep neural networks, but they also scale poorly. In th

is paper, drawing inspiration from teacher-student methods, we propose a scalable deep unlearning method that breaks free of previous limiting assumptions. Our thorough empirical investigation reveals that our approach significantly improves upon previous methods in being by far the most consistent in achieving unlearning in a wide range of scenarios, while incurring only a minimal performance degradation, if any, and being significantly more scalable than previous methods.

FIGARO: Controllable Music Generation using Learned and Expert Features
Dimitri von Rütte,Luca Biggio,Yannic Kilcher,Thomas Hofmann
Recent symbolic music generative models have achieved significant improvements in the quality of the generated samples. Nevertheless, it remains hard for users to control the output in such a way that it matches their expectation. To address this limitation, high-level, human-interpretable conditioning is essential. In this work, we release FIGARO, a Transformer-based conditional model trained to generate symbolic music based on a sequence of high-level control codes. To this end, we propose description-to-sequence learning, which consists of automatically extracting fine-grained, human-interpretable features (the description) and training a sequence-to-sequence model to reconstruct the original sequence given only the description as input. FIGARO achieves state-of-the-art performance in multi-track symbolic music generation both in terms of style transfer and sample quality. We show that performance can be further improved by combining human-interpretable with learned features. Our extensive experimental evaluation shows that FIGARO is able to generate samples that closely adhere to the content of the input descriptions, even when they deviate significantly from the training distribution.

A Neural PDE Solver with Temporal Stencil Modeling
Zhiqing Sun,Yiming Yang,Shinjae Yoo
Numerical simulation of non-linear partial differential equations plays a crucial role in modeling physical science and engineering phenomena, such as weather, climate, and aerodynamics. Recent Machine Learning (ML) models trained on low-resolution spatio-temporal signals have shown new promises in capturing important dynamics in high-resolution signals, under the condition that the models can effectively recover the missing details. However, this study shows that significant information is often lost in the low-resolution down-sampled features. To address such issues, we propose a new approach, namely Temporal Stencil Modeling (TSM), which combines the strengths of advanced time-series sequence modeling (with the HiPPO features) and state-of-the-art neural PDE solvers (with learnable stencil modeling). TSM aims to recover the lost information from the PDE trajectories and can be regarded as a temporal generalization of classic finite volume methods such as WENO. Our experimental results show that TSM achieves the new state-of-the-art simulation accuracy for 2-D incompressible Navier-Stokes turbulent flows: it significantly outperforms the previously reported best results by 19.9% in terms of the highly-correlated duration time, and reduces the inference latency into 80%. We also show a strong generalization ability of the proposed method to various out-of-distribution turbulent flow settings.
****

The Right Losses for the Right Gains: Improving the Semantic Consistency of Deep Text-to-Image Generation with Distribution-Sensitive Losses
Mahmoud Ahmed,Omer Moussa,Ismail Shaheen,Mohamed O Abdelfattah,Amr Adel Abdalla,Marwan Eid,Hesham Mohamed Eraqi,Mohamed N. Moustafa
One of the major challenges in training deep neural networks for text-to-image generation is the significant linguistic discrepancy between ground-truth captions of each image in most popular datasets. The large difference in the choice of words in such captions results in synthesizing images that are semantically dissimilar to each other and to their ground-truth counterparts. Moreover, existing models either fail to generate the fine-grained details of the image or require a huge number of parameters that renders them inefficient for text-to-image synthesis. To fill this gap in the literature, we propose using the contrastive learning approach with a novel combination of two loss functions: fake-to-fake loss

to increase the semantic consistency between generated images of the same caption, and fake-to-real loss to reduce the gap between the distributions of real images and fake ones. We test this approach on two baseline models: SSAGAN and AttnGAN (with style blocks to enhance the fine-grained details of the images.) Results show that our approach improves the qualitative results on AttnGAN with style blocks on the CUB dataset. Additionally, on the challenging COCO dataset, our approach achieves competitive results against the state-of-the-art Lafite model, outperforms the FID scores of SSAGAN and DALL-E models by 44% and 66.83% respectively, yet with only around 1% of the model size and training data of the huge DALL-E model.

****

Selection Collider Bias in Large Language Models

Emily McMilin

In this paper we motivate the causal mechanisms behind sample selection induced collider bias (selection collider bias) that can cause Large Language Mod- els (LLMs) to learn unconditional dependence between entities that are unconditionally independent in the real world. We show that selection collider bias can become amplified in underspecified learning tasks, and although difficult to overcome, we describe a method to exploit the resulting spurious correlations for determination of when a model may be uncertain about its prediction. We demonstrate an uncertainty metric that matches human uncertainty in tasks with gender pronoun underspecification on an extended version of the Winogender Schemas evaluation set, and we provide online demos where users can evaluate spurious correlations and apply our uncertainty metric to their own texts and models. Finally, we generalize our approach to address a wider range of prediction tasks.

CausalBench: A Large-scale Benchmark for Network Inference from Single-cell Perturbation Data

Mathieu Chevalley,Yusuf H Roohani,Arash Mehrjou,Jure Leskovec,Patrick Schwab

Mapping biological mechanisms in cellular systems is a fundamental step in early-stage drug discovery that serves to generate hypotheses on what disease-relevant molecular targets may effectively be modulated by pharmacological interventions. With the advent of high-throughput methods for measuring single-cell gene expression under genetic perturbations, we now have effective means for generating evidence for causal gene-gene interactions at scale. However, inferring graphical networks of the size typically encountered in real-world gene-gene interaction networks is difficult in terms of both achieving and evaluating faithfulness to the true underlying causal graph. Moreover, standardised benchmarks for comparing methods for causal discovery in perturbational single-cell data do not yet exist. Here, we introduce CausalBench - a comprehensive benchmark suite for evaluating network inference methods on large-scale perturbational single-cell gene expression data. CausalBench introduces several biologically meaningful performance metrics and operates on two large, curated and openly available benchmark data sets for evaluating methods on the inference of gene regulatory networks from single-cell data generated under perturbations. With real-world datasets consisting of over 200000 training samples under interventions, CausalBench could potentially help facilitate advances in causal network inference by providing what is - to the best of our knowledge - the largest openly available test bed for causal discovery from real-world perturbation data to date.

Language models are multilingual chain-of-thought reasoners

Freda Shi,Mirac Suzgun,Markus Freitag,Xuezhi Wang,Suraj Srivats,Soroush Vosoughi,Hyung Won Chung,Yi Tay,Sebastian Ruder,Denny Zhou,Dipanjan Das,Jason Wei

We evaluate the reasoning abilities of large language models in multilingual settings. We introduce the Multilingual Grade School Math (MGSM) benchmark, by manually translating 250 grade-school math problems from the GSM8K dataset (Cobbe et al., 2021) into ten typologically diverse languages. We find that the ability to solve MGSM problems via chain-of-thought prompting emerges with increasing model scale, and that models have strikingly strong multilingual reasoning abilities, even in underrepresented languages such as Bengali and Swahili. Finally, we s how that multilingual reasoning abilities of language models extend to other tasks such as commonsense reasoning and word-in-context semantic judgment. The MGSM benchmark is publicly available at AnonymousLink and the supplementary material.

DreamFusion: Text-to-3D using 2D Diffusion
Ben Poole,Ajay Jain,Jonathan T. Barron,Ben Mildenhall

Recent breakthroughs in text-to-image synthesis have been driven by diffusion models trained on billions of image-text pairs. Adapting this approach to 3D synthesis would require large-scale datasets of labeled 3D or multiview data and efficient architectures for denoising 3D data, neither of which currently exist. In this work, we circumvent these limitations by using a pretrained 2D text-to-image diffusion model to perform text-to-3D synthesis. We introduce a loss based on probability density distillation that enables the use of a 2D diffusion model as a prior for optimization of a parametric image generator. Using this loss in a DeepDream-like procedure, we optimize a randomly-initialized 3D model (a Neural Radiance Field, or NeRF) via gradient descent such that its 2D renderings from random angles achieve a low loss. The resulting 3D model of the given text can be viewed from any angle, relit by arbitrary illumination, or composited into any 3D environment. Our approach requires no 3D training data and no modifications to the image diffusion model, demonstrating the effectiveness of pretrained image diffusion models as priors.

****

Recitation-Augmented Language Models
Zhiqing Sun,Xuezhi Wang,Yi Tay,Yiming Yang,Denny Zhou

We propose a new paradigm to help Large Language Models (LLMs) generate more accurate factual knowledge without retrieving from an external corpus, called RECITation-augmented gEneration (RECITE). Different from retrieval-augmented language models that retrieve relevant documents before generating the outputs, given an input, RECITE first recites one or several relevant passages from LLMs’ own memory via sampling, and then produces the final answers. We show that RECITE is a powerful paradigm for knowledge-intensive NLP tasks. Specifically, we show that by utilizing recitation as the intermediate step, a recite-and-answer scheme can achieve new state-of-the-art performance in various closed-book question answering (CBQA) tasks. In experiments, we verify the effectiveness of RECITE on three pre-trained models (In-house LM, UL2, and OPT) and three CBQA tasks (Natural Questions, TriviaQA, and HotpotQA). Our code is available at "https://github.com/Edward-Sun/RECITE".

Continual Active Learning
Arnav Mohanty Das,Gantavya Bhatt,Megh Manoj Bhalerao,Vianne R. Gao,Rui Yang,Jeff Bilmes

While active learning (AL) improves the labeling efficiency of machine learning (by allowing models to query the labels of data samples), a major problem is that compute efficiency is decreased since models are typically retrained from scratch at each query round. In this work, we develop a new framework that circumvents this problem by biasing further training towards the recently labeled sets, thereby complementing existing work on AL acceleration. We employ existing and novel replay-based Continual Learning (CL) algorithms that are effective at quickly learning new samples without forgetting previously learned information, especially when data comes from a shifting or evolving distribution. We call this compute-efficient active learning paradigm $\textit{``Continual Active Learning" (CAL)}$. We demonstrate that standard AL with warm starting fails, both to accelerate training, and that naive fine-tuning suffers from catastrophic forgetting due to distribution shifts over query rounds. We then show CAL achieves significant speedups using a plethora of replay schemes that use model distillation, and that select diverse/uncertain points from the history, all while maintaining performance on par with standard AL. We conduct experiments across many data domains, including natural language, vision, medical imaging, and computational biolo

gy, each with very different neural architectures (Transformers/CNNs/MLPs). CAL consistently provides a 2-6x reduction in training time, thus showing its applicability across differing modalities.

KwikBucks: Correlation Clustering with Cheap-Weak and Expensive-Strong Signals
Sandeep Silwal,Sara Ahmadian,Andrew Nystrom,Andrew McCallum,Deepak Ramachandran,Seyed Mehran Kazemi

The unprecedented rate at which the sizes of machine learning (ML) models are growing necessitates novel approaches to enable efficient and scalable solutions. We contribute to this line of work by studying a novel version of the Budgeted Correlation Clustering problem (\bcc) where along with a limited number of queries to an expensive oracle for node similarities (e.g. a large ML model), we have unlimited access to a cheaper but less accurate second oracle. Our formulation is inspired by many practical scenarios where coarse approximations of the expensive similarity metric can be efficiently obtained via weaker models. We develop a theoretically motivated algorithm in this setting that leverages the cheap oracle to judiciously query the strong oracle while maintaining high clustering quality. We empirically demonstrate gains in query minimization and clustering metrics on a variety of datasets with diverse strong and cheap oracles. Most notably, we demonstrate a practical application in text clustering based on expensive cross-attention language models by showing that cheaper (but weaker) embedding-based models can be leveraged to substantially reduce the number of inference calls to the former.

Credible, Sealed-bid, Optimal Repeated Auctions With Differentiable Economics
Davidson Cheng,Yang Hong,Ian Miers,John P Dickerson,Michael Curry

Online advertisement auctions happen billions of times per day. Bidders in auctions strategize to improve their own utility, subject to published auctions' rules. Yet, bidders may not know that an auction has been run as promised. A credible auction is one in which bidders can trust the auctioneer to run its allocation and pricing mechanisms as promised. It is known that, assuming no communication between bidders, no credible, sealed-bid, and incentive compatible (aka ``truth-telling'' or otherwise truthful-participation-incentivizing) mechanism can exist. In reality, bidders can certainly communicate, so what happens if we relax this (typically unrealistic) constraint?

In this work, we propose a framework incorporating cryptography to allow computationally-efficient, credible, revenue-maximizing (aka ``optimal'') auctions in a repeated auction setting. Our contribution is two-fold: first, we introduce a protocol for running repeated auctions with a verification scheme, and we show such a protocol can eliminate the auctioneer's incentive to deviate while costing negligible additional computation. Secondly, we provide a method for training optimal auctions under uncertain bidder participation profiles, which generalizes our protocol to a much wider class of auctions in the online ad market. Our empirical results show strong support for both the theory and competency of the proposed method.
****

The Power of Feel-Good Thompson Sampling: A Unified Framework for Linear Bandits
Zhiyuan Fan,Quanquan Gu

Linear contextual bandit is one of the most popular models in online decision-making with bandit feedback. Prior work has studied different variants of this model, e.g., misspecified, non-stationary, and multi-task/life-long linear contextual bandits. However, there is no single framework that can unify the algorithm design and analysis for these variants. In this paper, we propose a unified framework for linear contextual bandits based on feel-good Thompson sampling (Zhang, 2021). The algorithm derived from our framework achieves nearly minimax optimal regret in various settings and resolves the respective open problem in each setting. Specifically, let d be the dimension of the context and T be the length of the horizon, our algorithm achieves an $\widetilde{\mathcal{O}}(d\sqrt{ST})$ regret bound for non-stationary linear bandits with at most S switches, $\wid etilde{\mathcal{O}}(d^{\frac{5}{6}} T^{\frac{2}{3}} P^{\frac{1}{3}})$ regret for non-stationary linear bandits with bounded path length P, and $\widetilde{\mathcal{O}}(d\sqrt{kT} + \sqrt{dkMT})$ regret for (generalized) lifelong linear bandits over M tasks that share an unknown representation of dimension k. We believe our framework will shed light on the design and analysis of other linear contextual bandit variants.

Two-Tailed Averaging: Anytime Adaptive Once-in-a-while Optimal Iterate Averaging for Stochastic Optimization

Gábor Melis

Tail averaging improves on Polyak averaging's non-asymptotic behaviour by excluding a number of leading iterates of stochastic optimization from its calculations.

In practice, with a finite number of optimization steps and a learning rate that cannot be annealed to zero, tail averaging can get much closer to a local minimum point of the training loss than either the individual iterates or the Polyak average.

However, the number of leading iterates to ignore is an important hyperparameter, and starting averaging too early or too late leads to inefficient use of resources or suboptimal solutions.

Setting this hyperparameter to improve generalization is even more difficult, especially in the presence of other hyperparameters and overfitting.

Furthermore, before averaging starts, the loss is only weakly informative of the final performance, which makes early stopping unreliable.

To alleviate these problems, we propose an anytime variant of tail averaging, that has no hyperparameters and approximates the optimal tail at all optimization steps.

Our algorithm is based on two running averages with adaptive lengths bounded in terms of the optimal tail length, one of which achieves approximate optimality with some regularity.

Requiring only the additional storage for two sets of weights and periodic evaluation of the loss, the proposed two-tailed averaging algorithm is a practical and widely applicable method for improving stochastic optimization.

****

Reward Design with Language Models

Minae Kwon,Sang Michael Xie,Kalesha Bullard,Dorsa Sadigh

Reward design in reinforcement learning (RL) is challenging since specifying human notions of desired behavior may be difficult via reward functions or require many expert demonstrations. Can we instead cheaply design rewards using a natural language interface? This paper explores how to simplify reward design by using a large language model (LLM) such as GPT-3 as a proxy reward function, where the user provides a textual prompt containing a few examples (few-shot) or a description (zero-shot) of desired behavior. Our approach leverages this proxy reward function in an RL framework. Specifically, users specify a prompt once at the beginning of training. During training, the LLM evaluates an RL agent's behavior against the desired behavior described by the prompt and outputs a corresponding reward signal. The RL agent then uses this reward to update its behavior. We evaluate whether our approach can train agents aligned with user objectives in the Ultimatum Game, matrix games, and the DealOrNoDeal negotiation task. In all three tasks, we show that RL agents trained with our framework are well-aligned with the user's objectives and outperforms RL agents trained with reward functions learned via supervised learning.

Calibrating the Rigged Lottery: Making All Tickets Reliable

Bowen Lei,Ruqi Zhang,Dongkuan Xu,Bani Mallick

Although sparse training has been successfully used in various deep learning tasks to save memory and reduce inference time, the reliability of the produced sparse models remains unexplored. Previous research has shown that deep neural networks tend to be over-confident, and we find that sparse training exacerbates thi s problem. Therefore, calibrating the sparse models is crucial for reliable prediction and decision making. In this paper, we propose a new sparse training method to produce sparse models with improved confidence calibration. In contrast to previous research that uses only one mask to control the sparse topology, our method utilizes two masks, including a deterministic mask and a random mask. The former efficiently searches and activates important weights by exploiting the magnitude of weights and gradients. While the latter brings better exploration and finds more appropriate weight values by random updates. Theoretically, we prove our method can be viewed as a hierarchical variational approximation of a probabilistic deep Gaussian process. Extensive experiments on multiple datasets, model architectures, and sparsities show that our method can reduce ECE values by up to 47.8\% and simultaneously maintain or even improve accuracy with only a slight increase in computational and storage burden.

****

Replay Buffer with Local Forgetting for Adaptive Deep Model-Based Reinforcement Learning

Ali Rahimi-Kalahroudi,Janarthanan Rajendran,Ida Momennejad,Harm van Seijen,Sarath Chandar

One of the key behavioral characteristics used in neuroscience to determine whether the subject of study---be it a rodent or a human---exhibits model-based learning is effective adaptation to local changes in the environment. In reinforcement learning, however, recent work has shown that modern deep model-based reinforcement-learning (MBRL) methods adapt poorly to such changes. An explanation for this mismatch is that MBRL methods are typically designed with sample-efficiency on a single task in mind and the requirements for effective adaptation are substantially higher, both in terms of the learned world model and the planning routine. One particularly challenging requirement is that the learned world model has to be sufficiently accurate throughout relevant parts of the state-space. This is challenging for deep-learning-based world models due to catastrophic forgetting. And while a replay buffer can mitigate the effects of catastrophic forgetting, the traditional first-in-first-out replay buffer precludes effective adaptation due to maintaining stale data. In this work, we show that a conceptually simple variation of this traditional replay buffer is able to overcome this limitation. By removing only samples from the buffer from the local neighbourhood of the newly observed samples, deep world models can be built that maintain their accuracy across the state-space, while also being able to effectively adapt to changes in the reward function. We demonstrate this by applying our replay-buffer variation to the classical Dyna method, as well as to recent methods such as PlaNet and DreamerV2, showing for the first time that deep model-based methods are able to achieve effective adaptation.

Contrastive Audio-Visual Masked Autoencoder

Yuan Gong,Andrew Rouditchenko,Alexander H. Liu,David Harwath,Leonid Karlinsky,Hilde Kuehne,James R. Glass

In this paper, we first extend the recent Masked Auto-Encoder (MAE) model from a single modality to audio-visual multi-modalities. Subsequently, we propose the Contrastive Audio-Visual Masked Auto-Encoder (CAV-MAE) by combining contrastive learning and masked data modeling, two major self-supervised learning frameworks, to learn a joint and coordinated audio-visual representation.

Our experiments show that the contrastive audio-visual correspondence learning objective not only enables the model to perform audio-visual retrieval tasks, but also helps the model learn a better joint representation. As a result, our fully self-supervised pretrained CAV-MAE achieves a new SOTA accuracy of 65.9% on VGGSound, and is comparable with the previous best supervised pretrained model on AudioSet in the audio-visual event classification task. Code and pretrained models are at https://github.com/yuangongnd/cav-mae.

****

The Asymmetric Maximum Margin Bias of Quasi-Homogeneous Neural Networks

Daniel Kunin,Atsushi Yamamura,Chao Ma,Surya Ganguli

In this work, we explore the maximum-margin bias of quasi-homogeneous neural net works trained with gradient flow on an exponential loss and past a point of separability. We introduce the class of quasi-homogeneous models, which is expressive enough to describe nearly all neural networks with homogeneous activations, even those with biases, residual connections, and normalization layers, while structured enough to enable geometric analysis of its gradient dynamics. Using this analysis, we generalize the existing results of maximum-margin bias for homogeneous networks to this richer class of models. We find that gradient flow implicitly favors a subset of the parameters, unlike in the case of a homogeneous model where all parameters are treated equally. We demonstrate through simple examples how this strong favoritism toward minimizing an asymmetric norm can degrade the robustness of quasi-homogeneous models. On the other hand, we conjecture that this norm-minimization discards, when possible, unnecessary higher-order parameters, reducing the model to a sparser parameterization. Lastly, by applying our theorem to sufficiently expressive neural networks with normalization layers, we reveal a universal mechanism behind the empirical phenomenon of Neural Collapse.

Soft Diffusion: Score Matching For General Corruptions

Giannis Daras,Mauricio Delbracio,Hossein Talebi,Alex Dimakis,Peyman Milanfar

We define a broader family of corruption processes that generalizes previously known diffusion models. To reverse these general diffusions, we propose a new objective called Soft Score Matching that provably learns the score function for any linear corruption process and yields state of the art results for CelebA. Soft Score Matching incorporates the degradation process in the network.

Our new loss trains the model to predict a clean image, that after corruption, matches the diffused observation.

We show that our objective learns the gradient of the likelihood under suitable regularity conditions for a family of corruption processes.

We further develop a principled way to select the corruption levels for general diffusion processes and a novel sampling method that we call Momentum Sampler.

We show experimentally that our framework works for general linear corruption processes, such as Gaussian blur and masking.

We achieve state-of-the-art FID score 1.85 on CelebA-64, outperforming all previous linear diffusion models.

We also show significant computational benefits compared to vanilla denoising diffusion.

****

Open-Vocabulary Panoptic Segmentation MaskCLIP

Zheng Ding,Jieke Wang,Zhuowen Tu

In this paper, we tackle an emerging computer vision task, open-vocabulary panoptic segmentation, that aims to perform panoptic segmentation (background semantic labeling + foreground instance segmentation) for arbitrary categories of text-based descriptions in inference time. We first build a baseline method by directly adopting pre-trained CLIP models without finetuning nor distillation. We then develop MaskCLIP, a Transformer-based approach with a Relative Mask Attention (RMA) module. The RMA is an encoder-only module that seamless integrates mask tokens with a pre-trained ViT CLIP model for semantic/instance segmentation and class prediction. MaskCLIP learns to efficiently and effectively utilize pre-trained dense/local CLIP features within the RMA that avoids the time-consuming student-teacher training process. We obtain encouraging results for open-vocabulary panoptic/instance segmentation and state-of-the-art results for semantic segmentation on ADE20K and PASCAL datasets. We show qualitative illustration for MaskCLIP with online custom categories.

****

Robust Federated Learning with Majority Adversaries via Projection-based Re-weighting

Xiaoyang Wang,Klara Nahrstedt,Oluwasanmi O Koyejo

Most robust aggregators for distributed or federated learning assume that adversarial clients are the minority in the system. In contrast, this paper considers the majority adversary setting. We first show that a filtering method using a few trusted clients can defend against many standard attacks. However, a new attac k called Mimic-Shift can circumvent simple filtering. To this end, we develop a re-weighting strategy that identifies and down-weights the potential adversaries under the majority adversary regime. We show that our aggregator converges to a neighborhood around the optimum under the Mimic-Shift attack. Empirical results further show that our aggregator achieves negligible accuracy loss with a majority of adversarial clients, outperforming strong baselines.

Double Wins: Boosting Accuracy and Efficiency of Graph Neural Networks by Reliable Knowledge Distillation

Qiaoyu Tan,Daochen Zha,Soo-Hyun Choi,Li Li,Rui Chen,Xia Hu

The recent breakthrough achieved by graph neural networks (GNNs) with few labeled data accelerates the pace of deploying GNNs on real-world applications. While several efforts have been made to scale GNNs training for large-scale graphs, GNNs still suffer from the scalability challenge of model inference, due to the graph dependency issue incurred by the message passing mechanism, therefore hindering its deployment in resource-constrained applications. A recent study~\citep{zhang2021graph} revealed that GNNs can be compressed to inference-friendly multi-layer perceptrons (MLPs), by training MLPs using the soft labels of labeled and unlabeled nodes from the teacher. However, blindly leveraging the soft labels of all unlabeled nodes may be suboptimal, since the teacher model would inevitably make wrong predictions. This intriguing observation motivates us to ask: \textit{Is it possible to train a stronger MLP student by making better use of the unlabeled data?}

This paper studies cross-model knowledge distillation - from GNN teacher to MLP student in a semi-supervised setting, showing their strong promise in achieving a ``sweet point'' in co-optimizing model accuracy and efficiency. Our proposed solution, dubbed \textit{Reliable Knowledge Distillation for MLP optimization} (\textbf{RKD-MLP}), is the first noise-aware knowledge distillation framework for GNNs distillation. Its core idea is to use a meta-policy to filter out those unreliable soft labels. To train the meta-policy, we design a reward-driven objective based on a meta-set and adopt policy gradient to optimize the expected reward. Then we apply the meta-policy to the unlabeled nodes and select the most reliable soft labels for distillation. Extensive experiments across various GNN backbones, on 7 small graphs and 2 large-scale datasets from the challenging Open Graph Benchmark, demonstrate the superiority of our proposal. Moreover, our RKD-MLP model shows good robustness w.r.t. graph topology and node feature noises. The code is available at \url{https://anonymous.4open.science/r/RKD-MLP-F2A6/}.

A Statistical Framework for Personalized Federated Learning and Estimation: Theory, Algorithms, and Privacy

Kaan Ozkara,Antonious M. Girgis,Deepesh Data,Suhas Diggavi

A distinguishing characteristic of federated learning is that the (local) client data could have statistical heterogeneity. This heterogeneity has motivated the design of personalized learning, where individual (personalized) models are trained, through collaboration. There have been various personalization methods proposed in literature, with seemingly very different forms and methods ranging from use of a single global model for local regularization and model interpolation, to use of multiple global models for personalized clustering, etc. In this work, we begin with a statistical framework that unifies several different algorithms as well as suggest new algorithms. We apply our framework to personalized estimation, and connect it to the classical empirical Bayes' methodology. We develop novel private personalized estimation under this framework. We then use our statistical framework to propose new personalized learning algorithms, including AdaPeD based on information-geometry regularization, which numerically outperforms several known algorithms. We develop privacy for personalized learning methods with guarantees for user-level privacy and composition. We numerically evaluate the performance as well as the privacy for both the estimation and learning problems, demonstrating the advantages of our proposed methods.

****

Invariant Aggregator for Defending against Federated Backdoor Attacks
Xiaoyang Wang,Dimitrios Dimitriadis,Oluwasanmi O Koyejo,Shruti Tople

Federated learning is gaining popularity as it enables training of high-utility models across several clients without directly sharing their private data. As a downside, the federated setting makes the model vulnerable to various adversarial attacks in the presence of malicious clients. Specifically, an adversary can perform backdoor attacks to control model predictions via poisoning the training dataset with a trigger. In this work, we propose a mitigation for backdoor attacks in a federated learning setup. Our solution forces the model optimization trajectory to focus on the invariant directions that are generally useful for utility and avoid selecting directions that favor few and possibly malicious clients. Concretely, we consider the sign consistency of the pseudo-gradient (the client update) as an estimation of the invariance. Following this, our approach performs dimension-wise filtering to remove pseudo-gradient elements with low sign consistency. Then, a robust mean estimator eliminates outliers among the remaining dimensions. Our theoretical analysis further shows the necessity of the defense combination and illustrates how our proposed solution defends the federated learning model. Empirical results on three datasets with different modalities and varying number of clients show that our approach mitigates backdoor attacks with a negligible cost on the model utility.

Laser: Latent Set Representations for 3D Generative Modeling
Pol Moreno,Adam R. Kosiorek,Heiko Strathmann,Daniel Zoran,Rosalia Galiazzi Schneider,Björn Winckler,Larisa Markeeva,Theophane Weber,Danilo Jimenez Rezende

NeRF provides unparalleled fidelity of novel view synthesis---rendering a 3D scene from an arbitrary viewpoint. NeRF requires training on a large number of views that fully cover a scene, which limits its applicability.

While these issues can be addressed by learning a prior over scenes in various forms, previous approaches have been either applied to overly simple scenes or struggling to render unobserved parts.

We introduce Laser-NV---a generative model which achieves high modelling capacity, and which is based on a set-valued latent representation modelled by normalizing flows.

Similarly to previous amortized approaches, Laser-NV learns structure from multiple scenes and is capable of fast, feed-forward inference from few views.

To encourage higher rendering fidelity and consistency with observed views, Laser-NV further incorporates a geometry-informed attention mechanism over the observed views.

Laser-NV further produces diverse and plausible completions of occluded parts of a scene while remaining consistent with observations.

Laser-NV shows state-of-the-art novel-view synthesis quality when evaluated on ShapeNet and on a novel simulated City dataset, which features high uncertainty in the unobserved regions of the scene.

Towards Efficient Gradient-Based Meta-Learning in Heterogenous Environments
Thomas Goerttler,Luis Müller,Klaus Obermayer

A challenging problem for machine learning is few-shot learning, as its models usually require many training samples. Since meta-learning models have strong fine-tuning capabilities for the distribution of tasks, many of them have been applied to few-shot learning. Model-agnostic meta-learning (MAML) is one of the most popular ones. Recent studies showed that MAML-trained models tend to reuse learned features and do not perform strong adaption, especially in the earlier layers. This paper presents an in-detail analysis of this phenomenon by analyzing MAML's components of different variants. Our results show an interesting relationship between the importance of fine-tuning earlier layers and the difference in the distribution between training and testing. As a result, we determine a fundamental weakness of existing MAML variants when the task distribution is heterogeneous, e.g., the numbers of classes do not match during testing and training. We propose a novel nonparametric version of MAML that overcomes these issues while s

till being able to perform cross-domain adaption.

Optimal Transport for Offline Imitation Learning

Yicheng Luo,zhengyao jiang,Samuel Cohen,Edward Grefenstette,Marc Peter Deisenroth

With the advent of large datasets, offline reinforcement learning is a promising framework for learning good decision-making policies without the need to interact with the real environment.

However, offline RL requires the dataset to be reward-annotated, which presents practical challenges when reward engineering is difficult or when obtaining reward annotations is labor-intensive.

In this paper, we introduce Optimal Transport Relabeling (OTR), an imitation learning algorithm that can automatically relabel offline data of mixed and unknown quality with rewards from a few good demonstrations. OTR's key idea is to use optimal transport to compute an optimal alignment between an unlabeled trajectory in the dataset and an expert demonstration to obtain a similarity measure that can be interpreted as a reward, which can then be used by an offline RL algorithm to learn the policy. OTR is easy to implement and computationally efficient. On D4RL benchmarks, we demonstrate that OTR with a single demonstration can consistently match the performance of offline RL with ground-truth rewards.

FedorAS: Federated Architecture Search under system heterogeneity

■ukasz Dudziak,Stefanos Laskaridis,Javier Fernandez-Marques

Federated learning (FL) has recently gained considerable attention due to its ability to learn on decentralised data while preserving client privacy. However, it also poses additional challenges related to the heterogeneity of the participating devices, both in terms of their computational capabilities and contributed data. Meanwhile, Neural Architecture Search (NAS) has been successfully used with centralised datasets, producing state-of-the-art results in constrained or unconstrained settings. However, such centralised datasets may not be always available for training. Most recent work at the intersection of NAS and FL attempts to alleviate this issue in a cross-silo federated setting, which assumes homogeneous compute environments with datacenter-grade hardware.

In this paper we explore the question of whether we can design architectures of different footprints in a cross-device federated setting, where the device landscape, availability and scale are very different. To this end, we design our system, FedorAS, to discover and train promising architectures in a resource-aware manner when dealing with devices of varying capabilities holding non-IID distributed data. We present empirical evidence of its effectiveness across different settings, spanning across three different modalities (vision, speech, text), and showcase its better performance compared to state-of-the-art federated solutions, while maintaining resource efficiency.

Is Reinforcement Learning (Not) for Natural Language Processing: Benchmarks, Baselines, and Building Blocks for Natural Language Policy Optimization

Rajkumar Ramamurthy,Prithviraj Ammanabrolu,Kianté Brantley,Jack Hessel,Rafet Sifa,Christian Bauckhage,Hannaneh Hajishirzi,Yejin Choi

We tackle the problem of aligning pre-trained large language models (LMs) with human preferences. If we view text generation as a sequential decision-making problem, reinforcement learning (RL) appears to be a natural conceptual framework. However, using RL for LM-based generation faces empirical challenges, including training instability due to the combinatorial action space, as well as a lack of open-source libraries and benchmarks customized for LM alignment. Thus, a question rises in the research community: is RL a practical paradigm for NLP?

To help answer this, we first introduce an open-source modular library, $RL4LMs$ (Reinforcement Learning for Language Models), for optimizing language generators with RL. The library consists of on-policy RL algorithms that can be used to train any encoder or encoder-decoder LM in the HuggingFace library (Wolf et al. 2

020) with an arbitrary reward function. Next, we present the $GRUE$ (General Reinforced-language Understanding Evaluation) benchmark, a set of 6 language generation tasks which are supervised not by target strings, but by reward functions which capture automated measures of human preference.GRUE is the first leaderboard-style evaluation of RL algorithms for NLP tasks. Finally, we introduce an easy-to-use, performant RL algorithm, $NLPO$ (Natural Language Policy Optimization)} that learns to effectively reduce the combinatorial action space in language generation. We show 1) that RL techniques are generally better than supervised methods at aligning LMs to human preferences; and 2) that NLPO exhibits greater stability and performance than previous policy gradient methods (e.g., PPO (Schulman et al. 2017)), based on both automatic and human evaluations.

Learning multi-scale local conditional probability models of images
Zahra Kadkhodaie,Florentin Guth,Stéphane Mallat,Eero P Simoncelli
Deep neural networks can learn powerful prior probability models for images, as evidenced by the high-quality generations obtained with recent score-based diffusion methods. But the means by which these networks capture complex global statistical structure, apparently without suffering from the curse of dimensionality, remain a mystery. To study this, we incorporate diffusion methods into a multi-scale decomposition, reducing dimensionality by assuming a stationary local Markov model for wavelet coefficients conditioned on coarser-scale coefficients. We instantiate this model using convolutional neural networks (CNNs) with local receptive fields, which enforce both the stationarity and Markov properties. Global structures are captured using a CNN with receptive fields covering the entire (but small) low-pass image. We test this model on a dataset of face images, which are highly non-stationary and contain large-scale geometric structures.
Remarkably, denoising, super-resolution, and image synthesis results all demonstrate that these structures can be captured with significantly smaller conditioning neighborhoods than required by a Markov model implemented in the pixel domain. Our results show that score estimation for large complex images can be reduced to low-dimensional Markov conditional models across scales, alleviating the curse of dimensionality.
****

Sampling is as easy as learning the score: theory for diffusion models with minimal data assumptions
Sitan Chen,Sinho Chewi,Jerry Li,Yuanzhi Li,Adil Salim,Anru Zhang
We provide theoretical convergence guarantees for score-based generative models (SGMs) such as denoising diffusion probabilistic models (DDPMs), which constitute the backbone of large-scale real-world generative models such as DALL$\cdot$E 2. Our main result is that, assuming accurate score estimates, such SGMs can efficiently sample from essentially any realistic data distribution. In contrast to prior works, our results (1) hold for an L^2-accurate score estimate (rather than L^∞-accurate); (2) do not require restrictive functional inequality conditions that preclude substantial non-log-concavity; (3) scale polynomially in all relevant problem parameters; and (4) match state-of-the-art complexity guarantees for discretization of the Langevin diffusion, provided that the score error is sufficiently small. We view this as strong theoretical justification for the empirical success of SGMs. We also examine SGMs based on the critically damped Langevin diffusion (CLD). Contrary to conventional wisdom, we provide evidence that the use of the CLD does *not* reduce the complexity of SGMs.

Online Continual Learning with Feedforward Adaptation
ABULIKEMU ABUDUWEILI,Changliu Liu
Recently deep learning has been widely used in time-series prediction tasks. Although a trained deep neural network model typically performs well on the training set, performance drop significantly in a test set under slight distribution shifts. This challenge motivates the adoption of online adaptation algorithms to update the prediction models in real-time to improve the prediction performance.
Existing online adaptation methods optimize the prediction model by feeding back the latest prediction error computed with respect to the latest observation. Ho

wever, feedback based approach is prone to forgetting past information.

In this work, we propose an online adaptation method with feedforward compensation, which uses critical data samples from a memory buffer, instead of the latest samples, to optimize the prediction model. We prove that the proposed feedforward approach has a smaller error bound than the feedback approach in slow time-varying systems. The experiments on several time-series prediction tasks show that the proposed feedforward adaptation outperforms conventional feedback adaptation by more than 10%. In addition, the proposed feedforward adaptation method is able to estimate an uncertainty bound of the prediction that is agnostic from specific optimizers, while existing feedback adaptation could not.

Mind the Privacy Budget: How Generative Models Spend their Privacy Budgets

Georgi Ganev,Kai Xu,Emiliano De Cristofaro

Numerous Differentially Private (DP) generative models have been presented that aim to produce synthetic data while minimizing privacy risks.

As there is no single model that works well in all settings, empirical analysis is needed to establish and optimize trade-offs vis-\`a-vis the intended use of the synthetic data.

In this paper, we identify and address several challenges in the empirical evaluation of such models.

First, we analyze the steps in which different algorithms ``spend'' their privacy budget.

We evaluate the effects on the performance of downstream tasks to identify problem settings they are most likely to be successful at.

Then, we experiment with increasingly wider and taller training sets with various features, decreasing privacy budgets, and different DP mechanisms and generative models.

Our empirical evaluation, performed on both graphical and deep generative models, sheds light on the distinctive features of different models/mechanisms that make them well-suited for different settings and tasks.

Graphical models distribute the privacy budget horizontally and cannot handle relatively wide datasets, while the performance on the task they were optimized for monotonically increases with more data.

Deep generative models spend their budget per iteration, and their behavior is less predictable with varying dataset dimensions, but could perform better if trained on more features.

Also, low levels of privacy ($\epsilon\geq100$) could help some models generalize, achieving better results than without applying DP.

Resource Efficient Self-Supervised Learning for Speech Recognition

Abhinav Mehrotra,Alberto Gil Couto Pimentel Ramos,Nicholas Donald Lane,Sourav Bhattacharya

Representation learning from sequential data using self-supervised learning (SSL) has proven to be a powerful technique and improved state-of-the-art (SOTA) results when fine tuned for various downstream tasks, including Automatic Speech Recognition (ASR). So far the success of SSL frameworks, e.g., Wav2Vec-2.0, for sequence-to-sequence (seq2seq) modeling is primarily carried out by masking intermediate features and then solving a contrastive task in an end-to-end manner. Although very successful, the overall training time (for example, days or weeks) and demanding resource requirements for achieving SOTA performance remain a significant barrier to further improving ASR solutions using such approaches. In this work we show that non-contrastive learning, such as an extension of the Barlow–Twins methodology, when applied to seq2seq SSL modeling improves convergence, while reducing training time. Our results show that Wav2Vec-2.0 architecture pre-training with a non-contrastive SSL approach reduces the GPU training hours by 2.3 times, compared to masking based SSL approaches, while achieving a significant improvement (i.e., up to 6% relative WER decrease) in the model performance for the ASR task. We further demonstrate that a combination of both masking based SSL and non-contrastive SSL improves the ASR performance, e.g., up to 12% relative

WER decrease, for all splits of LibriSpeech evaluation dataset.

Subsampling in Large Graphs Using Ricci Curvature

Shushan Wu,Huimin Cheng,Jiazhang Cai,Ping Ma,Wenxuan Zhong

In the past decades, many large graphs with millions of nodes have been collected/constructed. The high computational cost and significant visualization difficulty hinder the analysis of large graphs. To overcome the difficulties, researchers have developed many graph subsampling approaches to provide a rough sketch that preserves global properties. By selecting representative nodes, these graph subsampling methods can help researchers estimate the graph statistics, e.g., the number of communities, of the large graph from the subsample. However, the available subsampling methods, e.g., degree node sampler and random walk sampler, tend to leave out minority communities because nodes with high degrees are more likely to be sampled. To overcome the shortcomings of the existing methods, we are motivated to apply the community information hidden in the graph to the subsampling method. Though the community structure is unavailable, community structure information can be obtained by applying geometric methods to a graph. An analog of Ricci curvature in the manifold is defined for the graph, i.e., Ollivier Ricci curvature. Based on the asymptotic results about the within-community edge and between-community edge's OR curvature, we propose a subsampling algorithm based on our theoretical results, the Ollivier-Ricci curvature Gradient-based subsampling (ORG-sub) algorithm. The proposed ORG-sub algorithm has two main contributions: First, ORG-sub provides a rigorous theoretical guarantee that the probability of ORG-sub taking all communities into the final subgraph converges to one. Second, extensive experiments on synthetic and benchmark datasets demonstrate the advantages of our algorithm.

Membership Leakage in Pre-trained Language Models

Yuan Xin,Zheng Li,Ning Yu,Michael Backes,Yang Zhang

Pre-trained language models are becoming a dominating component in NLP domain and have achieved state-of-the-art in various downstream tasks. Recent research has shown that language models are vulnerable to privacy leakage of their training data, such as text extraction and membership leakage. However, existing works against NLP applications mainly focus on the privacy leakage of text generation and downstream classification, and the privacy leakage of pre-trained language models is largely unexplored. In this paper, we take the first step toward systematically auditing the privacy risks of pre-trained language models through the lens of membership leakage. In particular, we focus on membership leakage of pre-training data in the exposure of downstream models adapted from pre-trained language models. We conduct extensive experiments on a variety of pre-trained model architectures and different types of downstream tasks. Our empirical evaluations demonstrate that membership leakage of pre-trained language models exists even when only the downstream model output is exposed, thereby posing a more severe risk than previously thought. We further conduct sophisticated ablation studies to analyze the relationship between membership leakage of pre-trained models and the characteristic of downstream tasks, which can guide developers or researchers to be vigilant about the vulnerability of pre-trained language models. Lastly, we explore possible defenses against membership leakage of PLMs and propose two promising defenses based on empirical evaluations.

Universal Few-shot Learning of Dense Prediction Tasks with Visual Token Matching

Donggyun Kim,Jinwoo Kim,Seongwoong Cho,Chong Luo,Seunghoon Hong

Dense prediction tasks are a fundamental class of problems in computer vision. As supervised methods suffer from high pixel-wise labeling cost, a few-shot learning solution that can learn any dense task from a few labeled images is desired. Yet, current few-shot learning methods target a restricted set of tasks such as semantic segmentation, presumably due to challenges in designing a general and unified model that is able to flexibly and efficiently adapt to arbitrary tasks of unseen semantics. We propose Visual Token Matching (VTM), a universal few-sho t learner for arbitrary dense prediction tasks. It employs non-parametric matching on patch-level embedded tokens of images and labels that encapsulates all tasks. Also, VTM flexibly adapts to any task with a tiny amount of task-specific parameters that modulate the matching algorithm. We implement VTM as a powerful hierarchical encoder-decoder architecture involving ViT backbones where token matching is performed at multiple feature hierarchies. We experiment VTM on a challenging variant of Taskonomy dataset and observe that it robustly few-shot learns various unseen dense prediction tasks. Surprisingly, it is competitive with fully supervised baselines using only 10 labeled examples of novel tasks (0.004% of full supervision) and sometimes outperforms using 0.1% of full supervision. Codes are available at https://github.com/GitGyun/visual_token_matching.

The Game of Hidden Rules: A New Challenge for Machine Learning

Eric Pulick,Shubham Kumar Bharti,Yiding Chen,Vladimir Menkov,Yonatan Dov Mintz,Paul Kantor,Vicki M. Bier

Systematic examination of learning tasks remains an important but understudied area of machine learning (ML) research. To date, most ML research has focused on measuring performance on new tasks or surpassing state of the art performance on existing tasks. These efforts are vital but do not explain why some tasks are more difficult than others. Understanding how task characteristics affect difficulty is critical to formalizing ML's strengths and limitations; a rigorous assessment of which types of tasks are well-suited to a specific algorithm and, conversely, which algorithms are well-suited to a specific task would mark an important step forward for the field. To assist researchers in this effort, we introduce a novel learning environment designed to study how task characteristics affect measured difficulty for the learner. This tool frames learning tasks as a ``board-clearing game,'' which we call the Game of Hidden Rules (GOHR). In each instance of the game, the researcher encodes a specific rule, unknown to the learner, that determines which moves are allowed at each state of the game. The learner must infer the rule through play. We detail the game's expressive rule syntax and show how it gives researchers granular control over learning tasks. We present sample rules, a sample ML algorithm, and methods to assess algorithm performance. Separately, we provide additional benchmark rules, a public leaderboard for performance on these rules, and documentation for installing and using the GOHR environment.

Graph schemas as abstractions for transfer learning, inference, and planning

J Swaroop Guntupalli,Rajkumar Vasudeva Raju,Shrinu Kushagra,Danny Sawyer,Ishan Deshpande,Guangyao Zhou,Miguel Lazaro-Gredilla,Dileep George

We propose schemas as a model for abstractions that can be used for rapid transfer learning, inference, and planning. Common structured representations of concepts and behaviors---schemas---have been proposed as a powerful way to encode abstractions. Latent graph learning is emerging as a new computational model of the hippocampus to explain map learning and transitive inference. We build on this work to show that learned latent graphs in these models have a slot structure---schemas---that allow for quick knowledge transfer across environments. In a new environment, an agent can rapidly learn new bindings between the sensory stream to multiple latent schemas and select the best fitting one to guide behavior. To evaluate these graph schemas, we use two previously published challenging tasks: the memory \& planning game and one-shot StreetLearn, that are designed to test rapid task solving in novel environments. Graph schemas can be learned in far fewer episodes than previous baselines, and can model and plan in a few steps in novel variations of these tasks. We further demonstrate learning, matching, and reusing graph schemas in navigation tasks in more challenging environments with aliased observations and size variations, and show how different schemas can be composed to model larger environments.

Conservative Bayesian Model-Based Value Expansion for Offline Policy Optimization

Jihwan Jeong,Xiaoyu Wang,Michael Gimelfarb,Hyunwoo Kim,Baher abdulhai,Scott Sann er

Offline reinforcement learning (RL) addresses the problem of learning a performant policy from a fixed batch of data collected by following some behavior policy. Model-based approaches are particularly appealing in the offline setting since they can extract more learning signals from the logged dataset by learning a model of the environment. However, the performance of existing model-based approaches falls short of model-free counterparts, due to the compounding of estimation errors in the learned model. Driven by this observation, we argue that it is critical for a model-based method to understand when to trust the model and when to rely on model-free estimates, and how to act conservatively w.r.t. both. To this end, we derive an elegant and simple methodology called conservative Bayesian model-based value expansion for offline policy optimization (CBOP), that trades off model-free and model-based estimates during the policy evaluation step according to their epistemic uncertainties, and facilitates conservatism by taking a lower bound on the Bayesian posterior value estimate. On the standard D4RL continuous control tasks, we find that our method significantly outperforms previous model-based approaches: e.g., MOPO by 116.4%, MOReL by 23.2% and COMBO by 23.7%. Further, CBOP achieves state-of-the-art performance on 11 out of 18 benchmark datasets while doing on par on the remaining datasets.

****

Beam Tree Recursive Cells

Jishnu Ray Chowdhury,Cornelia Caragea

Recursive Neural Networks (RvNNs) generalize Recurrent Neural Networks (RNNs) by allowing sequential composition in a more flexible order, typically, based on some tree structure. While initially user-annotated tree structures were used, in due time, several approaches were proposed to automatically induce tree-structures from raw text to guide the recursive compositions in RvNNs. In this paper, we present an approach called Beam Tree Recursive Cell (or BT-Cell) based on a simple yet overlooked backpropagation-friendly framework. BT-Cell applies beam search on easy-first parsing for simulating RvNNs with automatic structure-induction. Our results show that BT-Cell achieves near-perfect performance on several aspects of challenging structure-sensitive synthetic tasks like ListOps and also comparable performance in realistic data to other RvNN-based models. We further introduce and analyze several extensions of BT-Cell based on relaxations of the hard top-k operators in beam search. We evaluate the models in different out of distribution splits in both synthetic and realistic data. Additionally, we identify a previously unknown failure case for neural models in generalization to unseen number of arguments in ListOps. We will release our code.

The Ultimate Combo: Boosting Adversarial Example Transferability by Composing Data Augmentations

Zebin Yun,Achi-Or Weingarten,Eyal Ronen,Mahmood Sharif

Transferring adversarial examples from surrogate (ML) models to evade target models is a common method for evaluating adversarial robustness in black-box settings. Researchers have invested substantial efforts to enhance transferability. Chiefly, attacks leveraging data augmentation have been found to help adversarial examples generalize better from surrogate to target models. Still, prior work has explored a limited set of augmentation techniques and their composition. To fill the gap, we conducted a systematic, comprehensive study of how data augmentation affects transferability. Particularly, we explored ten augmentation techniques of six categories originally proposed to help ML models generalize to unseen benign samples, and assessed how they influence transferability, both when applied individually and when composed. Our extensive experiments with the ImageNet dataset showed that simple color-space augmentations (e.g., color to greyscale) outperform the state of the art when combined with standard augmentations, such as translation and scaling. Additionally, except for two methods that may harm transferability, we found that composing augmentation methods impacts transferability monotonically (i.e., more methods composed $\rightarrow$ $\ge$transferability)---the best composition we found significantly outperformed the state of the art (e.g., 95.6% vs. 90.9% average transferability from normally trained surrogat

es to other normally trained models). We provide intuitive, empirically supported explanations for why certain augmentations fail to improve transferability.
****

Scaling up and Stabilizing Differentiable Planning with Implicit Differentiation
Linfeng Zhao,Huazhe Xu,Lawson L.S. Wong

Differentiable planning promises end-to-end differentiability and adaptivity. However, an issue prevents it from scaling up to larger-scale problems: they need to differentiate through forward iteration layers to compute gradients, which couples forward computation and backpropagation and needs to balance forward planner performance and computational cost of the backward pass. To alleviate this issue, we propose to differentiate through the Bellman fixed-point equation to decouple forward and backward passes for Value Iteration Network and its variants, which enables constant backward cost (in planning horizon) and flexible forward budget and helps scale up to large tasks. We study the convergence stability, scalability, and efficiency of the proposed implicit version of VIN and its variants and demonstrate their superiorities on a range of planning tasks: 2D navigation, visual navigation, and 2-DOF manipulation in configuration space and workspace.
****

Improving Aspect Ratio Distribution Fairness in Detector Pretraining via Cooperating RPN’s
Weilin Zhang,Xiang Li,Yu-Xiong Wang,David Forsyth

Region proposal networks (RPN) are a key component of modern object detectors. An RPN identifies image boxes likely to contain objects, and so worth further investigation. An RPN false negative is unrecoverable, so the performance of an object detector can be significantly affected by RPN behavior, particularly in low-data regimes. The RPN for a few shot detector is trained on base classes. Our experiments demonstrate that, if the distribution of box aspect ratios for base classes is different from that for novel classes, errors caused by RPN failure to propose a good box become significant. This is predictable: for example, an RPN trained on base classes that are mostly square will tend to miss short wide boxes. It has not been noticed to date because the (relatively few) standard base/novel class splits on current datasets do not display this effect. But changing the base/novel split highlights the problem. We describe datasets where the distribution shift is severe using PASCAL VOC, COCO, and LVIS datasets.

We show that the effect can be mitigated by training multiple distinct but cooperating specialized RPNs. Each specializes in a different aspect ratio, but cooperation constraints reduce the extent to which the RPNs are tuned. This means that if a box is missed by one RPN, it has a good chance of being picked up by another. Experimental evaluation confirms this approach results in substantial improvements in performance on the ARShift benchmarks, while remaining comparable to SOTA on conventional splits. Our approach applies to any few-shot detector and consistently improves performance of detectors.
****

UNDERSTANDING THE ROLE OF POSITIONAL ENCODINGS IN SENTENCE REPRESENTATIONS
Lihu Chen,Gael Varoquaux,Fabian M. Suchanek

Positional encodings are used to inject word-order information into transformer-based language models. While they can significantly enhance the quality of sentence representations, their specific contribution to language models are not fully understood, especially given recent findings that building natural-language understanding from language models with positional encodings is insensitive to word order. In this work, we investigate the role of positional encodings systematically. (1) We uncover the core function of existing positional encodings is to symmetrically combine local units by identifying two common properties, Locality, and Symmetry. (2) We reveal that positional and contextual encodings play a distinct role in understanding sentences. (3) Based on these findings, we propose a simplified new method to inject positional information into such models. Empirical studies demonstrate that this method can improve the performance of the BERT-based model on 10 downstream tasks. We hope these new probing results and findings can shed light on how to design and inject positional encodings into languag e models.

Artificial Replay: A Meta-Algorithm for Harnessing Historical Data in Bandits

Sid Banerjee,Sean R. Sinclair,Milind Tambe,Lily Xu,Christina Yu

While standard bandit algorithms sometimes incur high regret, their performance can be greatly improved by "warm starting" with historical data. Unfortunately, how best to incorporate historical data is unclear: naively initializing reward estimates using all historical samples can suffer from spurious data and imbalanced data coverage, leading to computational and storage issues - particularly in continuous action spaces. We address these two challenges by proposing Artificial Replay, a meta-algorithm for incorporating historical data into any arbitrary base bandit algorithm. Artificial Replayuses only a subset of the historical data as needed to reduce computation and storage. We show that for a broad class of base algorithms that satisfy independence of irrelevant data (IIData), a novel property that we introduce, our method achieves equal regret as a full warm-start approach while potentially using only a fraction of historical data. We complement these theoretical results with a case study of K-armed and continuous combinatorial bandit algorithms, including on a green security domain using real poaching data, to show the practical benefits of Artificial Replayin achieving optimal regret alongside low computational and storage costs.

Score-based Continuous-time Discrete Diffusion Models

Haoran Sun,Lijun Yu,Bo Dai,Dale Schuurmans,Hanjun Dai

Score-based modeling through stochastic differential equations (SDEs) has provided a new perspective on diffusion models, and demonstrated superior performance on continuous data. However, the gradient of the log-likelihood function, \ie, the score function, is not properly defined for discrete spaces. This makes it non-trivial to adapt SDE with score functions to categorical data. In this paper, we extend diffusion models to discrete variables by introducing a stochastic jump process where the reverse process denoises via a continuous-time Markov chain. This formulation admits an analytical simulation during backward sampling. To learn the reverse process, we extend score matching to general categorical data, and show that an unbiased estimator can be obtained via simple matching of the conditional marginal distributions. We demonstrate the effectiveness of the proposed method on a set of synthetic and real-world music and image benchmarks.

Decision Transformer under Random Frame Dropping

Kaizhe Hu,Ray Chen Zheng,Yang Gao,Huazhe Xu

Controlling agents remotely with deep reinforcement learning~(DRL) in the real world is yet to come. One crucial stepping stone is to devise RL algorithms that are robust in the face of dropped information from corrupted communication or malfunctioning sensors. Typical RL methods usually require considerable online interaction data that are costly and unsafe to collect in the real world. Furthermore, when applying to the frame dropping scenarios, they perform unsatisfactorily even with moderate drop rates. To address these issues, we propose Decision Transformer under Random Frame Dropping~(DeFog), an offline RL algorithm that enables agents to act robustly in frame dropping scenarios without online interaction. DeFog first randomly masks out data in the offline datasets and explicitly adds the time span of frame dropping as inputs. After that, a finetuning stage on the same offline dataset with a higher mask rate would further boost the performance. Empirical results show that DeFog outperforms strong baselines under severe frame drop rates like 90\%, while maintaining similar returns under non-frame-dropping conditions in the regular MuJoCo control benchmarks and the Atari environments. Our approach offers a robust and deployable solution for controlling agents in real-world environments with limited or unreliable data.

Semi-supervised consistency regularization for accurate cell type fraction and gene expression estimation

Robin Khatri,Pierre Machart,Stefan Bonn

Cell deconvolution is the estimation of cell type fractions and cell type-specific gene expression from mixed data with unknown composition. In biomedical research, cell deconvolution, which is a source separation task, is used to obtain mechanistic and diagnostic insights into human diseases. An unmet challenge in cell deconvolution, however, is the scarcity of realistic training data and the strong domain shift observed in synthetic training data that is used in contemporary methods. Here, we hypothesize that simultaneous consistency regularization of the target and training domains will improve deconvolution performance. By adding this biologically motivated consistency loss to two novel deep learning-based deconvolution algorithms, we achieve state-of-the-art performance on both cell fraction and gene expression estimation. Our method, DISSECT, outperforms competing algorithms across several biomedical gene expression datasets and can be easily adapted to deconvolve other biomedical data types, as exemplified by our spatial expression deconvolution experiments.
****

Adversarial Imitation Learning with Preferences

Aleksandar Taranovic,Andras Gabor Kupcsik,Niklas Freymuth,Gerhard Neumann

Designing an accurate and explainable reward function for many Reinforcement Learning tasks is a cumbersome and tedious process.
Instead, learning policies directly from the feedback of human teachers naturally integrates human domain knowledge into the policy optimization process.
However, different feedback modalities, such as demonstrations and preferences, provide distinct benefits and disadvantages. For example, demonstrations convey a lot of information about the task but are often hard or costly to obtain from real experts while preferences typically contain less information but are in most cases cheap to generate.
However, existing methods centered around human feedback mostly focus on a single teaching modality, causing them to miss out on important training data while making them less intuitive to use.
In this paper we propose a novel method for policy learning that incorporates two different feedback types, namely \emph{demonstrations} and \emph{preferences}.

To this end, we make use of the connection between discriminator training and density ratio estimation to incorporate preferences into the popular Adversarial Imitation Learning paradigm.
This insight allows us to express loss functions over both demonstrations and preferences in a unified framework.
Besides expert demonstrations, we are also able to learn from imperfect ones and combine them with preferences to achieve improved task performance.
We experimentally validate the effectiveness of combining both preferences and demonstrations on common benchmarks and also show that our method can efficiently learn challenging robot manipulation tasks.

SuperFed: Weight Shared Federated Learning

Alind Khare,Animesh Agrawal,Alexey Tumanov

Federated Learning (FL) is a well-established technique for privacy preserving distributed training. Much attention has been given to various aspects of FL training. A growing number of applications that consume FL-trained models, however, increasingly operate under dynamically and unpredictably variable conditions, rendering a single model insufficient. We argue for training a global “family of models” cost efficiently in a federated fashion. Training them independently for different tradeoff points incurs ≈ O(k) cost for any k architectures of interest, however.
Straightforward applications of FL techniques to recent weight-shared training approaches is either infeasible or prohibitively expensive. We propose SuperFed — an architectural framework that incurs O(1) cost to co-train a large family of models in a federated fashion by leveraging weight-shared learning. We achieve an order of magnitude cost savings on both communication and computation by proposing two novel training mechanisms: (a) distribution of weight-shared models to federated clients, (b) central aggregation of arbitrarily overlapping weight-sha

red model parameters. The combination of these mechanisms is shown to reach an order of magnitude (9.43x) reduction in computation and communication cost for training a 5*10^18-sized family of models, compared to independently training as few as k = 9 DNNs without any accuracy loss.

Is Model Ensemble Necessary? Model-based RL via a Single Model with Lipschitz Regularized Value Function

Ruijie Zheng,Xiyao Wang,Huazhe Xu,Furong Huang

Probabilistic dynamics model ensemble is widely used in existing model-based reinforcement learning methods as it outperforms a single dynamics model in both asymptotic performance and sample efficiency. In this paper, we provide both practical and theoretical insights on the empirical success of the probabilistic dynamics model ensemble through the lens of Lipschitz continuity. We find that, for a value function, the stronger the Lipschitz condition is, the smaller the gap between the true dynamics- and learned dynamics-induced Bellman operators is, thus enabling the converged value function to be closer to the optimal value function. Hence, we hypothesize that the key functionality of the probabilistic dynamics model ensemble is to regularize the Lipschitz condition of the value function using generated samples. To validate this hypothesis, we devise two practical robust training mechanisms through computing the adversarial noise and regularizing the value network’s spectral norm to directly regularize the Lipschitz condition of the value functions. Empirical results show that combined with our mechanisms, model-based RL algorithms with a single dynamics model outperform those with ensemble of the probabilistic dynamics models. These findings not only support the theoretical insight, but also provide a practical solution for developing computationally efficient model-based RL algorithms.

Recurrent Back-Projection Generative Adversarial Network for Video Super Resolution

Israa Sabry Fahmy,Marwah Hisham Sulaiman,Zahraa Shehabeldin,Mohamed Elnaggar,Dareen Hussein Hasan,Mohamed Yasser,Moustafa Youssef,Hesham Mohamed Eraqi

In this paper, we propose a new Video Super Resolution algorithm in an attempt to generate videos that are temporally coherent, spatially detailed, and match human perception. To achieve this, we developed a new generative adversarial network named RBPGAN which is composed of two main components: a generator Network that exceeds other models for producing very high-quality frames, and a discriminator which outperforms others in terms of temporal consistency. The generator of the model uses a reduced recurrent back-projection network that takes a set of neighboring frames and a target frame applies SISR (Single Image Super Resolution) on each frame, and applies MISR (Multiple Image Super Resolution) through an encoder-decoder Back-Projection based approach to concatenate them and produce x4 resolution version of the target frame. The Spatio-temporal discriminator uses triplets of frames and penalizes the generator to generate the desired results. Our contribution results in a model that outperforms earlier work in terms of perceptual similarity and natural flow of frames, while maintaining temporal coherence and high-quality spatial details. The algorithm was tested on different datasets to eliminate bias.

Neural Networks as Paths through the Space of Representations

Richard D Lange,Devin Kwok,Jordan Kyle Matelsky,Xinyue Wang,David Rolnick,Konrad Kording

Deep neural networks implement a sequence of layer-by-layer operations that are each relatively easy to understand, but the resulting overall computation is generally difficult to understand. We develop a simple idea for interpreting the layer-by-layer construction of useful representations: the role of each layer is to reformat information to reduce the "distance" to the desired outputs. With this framework, the layer-wise computation implemented by a deep neural network can be viewed as a path through a high-dimensional representation space. We formalize this intuitive idea of a "path" by leveraging recent advances in metric representational similarity. We extend existing representational distance methods by computing geodesics, angles, and projections of representations, going beyond mere layer distances. We then demonstrate these tools by visualizing and comparing the paths taken by ResNet and VGG architectures on CIFAR-10. We conclude by sketching additional ways that this kind of representational geometry can be used to understand and interpret network training, to describe novel kinds of similarities between different models, and for representation-learning without backpropagation.

From Points to Functions: Infinite-dimensional Representations in Diffusion Models

Sarthak Mittal,Guillaume Lajoie,Stefan Bauer,Arash Mehrjou

Diffusion-based generative models learn to iteratively transfer unstructured noise to a complex target distribution as opposed to Generative Adversarial Networks (GANs) or the decoder of Variational Autoencoders (VAEs) which produce samples from the target distribution in a single step. Thus, in diffusion models every sample is naturally connected to a random trajectory which is a solution to a learned stochastic differential equation (SDE). Generative models are only concerned with the final state of this trajectory that delivers samples from the desired distribution. \cite{abstreiter2021diffusion} showed that these stochastic trajectories can be seen as continuous filters that wash out information along the way. Consequently, it is reasonable to ask if there is an intermediate time step at which the preserved information is optimal for a given downstream task. In this work, we show that a combination of information content from different time steps gives a strictly better representation for the downstream task. We introduce an attention and recurrence based modules that ``learn to mix'' information content of various time-steps such that the resultant representation leads to superior performance in downstream tasks.

Disentanglement with Biological Constraints: A Theory of Functional Cell Types

James C. R. Whittington,Will Dorrell,Surya Ganguli,Timothy Behrens

Neurons in the brain are often finely tuned for specific task variables. Moreover, such disentangled representations are highly sought after in machine learning. Here we mathematically prove that simple biological constraints on neurons, namely nonnegativity and energy efficiency in both activity and weights, promote such sought after disentangled representations by enforcing neurons to become selective for single factors of task variation. We demonstrate these constraints lead to disentanglement in a variety of tasks and architectures, including variational autoencoders. We also use this theory to explain why the brain partitions its cells into distinct cell types such as grid and object-vector cells, and also explain when the brain instead entangles representations in response to entangled task factors. Overall, this work provides a mathematical understanding of why single neurons in the brain often represent single human-interpretable factors, and steps towards an understanding task structure shapes the structure of brain representation.

Efficient One-Shot Neural Architecture Search With Progressive Choice Freezing Evolutionary Search

Chen Zhang,Qiyu Wan,Lening Wang,Mingsong Chen,Jingweijia Tan,Kaige Yan,Xin Fu

Neural Architecture Search (NAS) is a fast-developing research field to promote automatic machine learning. Among the recently populated NAS methods, One-Shot NAS has attracted significant attention since it greatly reduces the training cost compared with the previous NAS methods. In One-Shot NAS, the best network architecture is searched within a supernet, which is trained only once. In practice, the search process involves numerous inference processes for each user case, which causes high overhead in terms of latency and energy consumption. To tackle this problem, we first observe that the choices of the first few blocks that belong to different candidate networks will become similar at the early search stage. Furthermore, these choices are already close to the optimal choices obtained at the end of the search. Leveraging this interesting feature, we propose a Progr essive Choice Freezing Evolutionary Search (PCF-ES) method that gradually freezes block choices for all subnets at different search generations. This approach gives us an opportunity to reuse intermediate data produced by the frozen block instead of re-computing them. The experiment results show that the proposed PCF-ES provides up to 55\% speedup and reduces energy consumption by 51\% during the searching stage.

Synthetic Data Generation of Many-to-Many Datasets via Random Graph Generation

Kai Xu,Georgi Ganev,Emile Joubert,Rees Davison,Olivier Van Acker,Luke Robinson

Synthetic data generation (SDG) has become a popular approach to release private datasets.

In SDG, a generative model is fitted on the private real data, and samples drawn from the model are released as the protected synthetic data.

While real-world datasets usually consist of multiple tables with potential \emph{many-to-many} relationships (i.e.~\emph{many-to-many datasets}), recent research in SDG mostly focuses on modeling tables \emph{independently} or only considers generating datasets with special cases of many-to-many relationships such as \emph{one-to-many}.

In this paper, we first study challenges of building faithful generative models for many-to-many datasets, identifying limitations of existing methods.

We then present a novel factorization for many-to-many generative models, which leads to a scalable generation framework by combining recent results from random graph theory and representation learning.

Finally, we extend the framework to establish the notion of (ϵ,δ)-differential privacy.

Through a real-world dataset, we demonstrate that our method can generate synthetic datasets while preserving information within and across tables better than its closest competitor.

Learning rigid dynamics with face interaction graph networks

Kelsey R Allen,Yulia Rubanova,Tatiana Lopez-Guevara,William F Whitney,Alvaro Sanchez-Gonzalez,Peter Battaglia,Tobias Pfaff

Simulating rigid collisions among arbitrary shapes is notoriously difficult due to complex geometry and the strong non-linearity of the interactions. While graph neural network (GNN)-based models are effective at learning to simulate complex physical dynamics, such as fluids, cloth and articulated bodies, they have been less effective and efficient on rigid-body physics, except with very simple shapes. Existing methods that model collisions through the meshes' nodes are often inaccurate because they struggle when collisions occur on faces far from nodes. Alternative approaches that represent the geometry densely with many particles are prohibitively expensive for complex shapes. Here we introduce the ``Face Interaction Graph Network'' (FIGNet) which extends beyond GNN-based methods, and computes interactions between mesh faces, rather than nodes. Compared to learned node- and particle-based methods, FIGNet is around 4x more accurate in simulating complex shape interactions, while also 8x more computationally efficient on sparse, rigid meshes. Moreover, FIGNet can learn frictional dynamics directly from real-world data, and can be more accurate than analytical solvers given modest amounts of training data. FIGNet represents a key step forward in one of the few remaining physical domains which have seen little competition from learned simulators, and offers allied fields such as robotics, graphics and mechanical design a new tool for simulation and model-based planning.

On the Importance of Contrastive Loss in Multimodal Learning

Yunwei Ren,Yuanzhi Li

Recently, contrastive learning approaches (e.g., CLIP (Radford et al., 2021)) have received huge success in multimodal learning, where the model tries to minimize the distance between the representations of different views (e.g., image and its caption) of the same data point, while keep the representations of different data points away from each other. However, from a theoretical perspective, it is unclear how contrastive learning can learn to align the representations from di■

erent views efficiently, especially in cases where the data is not isotropic. In this work, we analyze the training dynamics of a simple multimodal contrastive learning model, and show that contrastive pairs are important for the model to efficiently balance the learned representations. In particular, we reveal a stage-wise behavior of the learning process: In the first stage, the model aligns the feature representations using positive pairs and the condition number grows in this stage. Then, in the second stage, the model reduces the condition number of the learned representations using negative pairs.

MAD for Robust Reinforcement Learning in Machine Translation

Domenic Donato,Lei Yu,Wang Ling,Chris Dyer

We introduce a new distributed policy gradient algorithm and show that it outperforms existing reward-aware training procedures such as REINFORCE, minimum risk training (MRT) and proximal policy optimization (PPO) in terms of training stability and generalization performance when optimizing machine translation models. Our algorithm, which we call MAD (on account of using the mean absolute deviation in the importance weighting calculation), has distributed data generators sampling multiple candidates per source sentence on worker nodes, while a central learner updates the policy. MAD depends crucially on two variance reduction strategies: (1) a conditional reward normalization method that ensures each source sentence has both positive and negative reward translation examples and (2) a new robust importance weighting scheme that acts as a conditional entropy regularizer. Experiments on a variety of translation tasks show that policies learned using the MAD algorithm perform very well when using both greedy decoding and beam search, and that the learned policies are sensitive to the specific reward used during training.

An Exploration of Conditioning Methods in Graph Neural Networks

Yeskendir Koishekenov,Erik J Bekkers

The flexibility and effectiveness of message passing based graph neural networks (GNNs) induced considerable advances in deep learning on graph-structured data. In such approaches, GNNs recursively update node representations based on their neighbors and they gain expressivity through the use of node and edge attribute vectors. E.g., In computational tasks such as physics and chemistry usage of edge attributes such as relative position or distance proved to be essential. In this work, we address not what kind of attributes to use, but how to condition on this information to improve model performance. We consider three types of conditioning; weak, strong, and pure, which respectively relate to concatenation-based conditioning, gating, and transformations that are causally dependent on the attributes. This categorization provides a unifying viewpoint on different classes of GNNs, from separable convolutions to various forms of message passing networks. We provide an empirical study on the effect of conditioning methods in several tasks in computational chemistry.

Speed Up Iterative Non-Autoregressive Transformers by Distilling Multiple Steps

Sajad Norouzi,Rasa Hosseinzadeh,Felipe Perez,Maksims Volkovs

The computational benefits of iterative non-autoregressive transformers decrease as the number of decoding steps increases. As a remedy, we introduce Distill Multiple Steps (DiMS), a simple yet effective distillation technique to decrease the number of required steps to reach a certain translation quality. The distilled model enjoys the computational benefits of early iterations while preserving the enhancements from several iterative steps. DiMS relies on two models namely student and teacher. The student is optimized to predict the output of the teacher after multiple decoding steps while the teacher follows the student via a slow-moving average. The moving average keeps the teacher's knowledge updated and enhances the quality of the labels provided by the teacher. During inference, the student is used for translation and no additional computation is added. We verify the effectiveness of DiMS on various models obtaining 7 and 12.9 BLEU points improvements on distilled and raw versions of WMT'14 De-En, respectively.

Cross-Silo Training of Differentially Private Models with Secure Multiparty Computation
Sikha Pentyala,Davis Railsback,Ricardo José Menezes Maia,David Melanson,Rafael Dowsley,Anderson Nascimento,Martine De Cock
We address the problem of learning a machine learning model from training data that originates at multiple data holders in a cross-silo federated setup, while providing formal privacy guarantees regarding the protection of each holder's data. Existing solutions based on Differential Privacy (DP) achieve this at the cost of a drop in accuracy. Solutions based on Secure Multiparty Computation (MPC) do not incur such accuracy loss but leak information when the trained model is made publicly available. We propose an MPC solution for training differentially private models. Our solution relies on an MPC protocol for model training, and an MPC protocol for perturbing the trained model coefficients with Laplace noise in a privacy-preserving manner. The resulting MPC+DP approach achieves higher accuracy than a pure DP approach, while providing the same formal privacy guarantees.

HyperTime: Implicit Neural Representations for Time Series Generation
Elizabeth Fons,Alejandro Sztrajman,Yousef El-Laham,Alexandros Iosifidis,Svitlana Vyetrenko
Implicit neural representations (INRs) have recently emerged as a powerful tool that provides an accurate and resolution-independent encoding of data. Their robustness as general approximators has been shown in a wide variety of data sources, with applications on image, sound, and 3D scene representation. However, little attention has been given to leveraging these architectures for the representation and analysis of time series data. In this paper, we propose a new INR architecture for time series (iSIREN) designed to perform an accurate reconstruction of univariate and multivariate data, while also providing an interpretable encoding of the signal. We compare our architecture against SIREN and INRs with different activations, in terms of training convergence, and the reconstruction accuracy of both the signal and its spectral distribution.
To achieve generalization, we propose a hypernetwork architecture (HyperTime) that leverages iSIRENs to learn a latent representation of an entire time series dataset. In addition to the traditional reconstruction loss, we introduce an FFT-based loss that guides the training by enforcing a good match of the ground truth spectral distribution. We show how these architectures can be used for time series generation, and evaluate our method through fidelity metrics, presenting results that exceed the performance of state-of-the-art techniques. Finally, we propose an alternative hypernetwork architecture (iHyperTime) that incorporates interpretability into the latent representation, enabling the introduction of prior knowledge by imposing constraints into the generation process.

Homotopy Learning of Parametric Solutions to Constrained Optimization Problems
Shimiao Li,Jan Drgona,Aaron R Tuor,Larry Pileggi,Draguna L Vrabie
Building deep learning (DL) alternatives to constrained optimization problems has been proposed as a cheaper solution approach than classical constrained optimization solvers. However, these approximate learning-based solutions still suffer from constraint violations. From this perspective, reaching a reliable convergence remains an open challenge to DL models even with state-of-the-art methods to impose constraints, especially when facing a large set of nonlinear constraints forming a non-convex feasible set. In this paper, we propose the use of homotopy meta-optimization heuristics which creates a continuous transformation of the objective and constraints during training, to promote a more reliable convergence where the solution feasibility can be further improved. The method developed in this work includes 1) general-purpose homotopy heuristics based on the relaxation of objectives and constraint bounds to enlarge the basin of attraction and 2) physics-informed transformation of domain problem leading to trivial starting points lying within the basin of attraction. Experimentally, we demonstrate the efficacy of the proposed method on a set of abstract constrained optimization problems and real-world power grid optimal power flow problems with increasing co

mplexity. Results show that constrained deep learning models with homotopy heuristics can improve the feasibility of the resulting solutions while achieving near-optimal objective values when compared with non-homotopy counterparts.

When Rigid Coherency Hurts: Distributional Coherency Regularization for Probabilistic Hierarchical Time Series Forecasting

Harshavardhan Kamarthi,Lingkai Kong,Alexander Rodríguez,Chao Zhang,B. Aditya Prakash

Probabilistic hierarchical time-series forecasting is an important variant of time-series forecasting, where the goal is to model and forecast multivariate time-series that have hierarchical relations. Previous works all assume rigid consistency over the given hierarchies and do not adapt to real-world data that show deviation from this assumption. Moreover, recent state-of-art neural probabilistic methods also impose hierarchical relations on point predictions and samples of distribution. This does not account for full forecast distributions being coherent with the hierarchy and leads to poorly calibrated forecasts. We close both these gaps and propose PROFHIT, a probabilistic hierarchical forecasting model that jointly models forecast distributions over the entire hierarchy. PROFHIT (1) uses a flexible probabilistic Bayesian approach and (2) introduces soft distributional coherency regularization that enables end-to-end learning of the entire forecast distribution leveraging information from the underlying hierarchy. This enables robust and calibrated forecasts as well as adaptation to real-life data with varied hierarchical consistency. PROFHIT provides 41-88% better performance in accuracy and 23-33% better calibration over a wide range of dataset consistency. Furthermore, PROFHIT can robustly provide reliable forecasts even if up to 10% of input time-series data is missing, whereas other methods’ performance severely degrade by over 70%.

****

MALIBO: Meta-Learning for Likelihood-free Bayesian Optimization

Jiarong Pan,Stefan Falkner,Felix Berkenkamp,Joaquin Vanschoren

Bayesian Optimization (BO) is a popular method to optimize expensive black-box functions. Typically, BO only uses observations from the current task. Recently proposed methods try to warm-start BO by exploiting knowledge from related tasks, yet suffer from scalability issues and sensitivity to heterogeneous scale across multiple datasets. We propose a novel approach to solve these problems by combining a meta-learning technique and a likelihood-free acquisition function. The meta-learning model simultaneously learns the underlying (task-agnostic) data distribution and a latent feature representation for individual tasks. The likelihood-free BO technique has less stringent assumptions about the problems and works with any classification algorithm, making it computation efficient and robust to different scales across tasks. Finally, gradient boosting is used as a residual model on top to adapt to distribution drifts between new and prior tasks, which might otherwise weaken the usefulness of the meta-learned features. Experiments show that the meta-model learns an effective prior for warm-starting optimization algorithms, while being cheap to evaluate and invariant to changes of scale across different datasets.

Finding and only finding local Nash equilibria by both pretending to be a follower

Xuchan Bao,Guodong Zhang

Finding (local) Nash equilibria in two-player differentiable games is a classical problem in game theory with important relevance in machine learning. We propose double Follow-the-Ridge (double-FTR), an algorithm that locally converges to and only to local Nash equilibria in general-sum two-player differentiable games. To our knowledge, double-FTR is the first algorithm with such guarantees for general-sum games. Furthermore, we show that by varying its preconditioner, double-FTR leads to a broader family of algorithms with the same convergence guarantee. In addition, double-FTR avoids oscillation near equilibria due to the real-eigenvalues of its Jacobian at fixed points.

Empirically, we validate the double-FTR algorithm on a range of simple zero-sum and general sum games, as well as simple Generative Adversarial Network (GAN) tasks.

Learning Low Dimensional State Spaces with Overparameterized Recurrent Neural Nets
Edo Cohen-Karlik,Itamar Menuhin-Gruman,Raja Giryes,Nadav Cohen,Amir Globerson
Overparameterization in deep learning refers to settings where a trained Neural Network (NN) has representational capacity to fit the training data in many ways, some of which generalize well, while others do not. In the case of Recurrent Neural Networks (RNNs) there exists an additional layer of overparameterization, in the sense that a model may exhibit many solutions that generalize well for sequence lengths seen in training, some of which \emph{extrapolate} to longer sequences, while others do not. Numerous works studied the tendency of Gradient Descent (GD) to fit overparameterized NNs with solutions that generalize well. On the other hand, its tendency to fit overparameterized RNNs with solutions that extrapolate has been discovered only lately, and is far less understood. In this paper, we analyze the extrapolation properties of GD when applied to overparameterized linear RNNs. In contrast to recent arguments suggesting an implicit bias towards short-term memory, we provide theoretical evidence for learning low dimensional state spaces, which can also model long-term memory. Our result relies on a dynamical characterization showing that GD (with small step size and near zero initialization) strives to maintain a certain form of balancedness, as well as tools developed in the context of the \emph{moment problem} from statistics (recovery of discrete probability distribution from its moments). Experiments corroborate our theory, demonstrating extrapolation via learning low dimensional state spaces with both linear and non-linear RNNs.

****

Images as Weight Matrices: Sequential Image Generation Through Synaptic Learning Rules
Kazuki Irie,Jürgen Schmidhuber
Work on fast weight programmers has demonstrated the effectiveness of key/value outer product-based learning rules for sequentially generating a weight matrix (WM) of a neural net (NN) by another NN or itself. However, the weight generation steps are typically not visually interpretable by humans, because the contents stored in the WM of an NN are not. Here we apply the same principle to generate natural images. The resulting fast weight painters (FPAs) learn to execute sequences of delta learning rules to sequentially generate images as sums of outer products of self-invented keys and values, one rank at a time, as if each image was a WM of an NN. We train our FPAs in the generative adversarial networks framework, and evaluate on various image datasets. We show how these generic learning rules can generate images with respectable visual quality without any explicit inductive bias for images. While the performance largely lags behind the one of specialised state-of-the-art image generators, our approach allows for visualising how synaptic learning rules iteratively produce complex connection patterns, yielding human-interpretable meaningful images. Finally, we also show that an additional convolutional U-Net (now popular in diffusion models) at the output of an FPA can learn one-step "denoising" of FPA-generated images to enhance their quality.
Our code is public.

SurCo: Learning Linear Surrogates for Combinatorial Nonlinear Optimization Problems
Aaron M Ferber,Taoan Huang,Daochen Zha,Martin Schubert,Benoit Steiner,Bistra Dilkina,Yuandong Tian
Optimization problems with expensive nonlinear cost functions and combinatorial constraints appear in many real-world applications, but remain challenging to solve efficiently. Existing combinatorial solvers like Mixed Integer Linear Programming can be fast in practice but cannot readily optimize nonlinear cost functions, while general nonlinear optimizers like gradient descent often do not handle complex combinatorial structures, may require many queries of the cost function

, and are prone to local optima. To bridge this gap, we propose SurCo that learns linear Surrogate costs which can be used by existing Combinatorial solvers to output good solutions to the original nonlinear combinatorial optimization problem, combining the flexibility of gradient-based methods with the structure of linear combinatorial optimization. We learn these linear surrogates end-to-end with the nonlinear loss by differentiating through the linear surrogate solver. Three variants of SurCo are proposed: SurCo-zero operates on individual nonlinear problems, SurCo-prior trains a linear surrogate predictor on distributions of problems, and SurCo-hybrid uses a model trained offline to warm start online solving for SurCo-zero. We analyze our method theoretically and empirically, showing smooth convergence and improved performance. Experiments show that compared to state-of-the-art approaches and expert-designed heuristics, SurCo obtains lower cost solutions with comparable or faster solve time for two real-world industry-level applications: embedding table sharding and inverse photonic design.
****

DT+GNN: A Fully Explainable Graph Neural Network using Decision Trees
Peter Müller,Lukas Faber,Karolis Martinkus,Roger Wattenhofer
We propose a new Decision Tree Graph Neural Network (DT+GNN) architecture for Graph Neural Network (GNN) explanation. Existing post-hoc explanation methods highlight important inputs but fail to reveal how a GNN uses these inputs. In contrast DT+GNN is fully explainable: Humans can inspect and understand the decision making of DT+GNN at every step. DT+GNN internally uses a novel GNN layer that is restricted to categorical state spaces for nodes and messages. After training with gradient descent we can easily distill these layers into decision trees. These trees are further pruned using our newly proposed method to ensure they are small and easy to interpret. DT+GNN can also compute node-level importance scores like the existing explanation methods. We demonstrate on real-world GNN benchmarks that DT+GNN has competitive classification accuracy and computes competitive explanations. Furthermore, we leverage DT+GNN's full explainability to inspect the decision processes in synthetic and real-world datasets with surprising results. We make this inspection accessible through an interactive web tool.

Why (and When) does Local SGD Generalize Better than SGD?
Xinran Gu,Kaifeng Lyu,Longbo Huang,Sanjeev Arora
Local SGD is a communication-efficient variant of SGD for large-scale training, where multiple GPUs perform SGD independently and average the model parameters periodically. It has been recently observed that Local SGD can not only achieve the design goal of reducing the communication overhead but also lead to higher test accuracy than the corresponding SGD baseline (Lin et al., 2020b), though the training regimes for this to happen are still in debate (Ortiz et al., 2021). This paper aims to understand why (and when) Local SGD generalizes better based on Stochastic Differential Equation (SDE) approximation. The main contributions of this paper include (i) the derivation of an SDE that captures the long-term behavior of Local SGD in the small learning rate regime, showing how noise drives the iterate to drift and diffuse after it has reached close to the manifold of local minima, (ii) a comparison between the SDEs of Local SGD and SGD, showing that Local SGD induces a stronger drift term that can result in a stronger effect of regularization, e.g., a faster reduction of sharpness, and (iii) empirical evidence validating that having a small learning rate and long enough training time enables the generalization improvement over SGD but removing either of the two conditions leads to no improvement.

Function-space regularized Rényi divergences
Jeremiah Birrell,Yannis Pantazis,Paul Dupuis,Luc Rey-Bellet,Markos Katsoulakis
We propose a new family of regularized Rényi divergences parametrized not only by the order α but also by a variational function space. These new objects are defined by taking the infimal convolution of the standard Rényi divergence with the integral probability metric (IPM) associated with the chosen function space. We derive a novel dual variational representation that can be used to construct numerically tractable divergence estimators. This representation avoids ri

sk-sensitive terms and therefore exhibits lower variance, making it well-behaved when $\alpha>1$; this addresses a notable weakness of prior approaches. We prove several properties of these new divergences, showing that they interpolate between the classical Rényi divergences and IPMs. We also study the $\alpha\to\infty$ limit, which leads to a regularized worst-case-regret and a new variational representation in the classical case. Moreover, we show that the proposed regularized Rényi divergences inherit features from IPMs such as the ability to compare distributions that are not absolutely continuous, e.g., empirical measures and distributions with low-dimensional support. We present numerical results on both synthetic and real datasets, showing the utility of these new divergences in both estimation and GAN training applications; in particular, we demonstrate significantly reduced variance and improved training performance.

Constant-Factor Approximation Algorithms for Socially Fair k-Clustering

Mehrdad Ghadiri,Mohit Singh,Santosh Vempala

We study approximation algorithms for the socially fair (ℓ_p, k)-clustering problem with m groups which include the socially fair k-median ($p=1$) and k-means ($p=2$). We present (1) a polynomial-time $(5+2\sqrt{6})^p$-approximation with at most $k+m$ centers (2) a $(5+2\sqrt{6}+\epsilon)^p$-approximation with k centers in time $(nk)^{{2^{O(p)} m^2}/\epsilon}$, and (3) a $(15+6\sqrt{6})^p$ approximation with k centers in time $k^{m}\cdot\text{poly}(n)$. The former is obtained by a refinement of the iterative rounding method via a sequence of linear programs. The latter two are obtained by converting a solution with up to $k+m$ centers to one with k centers by sparsification methods for (2) and via an exhaustive search for (3). We also compare the performance of our algorithms with existing approximation algorithms on benchmark datasets, and find that our algorithms outperform existing methods.

Implicit Bias of Large Depth Networks: a Notion of Rank for Nonlinear Functions

Arthur Jacot

We show that the representation cost of fully connected neural networks with homogeneous nonlinearities - which describes the implicit bias in function space of networks with L_2-regularization or with losses such as the cross-entropy - converges as the depth of the network goes to infinity to a notion of rank over nonlinear functions. We then inquire under which conditions the global minima of the loss recover the `true' rank of the data: we show that for too large depths the global minimum will be approximately rank 1 (underestimating the rank); we then argue that there is a range of depths which grows with the number of datapoints where the true rank is recovered. Finally, we discuss the effect of the rank of a classifier on the topology of the resulting class boundaries and show that autoencoders with optimal nonlinear rank are naturally denoising.

****

Depth Separation with Multilayer Mean-Field Networks

Yunwei Ren,Mo Zhou,Rong Ge

Depth separation—why a deeper network is more powerful than a shallow one—has been a major problem in deep learning theory. Previous results often focus on representation power, for example, Safran et al. (2019) constructed a function that is easy to approximate using a 3-layer network but not approximable by any 2-layer network. In this paper, we show that this separation is in fact algorithmic: one can learn the function constructed by Safran et al. (2019) using an overparametrized network with polynomially many neurons efficiently. Our result relies on a new way of extending the mean-field limit to multilayer networks, and a decomposition of loss that factors out the error introduced by the discretization of infinite-width mean-field networks.

Robust Policy Optimization in Deep Reinforcement Learning

Md Masudur Rahman,Yexiang Xue

Entropy can play an essential role in policy optimization by selecting the stochastic policy, which eventually helps better explore the environment in reinforcement learning (RL). A proper balance between exploration and exploitation is cha llenging and might depend on the particular RL task. However, the stochasticity often reduces as the training progresses; thus, the policy becomes less exploratory. Therefore, in many cases, the policy can converge to sub-optimal due to a lack of representative data during training. Moreover, this issue can even be severe in high-dimensional environments. This paper investigates whether keeping a certain entropy threshold throughout training can help better policy learning. In particular, we propose an algorithm Robust Policy Optimization (RPO), which leverages a perturbed Gaussian distribution to encourage high-entropy actions. We evaluated our methods on various continuous control tasks from DeepMind Control, OpenAI Gym, Pybullet, and IsaacGym. We observed that in many settings, RPO increases the policy entropy early in training and then maintains a certain level of entropy throughout the training period. Eventually, our agent RPO shows consistently improved performance compared to PPO and other techniques such as data augmentation and entropy regularization. Furthermore, in several settings, our method stays robust in performance, while other baseline mechanisms fail to improve and even worsen the performance.

Analogical Networks for Memory-Modulated 3D Parsing

Nikolaos Gkanatsios,Mayank Singh,Zhaoyuan Fang,Shubham Tulsiani,Katerina Fragkiadaki

Despite recent breakthroughs in the applications of deep neural networks in visual perception, one setting that presents a persistent challenge is that of “few-shot learning.” Works in the area of few shot visual learning mostly address the task of coarse image classification. Fine-grain visual parsing is necessary for scene understanding and action recognition. Thus far, a separate neural model is trained to parse each semantic category, which hinders knowledge sharing across objects, let alone few shot visual parsing. We present Analogical Networks, a model that casts fine-grained visual parsing into analogical inference: instead of mapping input scenes to part labels, which is hard to adapt in a few-shot manner to novel inputs, our model retrieves related scenes from memory and their corresponding part structures, and predicts analogous part structures in the input scene, via an end-to-end learnable modulation mechanism. By conditioning on more than one memory, compositions of structures are predicted, that mix and match parts from different visual experiences. We show Analogical Networks excel at few-shot learning, where instances of novel object categories are successfully parsed simply by expanding the model’s memory, without any weight updates. Analogical Networks outperform existing state-of-the-art detection transformer models at part segmentation, as well as paradigms of meta-learning and few-shot learning. We show part correspondences emerge across memory and input scenes by simply training for a label-free segmentation objective, as a byproduct of the analogical inductive bias.

Fake It Until You Make It : Towards Accurate Near-Distribution Novelty Detection

Hossein Mirzaei,Mohammadreza Salehi,Sajjad Shahabi,Efstratios Gavves,Cees G. M. Snoek,Mohammad Sabokrou,Mohammad Hossein Rohban

We aim for image-based novelty detection. Despite considerable progress, existing models either fail or face dramatic drop under the so-called ``near-distribution" setup, where the differences between normal and anomalous samples are subtle. We first demonstrate existing methods could experience up to 20\% decrease in their AUCs in the near-distribution setting. Next, we propose to exploit a score-based generative model to produce synthetic near-distribution anomalous data. Our model is then fine-tuned to distinguish such data from the normal samples. We make quantitative as well as qualitative evaluation of this strategy, and compare the results with a variety of GAN-based models. Effectiveness of our method for both near-distribution and standard novelty detection is assessed through extensive experiments on datasets in diverse applications such as medical images, object classification, and quality control. This reveals that our method significantly improves upon existing models, and consistently decreases the gap between the near-distribution and standard novelty detection AUCs by a considerable amount.

DySR: Adaptive Super-Resolution via Algorithm and System Co-design

Syed Zawad,Cheng Li,Zhewei Yao,Elton Zheng,Yuxiong He,Feng Yan

Super resolution (SR) is a promising approach for improving the quality of low resolution steaming services on mobile devices.

On mobile devices, the available computing and memory resources change dynamically depending on other running applications.

Due to the high computation and memory demands of SR models, it is essential to adapt the model according to available resources to harvest the best possible model performance while maintaining quality of service (QoS), such as meeting a minimum framerate and avoiding interruptions. Nevertheless, there is no SR model or machine learning system that supports adaptive SR, and enabling adaptive SR model on mobile devices is challenging because adapting model can cause significant framerate drop or even service interruption. To address this challenge, we take an algorithm and system co-design approach and propose DySR that maintains QoS while maximizing the model performance. During the training stage, DySR employs an adaption-aware one-shot Neural Architecture Search to produce sub-graphs that share kernel operation weights for low model adaption overhead while striking a balance between performance and framerate. During the inference stage, an incremental model adaption method is developed for further reducing the model adaption overhead. We evaluate on a diverse set of hardware and datasets to show that DySR can generate models close to the Pareto frontier while maintaining a steady framerate throughput with a memory footprint of around 40\% less compared to baseline methods.

Domain Invariant Q-Learning for model-free robust continuous control under visual distractions

Tom Dupuis,Jaonary Rabarisoa,Quoc Cuong PHAM,David Filliat

End-to-end reinforcement learning on images showed significant performance progress in the recent years, especially with regularization to value estimation brought by data augmentation \citep{yarats2020image}. At the same time, domain randomization and representation learning helped push the limits of these algorithms in visually diverse environments, full of distractors and spurious noise, making RL more robust to unrelated visual features. We present DIQL, a method that combines risk invariant regularization and domain randomization to reduce out-of-distribution generalization gap for temporal-difference learning. In this work, we draw a link by framing domain randomization as a richer extension of data augmentation to RL and support its generalized use. Our model-free approach improve baselines performances without the need of additional representation learning objectives and with limited additional computational cost. We show that DIQL outperforms existing methods on complex visuo-motor control environment with high visual perturbation. In particular, our approach achieves state-of the-art performance on the Distracting Control Suite benchmark, where we evaluate the robustness to a number of visual perturbators, as well as OOD generalization and extrapolation capabilities.

Continual Learning with Soft-Masking of Parameter-Level Gradient Flow

Tatsuya Konishi,Mori Kurokawa,Chihiro Ono,Zixuan Ke,Gyuhak Kim,Bing Liu

Existing research on task incremental learning in continual learning has primarily focused on preventing catastrophic forgetting (CF). Several techniques have achieved learning with no CF. However, they attain it by letting each task monopolize a sub-network in a shared network, which seriously limits knowledge transfer (KT) and causes over-consumption of the network capacity, i.e., as more tasks are learned, the performance deteriorates. The goal of this paper is threefold: (1) overcoming CF, (2) encouraging KT, and (3) tackling the capacity problem. A novel and simple technique (called SPG) is proposed that soft-masks (partially blocks) parameter updating in training based on the importance of each parameter to old tasks. Each task still uses the full network, i.e., no monopoly of any part of the network by any task, which enables maximum KT and reduction of capacity usage. Extensive experiments demonstrate the effectiveness of SPG in achieving

all three objectives. More notably, it attains significant transfer of knowledge not only among similar tasks (with shared knowledge) but also among dissimilar tasks (with little shared knowledge) while preventing CF.
****

Asynchronous Message Passing: A new Framework for Learning in Graphs
Lukas Faber,Roger Wattenhofer
This paper studies asynchronous message passing (AMP), a new framework for applying neural networks to graphs. Existing graph neural networks (GNNs) use the message passing framework which is based on the synchronous distributed computing model. In traditional GNNs, nodes aggregate their neighbors in each round, which causes problems such as oversmoothing and expressiveness limitations. On the other hand, our AMP framework is based on the \textit{asynchronous} model, where nodes react to messages of their neighbors individually. We prove (i) AMP is at least as powerful as the message passing framework, (ii) AMP is more powerful than the $1-$WL test for graph isomorphism, an important benchmark for message passing GNNs, and (iii) conceptually, AMP can even separate any pair of graphs and compute graph isomorphism. We experimentally validate the findings on AMP's expressiveness, and show that AMP might be better suited to propagate messages over large distances in graphs. We also demonstrate that AMP performs well on several graph classification benchmarks.

Integrating Symmetry into Differentiable Planning with Steerable Convolutions
Linfeng Zhao,Xupeng Zhu,Lingzhi Kong,Robin Walters,Lawson L.S. Wong
To achieve this, we draw inspiration from equivariant convolution networks and model the path planning problem as a set of signals over grids. We demonstrate that value iteration can be treated as a linear equivariant operator, which is effectively a steerable convolution. Building upon Value Iteration Networks (VIN), we propose a new Symmetric Planning (SymPlan) framework that incorporates rotation and reflection symmetry using steerable convolution networks. We evaluate our approach on four tasks: 2D navigation, visual navigation, 2 degrees of freedom (2-DOF) configuration space manipulation, and 2-DOF workspace manipulation. Our experimental results show that our symmetric planning algorithms significantly improve training efficiency and generalization performance compared to non-equivariant baselines, including VINs and GPPN.

MolJET: Multimodal Joint Embedding Transformer for Conditional de novo Molecular Design and Multi-Property Optimization
Orion Walker Dollar,Sameera Horawalavithana,Scott Vasquez,W. James Pfaendtner,Svitlana Volkova
Multi-property constrained optimization of molecules using generative de novo design models is vital for the successful application of Artificial Intelligence (AI) towards materials and drug discovery. Yet there remains a gap between the reported performance of such models in the literature and their practical utility in real world design scenarios. Furthermore, existing models are largely inaccessible to chemists without an extensive background in computer science. To address these challenges, we propose a generative foundation model, the Multimodal Joint Embedding Transformer (MolJET), which performs conditional generation of desired molecular distributions based on human-interpretable chemistry prompts in a zero-shot manner. We assess MolJET on the standard benchmarks available in the GuacaMol and MIMOSA evaluation frameworks. These include structure-based sampling tasks as well as a range of multi-property optimization tasks that probe a models ability to design drug-like molecules given realistic property constraints. We demonstrate that with self-supervised pretraining, MolJET outperforms 80% of task-optimized models while using zero-shot inferences and beats all baselines after minimal supervision. Moreover, the performance of MolJET on text-only conditioning tasks improves with the inclusion of property modalities during training, highlighting the importance of a multimodal approach to molecular design. MolJET is the first example of text-based de novo molecular design using large-scale multimodal foundation models and should serve as a building block towards further improvements to accessible AI for chemists.

The Challenges of Exploration for Offline Reinforcement Learning

Nathan Lambert,Markus Wulfmeier,William F Whitney,Arunkumar Byravan,Michael Bloesch,Vibhavari Dasagi,Tim Hertweck,Martin Riedmiller

Offline Reinforcement Learning (ORL) enables us to separately study the two interlinked processes of reinforcement learning: collecting informative experience and inferring optimal behaviour. The second step has been widely studied in the offline setting, but just as critical to data-efficient RL is the collection of informative data. The task-agnostic setting for data collection, where the task is not known a priori, is of particular interest due to the possibility of collecting a single dataset and using it to solve several downstream tasks as they arise. We investigate this setting via curiosity-based intrinsic motivation, a family of exploration methods which encourage the agent to explore those states or transitions it has not yet learned to model. With Explore2Offline, we propose to evaluate the quality of collected data by transferring the collected data and inferring policies with reward relabelling and standard offline RL algorithms. We evaluate a wide variety of data collection strategies, including a new exploration agent, Intrinsic Model Predictive Control (IMPC), using this scheme and demonstrate their performance on various tasks. We use this decoupled framework to strengthen intuitions about exploration and the data prerequisites for effective offline RL.

SGD with large step sizes learns sparse features

Maksym Andriushchenko,Aditya Vardhan Varre,Loucas Pillaud-Vivien,Nicolas Flammarion

We showcase important features of the dynamics of the Stochastic Gradient Descent (SGD) in the training of neural networks. We present empirical observations that the commonly used large step sizes (i) lead the iterates to jump from one side of a valley to the other causing \textit{loss stabilisation} (ii) this stabilisation induces a hidden stochastic dynamics orthogonal to the bouncing directions that \textit{biases it implicitly} toward simple predictors. Furthermore, we show empirically that the longer large step sizes keep SGD high in the loss landscape valleys, the better the implicit regularization can operate and find sparse representations. Notably, no explicit regularization is used so that the regularization effect comes solely from the SGD training dynamics influenced by the step size schedule. Therefore, these observations unveil how, through the step size schedules, both gradient and noise drive together the SGD dynamics through the loss landscape of neural networks. We justify these findings theoretically through the study of simple neural network models. Finally, we shed a new light on some common practice and observed phenomena when training neural networks.

Synergies Between Disentanglement and Sparsity: a Multi-Task Learning Perspective

Sebastien Lachapelle,Tristan Deleu,Divyat Mahajan,Ioannis Mitliagkas,Yoshua Bengio,Simon Lacoste-Julien,Quentin Bertrand

Although disentangled representations are often said to be beneficial for downstream tasks, current empirical and theoretical understanding is limited. In this work, we provide evidence that disentangled representations coupled with sparse base-predictors improve generalization. In the context of multi-task learning, we prove a new identifiability result that provides conditions under which maximally sparse base-predictors yield disentangled representations. Motivated by this theoretical result, we propose a practical approach to learn disentangled representations based on a sparsity-promoting bi-level optimization problem. Finally, we explore a meta-learning version of this algorithm based on group Lasso multiclass SVM base-predictors, for which we derive a tractable dual formulation. It obtains competitive results on standard few-shot classification benchmarks, while each task is using only a fraction of the learned representations.

Discerning Hydroclimatic Behavior with a Deep Convolutional Residual Regressive Neural Network

Albert Larson,Ali S Akanda,Abdeltawab Hendawi,Soni Pradhanang,Thomas Boving

Water impacts the globe daily in new and familiar ways such as the ongoing western United States drought and the 2022 Pakistan flood. These events sustain uncertainty, risk, and loss forces to the global ecosystem. Better forecasting tools are mandatory to calibrate our response in an effort to mitigate such natural hazards in our watersheds and adapt to the planet’s dynamic environment. Here, we present a Deep Convolutional Residual Regressive Neural Net (DCRRNN - pronounced “discern”) platform for obtaining, visualizing, and analyzing the basin response of watersheds to water cycle fluxes. We examine four very large basins, simulating river response to the hydroclimatic fluxes they face. Experiments modulating the lever of time lag between remotely sensed and ground truth measurements are performed to assess the metrological limits of this forecasting device. The resultant grand mean Nash Sutcliffe and Kling Gupta efficiency values are both of greater value than 90\%. Our results show that DCRRNN can become a powerful resource to simulate and forecast the impacts of hydroclimatic events as they relate to watershed response in a globally changing climate.

Causal Reasoning in the Presence of Latent Confounders via Neural ADMG Learning

Matthew Ashman,Chao Ma,Agrin Hilmkil,Joel Jennings,Cheng Zhang

Latent confounding has been a long-standing obstacle for causal reasoning from observational data. One popular approach is to model the data using acyclic directed mixed graphs (ADMGs), which describe ancestral relations between variables using directed and bidirected edges. However, existing methods using ADMGs are based on either linear functional assumptions or a discrete search that is complicated to use and lacks computational tractability for large datasets. In this work, we further extend the existing body of work and develop a novel gradient-based approach to learning an ADMG with nonlinear functional relations from observational data. We first show that the presence of latent confounding is identifiable under the assumptions of bow-free ADMGs with nonlinear additive noise models. With this insight, we propose a novel neural causal model based on autoregressive flows. This not only enables us to model complex causal relationships behind the data, but also estimate their functional relationships (hence treatment effects) simultaneously. We further validate our approach via experiments on both synthetic and real-world datasets, and demonstrate the competitive performance against relevant baselines.

Mitigating Gradient Bias in Multi-objective Learning: A Provably Convergent Approach

Heshan Devaka Fernando,Han Shen,Miao Liu,Subhajit Chaudhury,Keerthiram Murugesan,Tianyi Chen

Many machine learning problems today have multiple objective functions. They appear either in learning with multiple criteria where learning has to make a trade-off between multiple performance metrics such as fairness, safety and accuracy; or, in multi-task learning where multiple tasks are optimized jointly, sharing inductive bias between them. This problems are often tackled by the multi-objective optimization framework. However, existing stochastic multi-objective gradient methods and its variants (e.g., MGDA, PCGrad, CAGrad, etc.) all adopt a biased noisy gradient direction, which leads to degraded empirical performance.

To this end, we develop a stochastic multi-objective gradient correction (MoCo) method for multi-objective optimization. The unique feature of our method is that it can guarantee convergence without increasing the batch size even in the nonconvex setting. Simulations on multi-task supervised and reinforcement learning demonstrate the effectiveness of our method relative to the state-of-the-art methods.

Pareto Rank-Preserving Supernetwork for HW-NAS

Hadjer Benmeziane,Hamza Ouarnoughi,Smail Niar,Kaoutar El Maghraoui

In neural architecture search (NAS), training every sampled architecture is very time-consuming and should be avoided.

Weight-sharing is a promising solution to speed up the evaluation process.

However, a sampled subnetwork is not guaranteed to be estimated precisely unless a complete individual training process is done.

Additionally, practical deep learning engineering processes require incorporating realistic hardware-performance metrics into the NAS evaluation process, also known as hardware-aware NAS (HW-NAS).

HW-NAS results a Pareto front, a set of all architectures that optimize conflicting objectives, i.e. task-specific performance and hardware efficiency.

This paper proposes a supernetwork training methodology that preserves the Pareto ranking between its different subnetworks resulting in more efficient and accurate neural networks for a variety of hardware platforms. The results show a 97% near Pareto front approximation in less than 2 GPU days of search, which provides x2 speed up compared to state-of-the-art methods. We validate our methodology on NAS-Bench-201, DARTS and ImageNet. Our optimal model achieves 77.2% accuracy (+1.7% compared to baseline) with an inference time of 3.68ms on Edge GPU for ImageNet.

****

ProSampler: Improving Contrastive Learning by Better Mini-batch Sampling

Zhen Yang,Tinglin Huang,Ming Ding,Zhitao Ying,Yukuo Cen,Yangliao Geng,Yuxiao Dong,Jie Tang

In-batch contrastive learning has emerged as a state-of-the-art self-supervised learning solution, with the philosophy of bringing semantically similar instances closer while pushing dissimilar instances apart within a mini-batch. However, the in-batch negative sharing strategy is limited by the batch size and falls short of prioritizing the informative negatives (i.e., hard negatives) globally. In this paper, we propose to sample mini-batches with hard negatives on a proximity graph in which the instances (nodes) are connected according to the similarity measurement. Sampling on the proximity graph can better exploit the hard negatives globally by bridging in similar instances from the entire dataset. The proposed method can flexibly explore the negatives by modulating two parameters, and we show that such flexibility is the key to better exploit hard negative globally. We evaluate the proposed method on three representative contrastive learning algorithms, each of which corresponds to one modality: image, text, and graph. Besides, we also apply it to the variants of the InfoNCE objective to verify its generality. The results show that our method can consistently boost the performance of contrastive methods, with a relative improvement of 2.5% for SimCLR on ImageNet-100, 1.4% for SimCSE on the standard STS task, and 1.2% for GraphCL on the COLLAB dataset.

$O(T^{-1})$ Convergence of Optimistic-Follow-the-Regularized-Leader in Two-Player Zero-Sum Markov Games

Yuepeng Yang,Cong Ma

We prove that the optimistic-follow-the-regularized-leader (OFTRL) algorithm, together with smooth value updates, finds an $O(T^{-1})$ approximate Nash equilibrium in T iterations for two-player zero-sum Markov games with full information. This improves the $\tilde{O}(T^{-5/6})$ convergence rate recently shown by Zhang et al (2022). The refined analysis hinges on two essential ingredients. First, the sum of the regrets of the two players, though not necessarily non-negative as in normal-form games, is approximately non-negative in Markov games. This property allows us to bound the second-order path lengths of the learning dynamics. Second, we prove a tighter algebraic inequality regarding the weights deployed by OFTRL that shaves an extra $\log T$ factor. This crucial improvement enables the inductive analysis that leads to the final $O(T^{-1})$ rate.

****

Bispectral Neural Networks

Sophia Sanborn,Christian A Shewmake,Bruno Olshausen,Christopher J. Hillar

We present a neural network architecture, Bispectral Neural Networks (BNNs) for learning representations that are invariant to the actions of compact commutative groups on the space over which a signal is defined. The model incorporates the ansatz of the bispectrum, an analytically defined group invariant that is complete -- that is, it preserves all signal structure while removing only the variat ion due to group actions. Here, we demonstrate that BNNs are able to simultaneously learn groups, their irreducible representations, and corresponding equivariant and complete-invariant maps purely from the symmetries implicit in data. Further, we demonstrate that the completeness property endows these networks with strong invariance-based adversarial robustness. This work establishes Bispectral Neural Networks as a powerful computational primitive for robust invariant representation learning.

Cold Diffusion: Inverting Arbitrary Image Transforms Without Noise

Arpit Bansal,Eitan Borgnia,Hong-Min Chu,Jie S. Li,Hamid Kazemi,Furong Huang,Micah Goldblum,Jonas Geiping,Tom Goldstein

Standard diffusion models involve an image transform -- adding Gaussian noise -- and an image restoration operator that inverts this degradation. We observe that the generative behavior of diffusion models is not strongly dependent on the choice of image degradation, and in fact an entire family of generative models can be constructed by varying this choice. Even when using completely deterministic degradations (e.g., blur, masking, and more), the training and test-time update rules that underlie diffusion models can be easily generalized to create generative models. The success of these fully deterministic models calls into question the community's understanding of diffusion models, which relies on noise in either gradient Langevin dynamics or variational inference, and paves the way for generalized diffusion models that invert arbitrary processes.

****

Beyond Lipschitz: Sharp Generalization and Excess Risk Bounds for Full-Batch GD

Konstantinos Nikolakakis,Farzin Haddadpour,Amin Karbasi,Dionysios Kalogerias

We provide sharp path-dependent generalization and excess risk guarantees for the full-batch Gradient Descent (GD) algorithm on smooth losses (possibly non-Lipschitz, possibly nonconvex). At the heart of our analysis is an upper bound on the generalization error, which implies that average output stability and a bounded expected optimization error at termination lead to generalization. This result shows that a small generalization error occurs along the optimization path, and allows us to bypass Lipschitz or sub-Gaussian assumptions on the loss prevalent in previous works. For nonconvex, convex, and strongly convex losses, we show the explicit dependence of the generalization error in terms of the accumulated path-dependent optimization error, terminal optimization error, number of samples, and number of iterations. For nonconvex smooth losses, we prove that full-batch GD efficiently generalizes close to any stationary point at termination, and recovers the generalization error guarantees of stochastic algorithms with fewer assumptions. For smooth convex losses, we show that the generalization error is tighter than existing bounds for SGD (up to one order of error magnitude). Consequently the excess risk matches that of SGD for quadratically less iterations. Lastly, for strongly convex smooth losses, we show that full-batch GD achieves essentially the same excess risk rate as compared with the state of the art on SGD, but with an exponentially smaller number of iterations (logarithmic in the dataset size).

Zero-Shot Retrieval with Search Agents and Hybrid Environments

Michelle Chen Huebscher,Christian Buck,Massimiliano Ciaramita,Sascha Rothe

Learning to search is the task of building artificial agents that learn to autonomously use a search box to find information. So far, it has been shown that current language models can learn symbolic query reformulation policies, in combination with traditional term-based retrieval, but fall short of outperforming neural retrievers. We extend the previous learning to search setup to a hybrid environment, which accepts discrete query refinement operations, after a first-pass retrieval step performed by a dual encoder. Experiments on the BEIR task show that search agents, trained via behavioral cloning, outperform the underlying search system based on a combined dual encoder retriever and cross encoder reranker. Furthermore, we find that simple heuristic Hybrid Retrieval Environments (HRE) can improve baseline performance by several nDCG points. The search agent based on the HRE environment (HaRE) produces state-of-the-art performance on both zero-shot and in-domain evaluations. We carry out an extensive qualitative analysis to shed light on the agents policies.

Hyper-Decision Transformer for Efficient Online Policy Adaptation

Mengdi Xu,Yuchen Lu,Yikang Shen,Shun Zhang,Ding Zhao,Chuang Gan

Decision Transformers (DT) have demonstrated strong performances in offline reinforcement learning settings, but quickly adapting to unseen novel tasks remains challenging. To address this challenge, we propose a new framework, called Hyper-Decision Transformer (HDT), that can generalize to novel tasks from a handful of demonstrations in a data- and parameter-efficient manner. To achieve such a goal, we propose to augment the base DT with an adaptation module, whose parameters are initialized by a hyper-network. When encountering unseen tasks, the hyper-network takes a handful of demonstrations as inputs and initializes the adaptation module accordingly. This initialization enables HDT to efficiently adapt to novel tasks by only fine-tuning the adaptation module. We validate HDT's generalization capability on object manipulation tasks. We find that with a single expert demonstration and fine-tuning only 0.5% of DT parameters, HDT adapts faster to unseen tasks than fine-tuning the whole DT model. Finally, we explore a more challenging setting where expert actions are not available, and we show that HDT outperforms state-of-the-art baselines in terms of task success rates by a large margin. Demos are available on our project page: https://sites.google.com/view/hdtforiclr2023/home.

Deep Learning of Intrinsically Motivated Options in the Arcade Learning Environment

Louis Bagot,Kevin Mets,Tom De Schepper,Steven Latre

In Reinforcement Learning, Intrinsic Motivation motivates directed behaviors through a wide range of reward-generating methods. Depending on the task and environment, these rewards can be useful, might complement each other, but can also break down entirely, as seen with the noisy TV problem for curiosity. We therefore argue that scalability and robustness, among others, are key desirable properties of a method to incorporate intrinsic rewards, which a simple weighted sum of reward lacks. In a tabular setting, Explore Options let the agent call an intrinsically motivated policy in order to learn from its trajectories. We introduce Deep Explore Options, revising Explore Options within the Deep Reinforcement Learning paradigm to tackle complex visual problems. Deep Explore Options can naturally learn from several unrelated intrinsic rewards, ignore harmful intrinsic rewards, learn to balance exploration, but also isolate exploitative and exploratory behaviors for independent usage.

We test Deep Explore Options on hard and easy exploration games of the Atari Suite, following a benchmarking study to ensure fairness. Our empirical results show that they achieve similar results than weighted sum baselines, while maintaining their key properties.

Solving Continuous Control via Q-learning

Tim Seyde,Peter Werner,Wilko Schwarting,Igor Gilitschenski,Martin Riedmiller,Daniela Rus,Markus Wulfmeier

While there has been substantial success for solving continuous control with actor-critic methods, simpler critic-only methods such as Q-learning find limited application in the associated high-dimensional action spaces. However, most actor-critic methods come at the cost of added complexity: heuristics for stabilisation, compute requirements and wider hyperparameter search spaces. We show that a simple modification of deep Q-learning largely alleviates these issues. By combining bang-bang action discretization with value decomposition, framing single-agent control as cooperative multi-agent reinforcement learning (MARL), this simple critic-only approach matches performance of state-of-the-art continuous actor-critic methods when learning from features or pixels. We extend classical bandit examples from cooperative MARL to provide intuition for how decoupled critics leverage state information to coordinate joint optimization, and demonstrate surp risingly strong performance across a variety of continuous control tasks.

Make-A-Video: Text-to-Video Generation without Text-Video Data

Uriel Singer,Adam Polyak,Thomas Hayes,Xi Yin,Jie An,Songyang Zhang,Qiyuan Hu,Harry Yang,Oron Ashual,Oran Gafni,Devi Parikh,Sonal Gupta,Yaniv Taigman

We propose Make-A-Video -- an approach for directly translating the tremendous recent progress in Text-to-Image (T2I) generation to Text-to-Video (T2V). Our intuition is simple: learn what the world looks like and how it is described from paired text-image data, and learn how the world moves from unsupervised video footage. Make-A-Video has three advantages: (1) it accelerates training of the T2V model (it does not need to learn visual and multimodal representations from scratch), (2) it does not require paired text-video data, and (3) the generated videos inherit the vastness (diversity in aesthetic, fantastical depictions, etc.) of today's image generation models.

We design a simple yet effective way to build on T2I models with novel and effective spatial-temporal modules. First, we decompose the full temporal U-Net and attention tensors and approximate them in space and time. Second, we design a spatial temporal pipeline to generate high resolution and frame rate videos with a video decoder, interpolation model and two super resolution models that can enable various applications besides T2V. In all aspects, spatial and temporal resolution, faithfulness to text, and quality, Make-A-Video sets the new state-of-the-art in text-to-video generation, as determined by both qualitative and quantitative measures.

****

Unsupervised Adaptation for Fairness under Covariate Shift

Jatin Chauhan,Shreyas Havaldar,Karthikeyan Shanmugam,Jay Nandy,Aravindan Raghuveer

Training fair models typically involves optimizing a composite objective accounting for both prediction accuracy and some fairness measure. However, due to a shift in the distribution of the covariates at test time, the learnt fairness tradeoffs may no longer be valid, which we verify experimentally. To address this, we consider an unsupervised adaptation problem of training fair classifiers when only a small set of unlabeled test samples is available along with a large labeled training set. We propose a novel modification to the traditional composite objective by adding a weighted entropy objective on the unlabeled test dataset. This involves a min-max optimization where weights are optimized to mimic the importance weighting ratios followed by classifier optimization. We demonstrate that our weighted entropy objective provides an upper bound on the standard importance sampled training objective common in covariate shift formulations under some mild conditions. Experimentally, we demonstrate that Wasserstein distance based penalty for representation matching across protected sub groups together with the above loss outperforms existing baselines. Our method achieves the best accuracy-equalized odds tradeoff under the covariate shift setup. We find that, for the same accuracy, we get upto 2x improvement in equalized odds on notable benchmarks.

Pushing the limits of self-supervised learning: Can we outperform supervised learning without labels?

Nenad Tomasev,Ioana Bica,Brian McWilliams,Lars Holger Buesing,Razvan Pascanu,Charles Blundell,Jovana Mitrovic

Despite recent progress made by self-supervised methods in representation learning with residual networks, they still underperform supervised learning on the ImageNet classification benchmark, limiting their applicability in performance critical settings. Building on prior theoretical insights from RELIC [Mitrovic et al., 2021], we include additional inductive biases into self-supervised learning. We propose a new self-supervised representation learning method, RELICv2,which combines an explicit invariance loss with a contrastive objective over avaried set of appropriately constructed data views to avoid learning spurious cor-relations and obtain more informative representations. RELICv2 achieves 77.1% top-1 classification accuracy on ImageNet using linear evalu ation with a ResNet50 architecture and 80.6% with larger ResNet models, outperforming previous state-of-the-art self-supervised approaches by a wide margin. Most notably, RELICv2 is the first unsupervised representation learning method to consistently outperform the supervised baseline in a like-for-like comparison over a range of ResNet architectures. Finally, we show that despite using ResNet encoders, RELICv2 is comparable to state-of-the-art self-supervised vision transformers.

****

Personalized Reward Learning with Interaction-Grounded Learning (IGL)

Jessica Maghakian,Paul Mineiro,Kishan Panaganti,Mark Rucker,Akanksha Saran,Cheng Tan

In an era of countless content offerings, recommender systems alleviate information overload by providing users with personalized content suggestions. Due to the scarcity of explicit user feedback, modern recommender systems typically optimize for the same fixed combination of implicit feedback signals across all users. However, this approach disregards a growing body of work highlighting that (i) implicit signals can be used by users in diverse ways, signaling anything from satisfaction to active dislike, and (ii) different users communicate preferences in different ways. We propose applying the recent Interaction Grounded Learning (IGL) paradigm to address the challenge of learning representations of diverse user communication modalities. Rather than requiring a fixed, human-designed reward function, IGL is able to learn personalized reward functions for different users and then optimize directly for the latent user satisfaction. We demonstrate the success of IGL with experiments using simulations as well as with real-world production traces.

****

From Adaptive Query Release to Machine Unlearning

Enayat Ullah,Raman Arora

We formalize the problem of machine unlearning as design of efficient unlearning algorithms corresponding to learning algorithms which perform a selection of adaptive queries from structured query classes. We give efficient unlearning algorithms for linear and prefix-sum query classes. As applications, we show that unlearning in many problems, in particular, stochastic convex optimization (SCO), can be reduced to the above, yielding improved guarantees for the problem. In particular, for smooth Lipschitz losses and any $\rho>0$, our results yield an unlearning algorithm with excess population risk of $\tilde O\big(\frac{1}{\sqrt{n}}+\frac{\sqrt{d}}{n\rho}\big)$ with unlearning query (gradient) complexity $\tilde O(\rho \cdot \text{Retraining Complexity})$, where d is the model dimensionality and n is the initial number of samples. For non-smooth Lipschitz losses, we give an unlearning algorithm with excess population risk $\tilde O\big(\frac{1}{\sqrt{n}}+\big(\frac{\sqrt{d}}{n\rho}\big)^{1/2}\big)$ with the same unlearning query (gradient) complexity. Furthermore, in the special case of Generalized Linear Models (GLMs), such as those in linear and logistic regression, we get dimension-independent rates of $\tilde O\big(\frac{1}{\sqrt{n}} +\frac{1}{(n\rho)^{2/3}}\big)$ and $\tilde O\big(\frac{1}{\sqrt{n}} +\frac{1}{(n\rho)^{1/3}}\big)$ for smooth Lipschitz and non-smooth Lipschitz losses respectively. Finally, we give generalizations of the above from one unlearning request to dynamic streams consisting of insertions and deletions.

ReAct: Synergizing Reasoning and Acting in Language Models

Shunyu Yao,Jeffrey Zhao,Dian Yu,Nan Du,Izhak Shafran,Karthik R Narasimhan,Yuan Cao

While large language models (LLMs) have demonstrated impressive capabilities across tasks in language understanding and interactive decision making, their abilities for reasoning (e.g. chain-of-thought prompting) and acting (e.g. action plan generation) have primarily been studied as separate topics. In this paper, we explore the use of LLMs to generate both reasoning traces and task-specific actions in an interleaved manner, allowing for greater synergy between the two: reasoning traces help the model induce, track, and update action plans as well as ha ndle exceptions, while actions allow it to interface with external sources, such as knowledge bases or environments, to gather additional information. We apply our approach, named ReAct, to a diverse set of language and decision making tasks and demonstrate its effectiveness over state-of-the-art baselines, as well as improved human interpretability and trustworthiness over methods without reasoning or acting components. Concretely, on question answering (HotpotQA) and fact verification (Fever), ReAct overcomes issues of hallucination and error propagation prevalent in chain-of-thought reasoning by interacting with a simple Wikipedia API, and generates human-like task-solving trajectories that are more interpretable than baselines without reasoning traces. On two interactive decision making benchmarks (ALFWorld and WebShop), ReAct outperforms imitation and reinforcement learning methods by an absolute success rate of 34% and 10% respectively, while being prompted with only one or two in-context examples.

Towards convergence to Nash equilibria in two-team zero-sum games
Fivos Kalogiannis,Ioannis Panageas,Emmanouil-Vasileios Vlatakis-Gkaragkounis

Contemporary applications of machine learning raise important and overlooked theoretical questions regarding optimization in two-team games. Formally, two-team zero-sum games are defined as multi-player games where players are split into two competing sets of agents, each experiencing a utility identical to that of their teammates and opposite to that of the opposing team. We focus on the solution concept of Nash equilibria and prove $\textrm{CLS}$-hardness of computing them in this class of games. To further examine the capabilities of online learning algorithms in games with full-information feedback, we propose a benchmark of a simple ---yet nontrivial--- family of such games. These games do not enjoy the properties used to prove convergence for relevant algorithms. In particular, we use a dynamical systems perspective to demonstrate that gradient descent-ascent, its optimistic variant, optimistic multiplicative weights update, and extra gradient fail to converge (even locally) to a Nash equilibrium. On a brighter note, we propose a first-order method that leverages control theory techniques and under some conditions enjoys last-iterate local convergence to a Nash equilibrium. We also believe our proposed method is of independent interest for general min-max optimization.

Ensemble Homomorphic Encrypted Data Classification
Dana R Alsagheer,Hadi Mansouifar,lei Xu,Qian Lou,Weidong Shi,lin chen

Homomorphic encryption (HE) is encryption that permits users to perform computations on encrypted data without first decrypting it. HE can be used for privacy-preserving outsourced computation and analysis, allowing data to be encrypted and outsourced to commercial cloud environments for processing while encrypted or sensitive data. HE enables new services by removing privacy barriers inhibiting data sharing or increasing the security of existing services. A convolution neural network (CNN) with shallow architecture can be homomorphically evaluated using addition and multiplication by replacing the activation function, such as ReLU, with a low polynomial degree. To achieve the same performance as the ReLU activation function, we study the impact of applying the ensemble techniques to solve the accuracy problem. Our experimental results empirically show that the ensemble approach can reduce bias, and variance, increasing accuracy to achieve the same ReLU performance with parallel and sequential techniques. We demonstrate the effectiveness and robustness of our method using three data sets: MNIST, FMNIST, and CIFAR-10

Generative Pretraining for Black-Box Optimization
Siddarth Krishnamoorthy,Satvik Mehul Mashkaria,Aditya Grover

Many problems in science and engineering involve optimizing an expensive black-box function over a high-dimensional space. For such black-box optimization (BBO) problems, we typically assume a small budget for online function evaluations, but also often have access to a fixed, offline dataset for pretraining. Prior approaches seek to utilize the offline data to approximate the function or its inverse but are not sufficiently accurate far from the data distribution. We propose

BONET, a generative framework for pretraining a novel black-box optimizer using offline datasets. In BONET, we train an autoregressive model on fixed-length trajectories corresponding to runs of implicit black-box function optimizers. We design a sampling strategy to synthesize trajectories from offline data using a simple heuristic of rolling out monotonic transitions from low-fidelity to high-fidelity samples. Empirically, we instantiate BONET using a causally masked Transformer and evaluate it on Design-Bench, where we rank the best on average, outperforming state-of-the-art baselines.

Discovering Evolution Strategies via Meta-Black-Box Optimization
Robert Tjarko Lange,Tom Schaul,Yutian Chen,Tom Zahavy,Valentin Dalibard,Chris Lu,Satinder Singh,Sebastian Flennerhag
Optimizing functions without access to gradients is the remit of black-box methods such as evolution strategies. While highly general, their learning dynamics are often times heuristic and inflexible — exactly the limitations that meta-learning can address. Hence, we propose to discover effective update rules for evolution strategies via meta-learning. Concretely, our approach employs a search strategy parametrized by a self-attention-based architecture, which guarantees the update rule is invariant to the ordering of the candidate solutions. We show that meta-evolving this system on a small set of representative low-dimensional analytic optimization problems is sufficient to discover new evolution strategies capable of generalizing to unseen optimization problems, population sizes and optimization horizons. Furthermore, the same learned evolution strategy can outperform established neuroevolution baselines on supervised and continuous control tasks. As additional contributions, we ablate the individual neural network components of our method; reverse engineer the learned strategy into an explicit heuristic form, which remains highly competitive; and show that it is possible to self-referentially train an evolution strategy from scratch, with the learned update rule used to drive the outer meta-learning loop.

The Use of Open-Source Boards for Data Collection and Machine Learning in Remote Deployments
Gabriel Kiarie,Jason Kabi,Lorna Mugambi,Ciira wa Maina
Machine learning is being adopted in many walks of life to solve various problems. This is being driven by development of robust machine learning algorithms, availability of large datasets and low cost computation resources. Some machine learning applications require deployment of devices off-the-grid for data collection and real time monitoring. Such applications require development of systems that can operate autonomously during their deployment. Advancement in technology has seen development of low-cost and low-power open-source microcontrollers and single board computers. These boards can be interfaced with a wide array of sensors and can perform computation processes. The boards are finding wide applications in data collection and machine learning initiatives. This paper will describe how the boards are leveraged for off-grid deployments.

Rhino: Deep Causal Temporal Relationship Learning with History-dependent Noise
Wenbo Gong,Joel Jennings,Cheng Zhang,Nick Pawlowski
Discovering causal relationships between different variables from time series data has been a long-standing challenge for many domains. For example, in stock markets, the announcement of acquisitions from leading companies may have immediate effects on stock prices and increase the uncertainty of the future market due to this past action. To discover causal relations in such case, the model needs to consider non-linear relations between variables, instantaneous effect and the change of noise distribution due to past actions. We name the latter as history-dependent noise. However, previous works do not offer a solution addressing all these problems together. In this paper, we propose a structural equation model, called Rhino, which combines vector auto-regression, deep learning and variational inference to model non-linear relationships with instantaneous effects while allowing the noise distribution to be modulated by history observations. Theoretically, we prove the structural identifiability of Rhino. Our empirical results

from extensive synthetic experiments and two real-world benchmarks demonstrate better discovery performance compared to relevant baselines, with ablation studies revealing its robustness under model misspecification.

DensePure: Understanding Diffusion Models for Adversarial Robustness

Chaowei Xiao,Zhongzhu Chen,Kun Jin,Jiongxiao Wang,Weili Nie,Mingyan Liu,Anima Anandkumar,Bo Li,Dawn Song

Diffusion models have been recently employed to improve certified robustness through the process of denoising. However, the theoretical understanding of why diffusion models are able to improve the certified robustness is still lacking, preventing from further improvement. In this study, we close this gap by analyzing the fundamental properties of diffusion models and establishing the conditions under which they can enhance certified robustness. This deeper understanding allows us to propose a new method DensePure, designed to improve the certified robustness of a pretrained model (i.e. classifier). Given an (adversarial) input, DensePure consists of multiple runs of denoising via the reverse process of the diffusion model (with different random seeds) to get multiple reversed samples, which are then passed through the classifier, followed by majority voting of inferred labels to make the final prediction. This design of using multiple runs of denoising is informed by our theoretical analysis of the conditional distribution of the reversed sample. Specifically, when the data density of a clean sample is high, its conditional density under the reverse process in a diffusion model is also high; thus sampling from the latter conditional distribution can purify the adversarial example and return the corresponding clean sample with a high probability. By using the highest density point in the conditional distribution as the reversed sample, we identify the robust region of a given instance under the diffusion model's reverse process. We show that this robust region is a union of multiple convex sets, and is potentially much larger than the robust regions identified in previous works. In practice, DensePure can approximate the label of the high density region in the conditional distribution so that it can enhance certified robustness. We conduct extensive experiments to demonstrate the effectiveness of DensePure by evaluating its certified robustness given a standard model via randomized smoothing. We show that DensePure is consistently better than existing methods on ImageNet, with 7% improvement on average.

Towards Understanding How Machines Can Learn Causal Overhypotheses

Eliza Kosoy,David Chan,Adrian Liu,Jasmine Collins,Bryanna Kaufmann,Sandy Huang,Jessica B Hamrick,John Canny,Nan Rosemary Ke,Alison Gopnik

Recent work in machine learning and cognitive science has suggested that understanding causal information is essential to the development of intelligence. One of the key challenges for current machine learning algorithms is modeling and understanding causal overhypotheses: transferable abstract hypotheses about sets of causal relationships. In contrast, even young children spontaneously learn causal overhypotheses, and use these to guide their exploration or to generalize to new situations. This has been demonstrated in a variety of cognitive science experiments using the “blicket detector” environment. We present a causal learning benchmark adapting the “blicket" environment for machine learning agents and evaluate a range of state-of-the-art methods in this environment. We find that although most agents have no problem learning causal structures seen during training, they are unable to learn causal overhypotheses from these experiences, and thus cannot generalize to new settings.

Grounding Graph Network Simulators using Physical Sensor Observations

Jonas Linkerhägner,Niklas Freymuth,Paul Maria Scheikl,Franziska Mathis-Ullrich,Gerhard Neumann

Physical simulations that accurately model reality are crucial for many engineering disciplines such as mechanical engineering and robotic motion planning. In recent years, learned Graph Network Simulators produced accurate mesh-based simulations while requiring only a fraction of the computational cost of traditional simulators. Yet, the resulting predictors are confined to learning from data gen erated by existing mesh-based simulators and thus cannot include real world sensory information such as point cloud data. As these predictors have to simulate complex physical systems from only an initial state, they exhibit a high error accumulation for long-term predictions. In this work, we integrate sensory information to ground Graph Network Simulators on real world observations. In particular, we predict the mesh state of deformable objects by utilizing point cloud data. The resulting model allows for accurate predictions over longer time horizons, even under uncertainties in the simulation, such as unknown material properties. Since point clouds are usually not available for every time step, especially in online settings, we employ an imputation-based model. The model can make use of such additional information only when provided, and resorts to a standard Graph Network Simulator, otherwise. We experimentally validate our approach on a suite of prediction tasks for mesh-based interactions between soft and rigid bodies. Our method results in utilization of additional point cloud information to accurately predict stable simulations where existing Graph Network Simulators fail.

Skill Decision Transformer

Shyam Sudhakaran,Sebastian Risi

Recent work has shown that Large Language Models (LLMs) can be incredibly effective for offline reinforcement learning (RL) by representing the traditional RL problem as a sequence modelling problem. However many of these methods only optimize for high returns, and may not extract much information from a diverse dataset of trajectories. Generalized Decision Transformers (GDTs) have shown that by utilizing future trajectory information, in the form of information statistics, can help extract more information from offline trajectory data. Building upon this, we propose Skill Decision Transformer (Skill DT). Skill DT draws inspiration from hindsight relabelling and skill discovery methods to discover a diverse set of \emph{primitive behaviors}, or skills. We show that Skill DT can not only perform offline state-marginal matching (SMM), but can discovery descriptive behaviors that can be easily sampled. Furthermore, we show that through purely reward-free optimization, Skill DT is still competitive with supervised offline RL approaches on the D4RL benchmark.

In-distribution and Out-of-distribution Generalization for Graph Neural Networks

Emmanuel Sales,Renjie Liao,Nick Harvey

Graph neural networks (GNNs) are models that allow learning with structured data of varying size. Despite their popularity, theoretical understanding of the generalization of GNNs is an under-explored topic. In this work, we expand the theoretical understanding of both in-distribution and out-of-distribution generalization of GNNs. Firstly, we improve upon the state-of-the-art PAC-Bayes (in-distribution) generalization bound primarily by reducing an exponential dependency on the node degree to a linear dependency. Secondly, utilizing tools from spectral graph theory, we prove some rigorous guarantees about the out-of-distribution (OOD) size generalization of GNNs, where graphs in the training set have different numbers of nodes and edges from those in the test set. To empirically verify our theoretical findings, we conduct experiments on both synthetic and real-world graph datasets. Our computed generalization gaps for the in-distribution case significantly improve the state-of-the-art PAC-Bayes results. For the OOD case, experiments on community classification tasks in large social networks show that GNNs achieve strong size generalization performance in cases guaranteed by our theory.

Where to Diffuse, How to Diffuse, and How to Get Back: Automated Learning for Multivariate Diffusions

Raghav Singhal,Mark Goldstein,Rajesh Ranganath

Diffusion-based generative models (DBGMs) perturb data to a target noise distribution and reverse this process to generate samples. The choice of noising process, or inference diffusion process, affects both likelihoods and sample quality. For example, extending the inference process with auxiliary variables leads to improved sample quality. While there are many such multivariate diffusions to ex plore, each new one requires significant model-specific analysis, hindering rapid prototyping and evaluation. In this work, we study Multivariate Diffusion Models (MDMs). For any number of auxiliary variables, we provide a recipe for maximizing a lower-bound on the MDMs likelihood without requiring any model-specific analysis. We then demonstrate how to parameterize the diffusion for a specified target noise distribution; these two points together enable optimizing the inference diffusion process. Optimizing the diffusion expands easy experimentation from just a few well-known processes to an automatic search over all linear diffusions. To demonstrate these ideas, we introduce two new specific diffusions as well as learn a diffusion process on the MNIST, CIFAR10, and ImageNet32 datasets. We show learned MDMs match or surpass bits-per-dims (BPDs) relative to fixed choices of diffusions for a given dataset and model architecture.

Contrastive Corpus Attribution for Explaining Representations

Chris Lin,Hugh Chen,Chanwoo Kim,Su-In Lee

Despite the widespread use of unsupervised models, very few methods are designed to explain them. Most explanation methods explain a scalar model output. However, unsupervised models output representation vectors, the elements of which are not good candidates to explain because they lack semantic meaning. To bridge this gap, recent works defined a scalar explanation output: a dot product-based similarity in the representation space to the sample being explained (i.e., an explicand). Although this enabled explanations of unsupervised models, the interpretation of this approach can still be opaque because similarity to the explicand's representation may not be meaningful to humans. To address this, we propose contrastive corpus similarity, a novel and semantically meaningful scalar explanation output based on a reference corpus and a contrasting foil set of samples. We demonstrate that contrastive corpus similarity is compatible with many post-hoc feature attribution methods to generate COntrastive COrpus Attributions (COCOA) and quantitatively verify that features important to the corpus are identified. We showcase the utility of COCOA in two ways: (i) we draw insights by explaining augmentations of the same image in a contrastive learning setting (SimCLR); and (ii) we perform zero-shot object localization by explaining the similarity of image representations to jointly learned text representations (CLIP).

The ethical ambiguity of AI data enrichment: Measuring gaps in research ethics norms and practices

Will Hawkins,Brent Mittelstadt

The technical progression of artificial intelligence (AI) research has been built on breakthroughs in fields such as computer science, statistics, and mathematics. However, in the past decade AI researchers have increasingly looked to the social sciences, turning to human interactions to solve the challenges of model development. Paying crowdsourcing workers to generate or curate data, or ‘data enrichment’, has become indispensable for many areas of AI research, from natural language processing to inverse reinforcement learning. Other fields that routinely interact with crowdsourcing workers, such as Psychology, have developed common governance requirements and norms to ensure research is undertaken ethically. This study explores how, and to what extent, comparable research ethics requirements and norms have developed for AI research and data enrichment. We focus on the approach taken by two leading AI conferences: ICLR and NeurIPS. In a longitudinal study of accepted papers, and a comparison with Springer journal articles and Psychology papers, this work finds that ICLR and NeurIPS have established protocols for human data collection which are inconsistently followed by authors. Whilst Psychology papers engaging with crowdsourcing workers frequently disclose ethics reviews, payment data, demographic data and other information, such disclosures are far less common in leading AI conferences despite similar guidance. The work concludes with hypotheses to explain these gaps in research ethics practices and considerations for its implications.

****

Spatio-temporal point processes with deep non-stationary kernels

Zheng Dong,Xiuyuan Cheng,Yao Xie

Point process data are becoming ubiquitous in modern applications, such as social networks, health care, and finance. Despite the powerful expressiveness of the popular recurrent neural network (RNN) models for point process data, they may not successfully capture sophisticated non-stationary dependencies in the data due to their recurrent structures. Another popular type of deep model for point process data is based on representing the influence kernel (rather than the intensity function) by neural networks. We take the latter approach and develop a new deep non-stationary influence kernel that can model non-stationary spatio-temporal point processes. The main idea is to approximate the influence kernel with a novel and general low-rank decomposition, enabling efficient representation through deep neural networks and computational efficiency and better performance. We also take a new approach to maintain the non-negativity constraint of the conditional intensity by introducing a log-barrier penalty. We demonstrate our proposed method's good performance and computational efficiency compared with the state-of-the-art on simulated and real data.

****

Federated Learning from Small Datasets

Michael Kamp,Jonas Fischer,Jilles Vreeken

Federated learning allows multiple parties to collaboratively train a joint model without having to share any local data. It enables applications of machine learning in settings where data is inherently distributed and undisclosable, such as in the medical domain. Joint training is usually achieved by aggregating local models. When local datasets are small, locally trained models can vary greatly from a globally good model. Bad local models can arbitrarily deteriorate the aggregate model quality, causing federating learning to fail in these settings. We propose a novel approach that avoids this problem by interleaving model aggregation and permutation steps. During a permutation step we redistribute local models across clients through the server, while preserving data privacy, to allow each local model to train on a daisy chain of local datasets. This enables successful training in data-sparse domains. Combined with model aggregation, this approach enables effective learning even if the local datasets are extremely small, while retaining the privacy benefits of federated learning.

Explainable Machine Learning Predictions for the Long-term Performance of Brain-Computer Interfaces

Morgan E Urdaneta,Nicole C Veit,Renae G Burke,Ian G Malone,Kaleb E Smith,Kevin J Otto

Brain computer interfaces (BCIs) can decode neural signals to control assistive technologies such as robotic limbs for people with paralysis. Neural recordings from intracortical microelectrodes offer the spatiotemporal resolution (e.g., sortable units) necessary for complex tasks, such as controlling a robotic arm with multiple degrees of freedom. However, the quality of these signals decays over time despite many attempts to prolong their longevity. This decrease in long-term performance limits the implementation of this potentially beneficial technology. Predicting whether a channel will have sortable units across time would mitigate this issue and increase the utility of these devices by reducing uncertainty, yet to-date, no such methods exist. Similarly, it would be useful to understand how variables like time post-implantation, electrochemical characteristics, and electrode design impact the long-term quality of these signals. Here, we obtained longitudinal neural recordings and electrochemical data from freely behaving rats implanted with a custom designed microelectrode array with varying site areas, shank positions, and site depths. This dataset was used to develop an explainable artificial intelligence pipeline that predicts with high accuracy the presence of sortable units on a given channel and elucidates the most important factors leading to these predictions. Our pipeline was able to predict whether a channel will be active with an AUC of 0.79 (95% C.I. 0.73–0.86) on unseen data. The most important features of the model were experimental subject, time post-implantation, and a channel’s previous spike metrics. Electrode site depth was the most important electrode design variable. Our results demonstrate the feasibility of implementing explainable artificial intelligence pipelines for longitudinal

BCI studies and support previous reports on how factors like time, inter-animal variability, and cortical depth impact long-term performance of BCIs. These results are an important step forward in improving efficient decoding performance and guiding device development, which stand to advance the field and benefit the lives of human BCI patients.

Effectively using public data in privacy preserving Machine learning

Milad Nasr,Saeed Mahloujifar,Xinyu Tang,Prateek Mittal,Amir Houmansadr

A key challenge towards differentially private machine learning is balancing the trade-off between privacy and utility.

A recent line of work has demonstrated that leveraging \emph{public data samples} can enhance the utility of DP-trained models (for the same privacy guarantees).

In this work, we show that public data can be used to improve utility in DP models significantly more than shown in recent works.

Towards this end, we introduce a modified DP-SGD algorithm that leverages public data during its training process.

Our technique uses public data in two complementary ways: (1) it uses generative models trained on public data to produce synthetic data that is effectively embedded in multiple steps of the training pipeline; (2) it uses a new gradient clipping mechanism (required for achieving differential privacy) which changes the \emph{origin} of gradient vectors using information inferred from available public and synthesized data.

Our experimental results demonstrate the effectiveness of our approach in improving the state-of-the-art in differentially private machine learning across multiple datasets, network architectures, and application domains.

Notably, we achieve a 75% accuracy on CIFAR10 when using only $2,000$ public images; this is \emph{significantly higher} than the state-of-the-art which is 68% for DP-SGD with the privacy budget of $\varepsilon=2,\delta=10^{-5}$ (given the same number of public data points).

****

Semantic Uncertainty: Linguistic Invariances for Uncertainty Estimation in Natural Language Generation

Lorenz Kuhn,Yarin Gal,Sebastian Farquhar

We introduce a method to measure uncertainty in large language models. For tasks like question answering, it is essential to know when we can trust the natural language outputs of foundation models. We show that measuring uncertainty in natural language is challenging because of "semantic equivalence"—different sentences can mean the same thing. To overcome these challenges we introduce semantic entropy—an entropy which incorporates linguistic invariances created by shared meanings. Our method is unsupervised, uses only a single model, and requires no modifications to off-the-shelf language models. In comprehensive ablation studies we show that the semantic entropy is more predictive of model accuracy on question answering data sets than comparable baselines.

****

Illusory Adversarial Attacks on Sequential Decision-Makers and Countermeasures

Tim Franzmeyer,Stephen Marcus McAleer,Joao F. Henriques,Philip Torr,Jakob Nicolaus Foerster,Adel Bibi,Christian Schroeder de Witt

Autonomous decision-making agents deployed in the real world need to be robust against possible adversarial attacks on sensory inputs. Existing work on adversarial attacks focuses on the notion of perceptual invariance popular in computer vision. We observe that such attacks can often be detected by victim agents, since they result in action-observation sequences that are not consistent with the dynamics of the environment. Furthermore, real-world agents, such as physical robots, commonly operate under human supervisors who are not susceptible to such attacks. We propose to instead focus on attacks that are statistically undetectable. Specifically, we propose illusory attacks, a novel class of adversarial attack that is consistent with the environment dynamics. We introduce a novel algorithm that can learn illusory attacks end-to-end. We empirically verify that our algorithm generates attacks that, in contrast to current methods, are undetectable

to both AI agents with an environment dynamics model, as well as to humans. Furthermore, we show that existing robustification approaches are relatively ineffective against illusory attacks. Our findings highlight the need to ensure that real-world AI, and human-AI, systems are designed to make it difficult to corrupt sensory observations in ways that are consistent with the environment dynamics.

Prompt Tuning with Prompt-aligned Gradient for Vision-Language Models
Beier Zhu,Yulei Niu,Yucheng Han,Yue Wu,Hanwang Zhang

Thanks to the large pre-trained vision-language models (VLMs) like CLIP, we can craft a zero-shot classifier by ``prompt'', e.g., using the model provided similarity measure between an image and the prompt sentence ``$\texttt{a photo of a [CLASS]}$'', as the confidence score of predicting the image is ``$\texttt{[CLASS]}$''. Therefore, prompt shows a great potential for fast adapting the VLMs to downstream tasks if we fine-tune the prompt-based similarity measure. However, we find a common failure that improper fine-tuning may not only undermine the prompt's inherent prediction for the task-related classes, but also for other classes in the VLM vocabulary. Existing methods still address this problem by using traditional anti-overfitting techniques such as early stopping and data augmentation, which lack a principled solution specific to prompt. We present Prompt-aligned Gradient, dubbed $\texttt{ProGrad}$, to prevent prompt tuning from forgetting the the general knowledge learned from VLMs. In particular, $\texttt{ProGrad}$ only updates the prompt whose gradient is aligned (or non-conflicting) to the ``general direction'', which is represented as the gradient of the KL loss of the pre-defined prompt prediction. Extensive experiments demonstrate the stronger few-shot generalization ability of $\texttt{ProGrad}$ over state-of-the-art prompt tuning methods. Codes are in Appendix.
****

Relative Behavioral Attributes: Filling the Gap between Symbolic Goal Specification and Reward Learning from Human Preferences
Lin Guan,Karthik Valmeekam,Subbarao Kambhampati

Generating complex behaviors that satisfy the preferences of non-expert users is a crucial requirement for AI agents. Interactive reward learning from trajectory comparisons (a.k.a. RLHF) is one way to allow non-expert users to convey complex objectives by expressing preferences over short clips of agent behaviors. Even though this parametric method can encode complex tacit knowledge present in the underlying tasks, it implicitly assumes that the human is unable to provide richer feedback than binary preference labels, leading to intolerably high feedback complexity and poor user experience. While providing a detailed symbolic closed-form specification of the objectives might be tempting, it is not always feasible even for an expert user. However, in most cases, humans are aware of how the agent should change its behavior along meaningful axes to fulfill their underlying purpose, even if they are not able to fully specify task objectives symbolically. Using this as motivation, we introduce the notion of Relative Behavioral Attributes, which allows the users to tweak the agent behavior through symbolic concepts (e.g., increasing the softness or speed of agents' movement). We propose two practical methods that can learn to model any kind of behavioral attributes from ordered behavior clips. We demonstrate the effectiveness of our methods on four tasks with nine different behavioral attributes, showing that once the attributes are learned, end users can produce desirable agent behaviors relatively effortlessly, by providing feedback just around ten times. This is over an order of magnitude less than that required by the popular learning-from-human-preferences baselines. The supplementary video and source code are available at: https://guansuns.github.io/pages/rba.

DINO as a von Mises-Fisher mixture model
Hariprasath Govindarajan,Per Sidén,Jacob Roll,Fredrik Lindsten

Self-distillation methods using Siamese networks are popular for self-supervised pre-training. DINO is one such method based on a cross-entropy loss between K-dimensional probability vectors, obtained by applying a softmax function to the dot product between representations and learnt prototypes. Given the fact that the learned representations are L^2-normalized, we show that DINO and its derivatives, such as iBOT, can be interpreted as a mixture model of von Mises-Fisher components. With this interpretation, DINO assumes equal precision for all components when the prototypes are also L^2-normalized. Using this insight we propose DINO-vMF, that adds appropriate normalization constants when computing the cluster assignment probabilities. Unlike DINO, DINO-vMF is stable also for the larger ViT-Base model with unnormalized prototypes. We show that the added flexibility of the mixture model is beneficial in terms of better image representations. The DINO-vMF pre-trained model consistently performs better than DINO on a range of downstream tasks. We obtain similar improvements for iBOT-vMF vs iBOT and thereby show the relevance of our proposed modification also for other methods derived from DINO.

Continuous Depth Recurrent Neural Differential Equations

Srinivas Anumasa,Geetakrishnasai Gunapati,P. K. Srijith

Recurrent neural networks (RNNs) have brought a lot of advancements in sequence labeling tasks and sequence data. However, their effectiveness is limited when the observations in the sequence are irregularly sampled, where the observations arrive at irregular time intervals. To address this, continuous time variants of the RNNs were introduced based on neural ordinary differential equations (NODE). They learn a better representation of the data using the continuous transformation of hidden states over time, taking into account the time interval between the observations. However, they are still limited in their capability as they use the discrete transformations and discrete number of layers (depth) over an input in the sequence to produce the output observation. We intend to address this limitation by proposing RNNs based on differential equations which model continuous transformations over depth and time to predict an output for a given input in the sequence. Specifically, we propose continuous depth recurrent neural differential equations (CDR-NDE) which generalizes RNN models by continuously evolving the hidden states in both the temporal and depth dimensions. CDR-NDE considers two separate differential equations over each of these dimensions and models the evolution in the temporal and depth directions alternatively. We also propose the CDR-NDE-heat model based on partial differential equations which treats the computation of hidden states as solving a heat equation over time. We demonstrate the effectiveness of the proposed models by comparing against the state-of-the-art RNN models on real world sequence modeling problems and datasets.

****

Optimal Membership Inference Bounds for Adaptive Composition of Sampled Gaussian Mechanisms

Saeed Mahloujifar,Alexandre Sablayrolles,Graham Cormode,Somesh Jha

Given a trained model and a data sample, membership-inference (MI) attacks predict whether the sample was in the model’s training set. A common counter- measure against MI attacks is to utilize differential privacy (DP) during model training to mask the presence of individual examples. While this use of DP is a principled approach to limit the efficacy of MI attacks, there is a gap between the bounds provided by DP and the empirical performance of MI attacks. In this paper, we derive bounds for the advantage of an adversary mounting a MI attack, and demonstrate tightness for the widely-used Gaussian mechanism. Our analysis answers an open problem in the field of differential privacy, namely the fact that membership inference is not 100% successful even for relatively high budgets ($\epsilon> 10$). Finally, using our analysis, we provide MI metrics for models trained on CIFAR10 dataset. To the best of our knowledge, our analysis provides the state-of-the-art membership inference bounds.

Advantage Constrained Proximal Policy Optimization in Multi-Agent Reinforcement Learning

Weifan Li

We explore the value-based method and policy gradient combination in multi-agent reinforcement learning (MARL). In value-based MARL, {\itshape{Individual-Global-Max}} (IGM) principle plays an important role, which maintains the consistency between joint and local action values. At the same time, IGM is difficult to guarantee in multi-agent policy gradient methods due to stochastic exploration and conflicting gradient directions. In this paper, we propose a novel multi-agent policy gradient algorithm called {\itshape{Advantage Constrained Proximal Policy Optimization}} (ACPPO). Based on {\itshape{multi-agent advantage decomposition lemma}}, ACPPO introduces an advantage network for each agent to estimate current local state-action advantage. The coefficient of each agent constrains the joint-action advantage according to the consistency of the estimated joint-action advantage and local advantage. Unlike previous policy gradient-based MARL algorithms, ACPPO does not need an extra sampled baseline to reduce variance. We evaluate the proposed methods for continuous matrix game and Multi-Agent MuJoCo tasks. Results show that ACPPO outperforms the baselines such as MAPPO, MADDPG, and HAPPO.

Scalable Batch-Mode Deep Bayesian Active Learning via Equivalence Class Annealing

Renyu Zhang,Aly A Khan,Robert L. Grossman,Yuxin Chen

Active learning has demonstrated data efficiency in many fields. Existing active learning algorithms, especially in the context of batch-mode deep Bayesian active models, rely heavily on the quality of uncertainty estimations of the model, and are often challenging to scale to large batches. In this paper, we propose Batch-BALanCe, a scalable batch-mode active learning algorithm, which combines insights from decision-theoretic active learning, combinatorial information measure, and diversity sampling. At its core, Batch-BALanCe relies on a novel decision-theoretic acquisition function that facilitates differentiation among different equivalence classes. Intuitively, each equivalence class consists of hypotheses (e.g., posterior samples of deep neural networks) with similar predictions, and Batch-BALanCe adaptively adjusts the size of the equivalence classes as learning progresses. To scale up the computation of queries to large batches, we further propose an efficient batch-mode acquisition procedure, which aims to maximize a novel combinatorial information measure defined through the acquisition function. We show that our algorithm can effectively handle realistic multi-class classification tasks, and achieves compelling performance on several benchmark datasets for active learning under both low- and large-batch regimes.

Neural multi-event forecasting on spatio-temporal point processes using probabilistically enriched transformers

Negar Erfanian,Santiago Segarra,Maarten V. de Hoop

Predicting discrete events in time and space has many scientific applications, such as predicting hazardous earthquakes and outbreaks of infectious diseases. History-dependent spatio-temporal Hawkes processes are often used to mathematically model these point events. However, previous approaches have faced numerous challenges, particularly when attempting to forecast multiple future events. In this work, we propose a new neural architecture for multi-event forecasting of spatio-temporal point processes, utilizing transformers, augmented with normalizing flows and probabilistic layers. Our network makes batched predictions of complex history-dependent spatio-temporal distributions of future discrete events, achieving state-of-the-art performance on a variety of benchmark datasets including the South California Earthquakes, Citibike, Covid19, and Hawkes synthetic Pinwheel datasets. More generally, we illustrate how our network can be applied to any dataset of discrete events with associated markers, even when no underlying physics is known.

Associative Memory Augmented Asynchronous Spatiotemporal Representation Learning for Event-based Perception

Uday Kamal,Saurabh Dash,Saibal Mukhopadhyay

We propose $\textit{EventFormer}$, a computationally efficient event-based representation learning framework for asynchronously processing event camera data. Ev entFormer treats sparse input events as a spatially unordered set and models their spatial interactions using self-attention mechanism. An associative memory-augmented recurrent module is used to correlate with the stored representation computed from past events. A memory addressing mechanism is proposed to store and retrieve the latent states only $\textit{where}$ these events occur and update them only $\textit{when}$ they occur. The representation learning shift from input space to the latent memory space resulting in reduced computation cost for processing each event. We show that EventFormer achieves 0.5$\%$ and 9$\%$ better accuracy with 30000$\times$ and 200$\times$ less computation compared to the state-of-the-art dense and event-based method, respectively, on event-based object recognition datasets.

Detecting Small Query Graphs in A Large Graph via Neural Subgraph Search
Yunsheng Bai,Derek Qiang Xu,Yizhou Sun,Wei Wang

Recent advances have shown the success of using reinforcement learning and search to solve NP-hard graph-related tasks, such as Traveling Salesman Optimization, Graph Edit Distance computation, etc. However, it remains unclear how one can efficiently and accurately detect the occurrences of a small query graph in a large target graph, which is a core operation in graph database search, biomedical analysis, social group finding, etc. This task is called Subgraph Matching which essentially performs subgraph isomorphism check between a query graph and a large target graph. One promising approach to this classical problem is the “learning-to-search” paradigm, where a reinforcement learning (RL) agent is designed with a learned policy to guide a search algorithm to quickly find the solution without any solved instances for supervision. However, for the specific task of Subgraph Matching, though the query graph is usually small given by the user as input, the target graph is often orders-of-magnitude larger. It poses challenges to the neural network design and can lead to solution and reward sparsity. In this paper, we propose NSUBS with two innovations to tackle the challenges: (1) A novel encoder-decoder neural network architecture to dynamically compute the matching information between the query and the target graphs at each search state; (2) A novel look-ahead loss function for training the policy network. Experiments on six large real-world target graphs show that NSUBS can significantly improve the subgraph matching performance.

Catastrophic overfitting is a bug but it is caused by features
Guillermo Ortiz-Jimenez,Pau de Jorge,Amartya Sanyal,Adel Bibi,Puneet K. Dokania,Pascal Frossard,Grégory Rogez,Philip Torr

Adversarial training (AT) is the de facto method to build robust neural networks, but it is computationally expensive. To overcome this, fast single-step attacks can be used, but doing so is prone to catastrophic overfitting (CO). This is when networks gain non-trivial robustness during the first stages of AT, but then reach a breaking point where they become vulnerable in just a few iterations. Although some works have succeeded at preventing CO, the different mechanisms that lead to this failure mode are still poorly understood. In this work, we study the onset of CO in single-step AT methods through controlled modifications of typical datasets of natural images. In particular, we show that CO can be induced when injecting the images with seemingly innocuous features that are very useful for non-robust classification but need to be combined with other features to obtain a robust classifier. This new perspective provides important insights into the mechanisms that lead to CO and improves our understanding of the general dynamics of adversarial training.

Semi-Parametric Inducing Point Networks and Neural Processes
Richa Rastogi,Yair Schiff,Alon Hacohen,Zhaozhi Li,Ian Lee,Yuntian Deng,Mert R. Sabuncu,Volodymyr Kuleshov

We introduce semi-parametric inducing point networks (SPIN), a general-purpose architecture that can query the training set at inference time in a compute-efficient manner. Semi-parametric architectures are typically more compact than parametric models, but their computational complexity is often quadratic. In contrast

, SPIN attains linear complexity via a cross-attention mechanism between datapoints inspired by inducing point methods. Querying large training sets can be particularly useful in meta-learning, as it unlocks additional training signal, but often exceeds the scaling limits of existing models. We use SPIN as the basis of the Inducing Point Neural Process, a probabilistic model which supports large contexts in meta-learning and achieves high accuracy where existing models fail. In our experiments, SPIN reduces memory requirements, improves accuracy across a range of meta-learning tasks, and improves state-of-the-art performance on an important practical problem, genotype imputation.

CADet: Fully Self-Supervised Anomaly Detection With Contrastive Learning

Charles Guille-Escuret,Pau Rodriguez,David Vazquez,Ioannis Mitliagkas,Joao Monteiro

Handling out-of-distribution (OOD) samples has become a major stake in the real-world deployment of machine learning systems. This work explores the application of self-supervised contrastive learning to the simultaneous detection of two types of OOD samples: unseen classes and adversarial perturbations. Since in practice the distribution of such samples is not known in advance, we do not assume access to OOD examples. We show that similarity functions trained with contrastive learning can be leveraged with the maximum mean discrepancy (MMD) two-sample test to verify whether two independent sets of samples are drawn from the same distribution. Inspired by this approach, we introduce CADet (Contrastive Anomaly Detection), a method based on image augmentations to perform anomaly detection on single samples. CADet compares favorably to adversarial detection methods to detect adversarially perturbed samples on ImageNet. Simultaneously, it achieves comparable performance to unseen label detection methods on two challenging benchmarks: ImageNet-O and iNaturalist. Additionally, CADet is fully self-supervised and requires neither labels for in-distribution samples nor access to out-of-distribution examples.

SPRINT: Scalable Semantic Policy Pre-training via Language Instruction Relabeling

Jesse Zhang,Karl Pertsch,Jiahui Zhang,Taewook Nam,Sung Ju Hwang,Xiang Ren,Joseph J Lim

We propose SPRINT, an approach for scalable offline policy pre-training based on natural language instructions. SPRINT pre-trains an agent’s policy to execute a diverse set of semantically meaningful skills that it can leverage to learn new tasks faster. Prior work on offline pre-training required tedious manual definition of pre-training tasks or learned semantically meaningless skills via random goal-reaching. Instead, our approach SPRINT (Scalable Pre-training via Relabeling Language INsTructions) leverages natural language instruction labels on offline agent experience, collected at scale (e.g., via crowd-sourcing), to define a rich set of tasks with minimal human effort. Furthermore, by using natural language to define tasks, SPRINT can use pre-trained large language models to automatically expand the initial task set. By relabeling and aggregating task instructions, even across multiple training trajectories, we can learn a large set of new skills during pre-training. In experiments using a realistic household simulator, we show that agents pre-trained with SPRINT learn new long-horizon household tasks substantially faster than with previous pre-training approaches.

SMART: Self-supervised Multi-task pretrAining with contRol Transformers

Yanchao Sun,Shuang Ma,Ratnesh Madaan,Rogerio Bonatti,Furong Huang,Ashish Kapoor

Self-supervised pretraining has been extensively studied in language and vision domains, where a unified model can be easily adapted to various downstream tasks by pretraining representations without explicit labels. When it comes to sequential decision-making tasks, however, it is difficult to properly design such a pretraining approach that can cope with both high-dimensional perceptual information and the complexity of sequential control over long interaction horizons. The challenge becomes combinatorially more complex if we want to pretrain representations amenable to a large variety of tasks. To tackle this problem, in this wor k, we formulate a general pretraining-finetuning pipeline for sequential decision making, under which we propose a generic pretraining framework \textit{Self-supervised Multi-task pretrAining with contRol Transformer (SMART)}. By systematically investigating pretraining regimes, we carefully design a Control Transformer (CT) coupled with a novel control-centric pretraining objective in a self-supervised manner. SMART encourages the representation to capture the common essential information relevant to short-term control and long-term control, which is transferrable across tasks. We show by extensive experiments in DeepMind Control Suite that SMART significantly improves the learning efficiency among seen and unseen downstream tasks and domains under different learning scenarios including Imitation Learning (IL) and Reinforcement Learning (RL). Benefiting from the proposed control-centric objective, SMART is resilient to distribution shift between pretraining and finetuning, and even works well with low-quality pretraining datasets that are randomly collected. The codebase, pretrained models and datasets are provided at https://github.com/microsoft/smart.

Evaluation of Active Feature Acquisition Methods under Missing Data

Henrik von Kleist,Alireza Zamanian,Ilya Shpitser,Narges Ahmidi

Machine learning (ML) methods generally assume the full set of features are available at no cost. If the acquisition of a certain feature is costly at run-time, one might want to balance the acquisition cost and the predictive value of the feature for the ML task. The task of training an AI agent to decide which features are necessary to be acquired is called active feature acquisition (AFA). Current AFA methods, however, are challenged when the AFA agent has to be trained/tested with datasets that contain missing data. We formulate, for the first time, the problem of active feature acquisition performance evaluation (AFAPE) under missing data, i.e. the problem of adjusting for the inevitable missingness distribution shift between train/test time and run-time. We first propose a new causal graph, the AFA graph, that characterizes the AFAPE problem as an intervention on the reinforcement learning environment used to train AFA agents. Here, we discuss that for handling missing data in AFAPE, the conventional approaches (off-policy reinforcement learning, blocked feature acquisitions, imputation and inverse probability weighting (IPW)) often lead to biased results or are data inefficient. We then propose active feature acquisition importance sampling (AFAIS), a novel estimator that is more data efficient than IPW. We demonstrate the detrimental conclusions to which biased estimators can lead as well as the high data efficiency of AFAIS in multiple experiments using simulated and real-world data under induced MCAR, MAR and MNAR missingness.

DAG Learning on the Permutahedron

Valentina Zantedeschi,Luca Franceschi,Jean Kaddour,Matt Kusner,Vlad Niculae

We propose a continuous optimization framework for discovering a latent directed acyclic graph (DAG) from observational data. Our approach optimizes over the polytope of permutation vectors, the so-called Permutahedron, to learn a topological ordering. Edges can be optimized jointly, or learned conditional on the ordering via a non-differentiable subroutine. Compared to existing continuous optimization approaches our formulation has a number of advantages including: 1. validity: optimizes over exact DAGs as opposed to other relaxations optimizing approximate DAGs; 2. modularity: accommodates any edge-optimization procedure, edge structural parameterization, and optimization loss; 3. end-to-end: either alternately iterates between node-ordering and edge-optimization, or optimizes them jointly; We demonstrate, on real-world data problems in protein-signaling and transcriptional network discovery, that our approach lies on the Pareto frontier of two key metrics, the SID and SHD.

****

Explicitly Minimizing the Blur Error of Variational Autoencoders

Gustav Bredell,Kyriakos Flouris,Krishna Chaitanya,Ertunc Erdil,Ender Konukoglu

Variational autoencoders (VAEs) are powerful generative modelling methods, however they suffer from blurry generated samples and reconstructions compared to the images they have been trained on. Significant research effort has been spent to increase the generative capabilities by creating more flexible models but often flexibility comes at the cost of higher complexity and computational cost. Several works have focused on altering the reconstruction term of the evidence lower bound (ELBO), however, often at the expense of losing the mathematical link to maximizing the likelihood of the samples under the modeled distribution. Here we propose a new formulation of the reconstruction term for the VAE that specifically penalizes the generation of blurry images while at the same time still maximizing the ELBO under the modeled distribution.

We show the potential of the proposed loss on three different data sets, where it outperforms several recently proposed reconstruction losses for VAEs.

GraphEditor: An Efficient Graph Representation Learning and Unlearning Approach

Weilin Cong,Mehrdad Mahdavi

As graph representation learning has received much attention due to its widespread applications, removing the effect of a specific node from the pre-trained graph representation learning model due to privacy concerns has become equally important.

However, due to the dependency between nodes in the graph, graph representation unlearning is notoriously challenging and still remains less well explored. To fill in this gap, we propose \textsc{GraphEditor}, an efficient graph representation \textit{learning} and \textit{unlearning} approach that supports node/edge deletion, node/edge addition, and node feature update. Compared to existing unlearning approaches, \textsc{GraphEditor} requires neither retraining from scratch nor of all data presented during unlearning, which is beneficial for the settings that not all the training data are available to retrain. Besides, since \textsc{GraphEditor} is exact unlearning, the removal of all the information associated with the deleted nodes/edges can be guaranteed. Empirical results on real-world datasets illustrate the effectiveness of \textsc{GraphEditor} for both node and edge unlearning tasks.

3D Equivariant Diffusion for Target-Aware Molecule Generation and Affinity Prediction

Jiaqi Guan,Wesley Wei Qian,Xingang Peng,Yufeng Su,Jian Peng,Jianzhu Ma

Rich data and powerful machine learning models allow us to design drugs for a specific protein target <em>in silico</em>. Recently, the inclusion of 3D structures during targeted drug design shows superior performance to other target-free models as the atomic interaction in the 3D space is explicitly modeled. However, current 3D target-aware models either rely on the voxelized atom densities or the autoregressive sampling process, which are not equivariant to rotation or easily violate geometric constraints resulting in unrealistic structures. In this work, we develop a 3D equivariant diffusion model to solve the above challenges. To achieve target-aware molecule design, our method learns a joint generative process of both continuous atom coordinates and categorical atom types with a SE(3)-equivariant network. Moreover, we show that our model can serve as an unsupervised feature extractor to estimate the binding affinity under proper parameterization, which provides an effective way for drug screening. To evaluate our model, we propose a comprehensive framework to evaluate the quality of sampled molecules from different dimensions. Empirical studies show our model could generate molecules with more realistic 3D structures and better affinities towards the protein targets, and improve binding affinity ranking and prediction without retraining.

****

PGASL: Predictive and Generative Adversarial Semi-supervised Learning for imbalanced data

Ru Huang,Yunlong Wang,Ruoxin Li,Wei Huang,Emily Zhao,Yilian Yuan

Modern machine learning techniques often suffer from class imbalance where only a small amount of data is available for minority classes. Classifiers trained on an imbalanced dataset, although have high accuracy on majority classes, can perform poorly on minority classes. This is problematic when minority classes are also important. Generative Adversarial Networks (GANs) have been proposed for gen erating artificial minority examples to balance the training. We propose a class-imbalanced semi-supervised learning algorithm PGASL which can be efficiently trained on unlabeled and class-imbalanced data. In this work, we use a predictive network which is trained adversarially for the discriminator to correct predictions on the unlabeled dataset. Experiments on text datasets show that PGASL outperforms state-of-the-art class-imbalanced learning algorithms by including both predictive network and generator.

Towards a More Rigorous Science of Blindspot Discovery in Image Models
Gregory Plumb,Nari Johnson,Angel Cabrera,Ameet Talwalkar
A growing body of work studies Blindspot Discovery Methods (BDMs): methods for finding semantically meaningful subsets of the data where an image classifier performs significantly worse, without making strong assumptions. Motivated by observed gaps in prior work, we introduce a new framework for evaluating BDMs, SpotCheck, that uses synthetic image datasets to train models with known blindspots and a new BDM, PlaneSpot, that uses a 2D image representation. We use SpotCheck to run controlled experiments that identify factors that influence BDM performance (e.g., the number of blindspot in a model) and show that PlaneSpot outperforms existing BDMs. Importantly, we validate these findings using real data. Overall, we hope that the methodology and analyses presented in this work will serve as a guide for future work on blindspot discovery.

****

How gradient estimator variance and bias impact learning in neural networks
Arna Ghosh,Yuhan Helena Liu,Guillaume Lajoie,Konrad Kording,Blake Aaron Richards
There is growing interest in understanding how real brains may approximate gradients and how gradients can be used to train neuromorphic chips. However, neither real brains nor neuromorphic chips can perfectly follow the loss gradient, so parameter updates would necessarily use gradient estimators that have some variance and/or bias. Therefore, there is a need to understand better how variance and bias in gradient estimators impact learning dependent on network and task properties. Here, we show that variance and bias can impair learning on the training data, but some degree of variance and bias in a gradient estimator can be beneficial for generalization. We find that the ideal amount of variance and bias in a gradient estimator are dependent on several properties of the network and task: the size and activity sparsity of the network, the norm of the gradient, and the curvature of the loss landscape. As such, whether considering biologically-plausible learning algorithms or algorithms for training neuromorphic chips, researchers can analyze these properties to determine whether their approximation to gradient descent will be effective for learning given their network and task properties.

****

Automatically Auditing Large Language Models via Discrete Optimization
Erik Jones,Anca Dragan,Aditi Raghunathan,Jacob Steinhardt
Auditing large language models for unexpected behaviors is critical to preempt catastrophic deployments, yet remains challenging. In this work, we cast auditing as a discrete optimization problem, where we automatically search for input-output pairs that match a desired target behavior. For example, we might aim to find non-toxic input that starts with ``Barack Obama'' and maps to a toxic output. Our optimization problem is difficult to solve as the set of feasible points is sparse, the space is discrete, and the language models we audit are non-linear and high-dimensional. To combat these challenges, we introduce a discrete optimization algorithm, ARCA, that is tailored to autoregressive language models. We demonstrate how our approach can: uncover derogatory completions about celebrities (e.g. ``Barack Obama is a legalized unborn'' $\rightarrow$ ``child murderer'), produce French inputs that complete to English outputs, and find inputs that generate a specific name. Our work offers a promising new tool to uncover models' failure-modes before deployment. $\textbf{Trigger Warning: This paper contains model behavior that can be offensive in nature.}$

Do We Really Need Complicated Model Architectures For Temporal Networks?

Weilin Cong,Si Zhang,Jian Kang,Baichuan Yuan,Hao Wu,Xin Zhou,Hanghang Tong,Mehrdad Mahdavi

Recurrent neural network (RNN) and self-attention mechanism (SAM) are the de facto methods to extract spatial-temporal information for temporal graph learning. Interestingly, we found that although both RNN and SAM could lead to a good performance, in practice neither of them is always necessary. In this paper, we propose GraphMixer, a conceptually and technically simple architecture that consists of three components: (1) a link-encoder that is only based on multi-layer perceptrons (MLP) to summarize the information from temporal links, (2) a node-encoder that is only based on neighbor mean-pooling to summarize node information, and (3) an MLP-based link classifier that performs link prediction based on the outputs of the encoders. Despite its simplicity, GraphMixer attains an outstanding performance on temporal link prediction benchmarks with faster convergence and better generalization performance. These results motivate us to rethink the importance of simpler model architecture.

On the System-Level Effectiveness of Physical Object-Hiding Adversarial Attack in Autonomous Driving

Ningfei Wang,Yunpeng Luo,TAKAMI SATO,Kaidi Xu,Qi Alfred Chen

In Autonomous Driving (AD) systems, perception is crucial for both security and safety. Among the different attacks on AD perception, the physical object-hiding adversarial attacks are especially severe due to their direct impact on road safety.

However, we find that all existing works so far only evaluate their attack effect at the targeted AI component level, without any evaluation \textit{at the system level}, i.e., with the entire system semantics and context such as the full AD system pipeline and closed-loop control. This thus inevitably raise a critical research question: can these existing research efforts actually effectively achieve the desired system-level attack effects (e.g., causing vehicle collisions, traffic rule violations, etc.) in the real-world AD system context?

In the paper, we thus perform the first measurement study on whether and how effective the existing designs can lead to system-level effects, where we take the STOP sign-hiding attack as our target. Our evaluation results show that all the representative prior works cannot achieve any system-level effect in a classical closed-loop AD setup in road speeds controlled by common STOP signs. With that, we then point out two limitation hypotheses that appear in all existing works: 1) the unpractical STOP sign size distribution in pixel sampling, and 2) missing particular consideration in system-critical attack range. Experimental results demonstrate that after overcoming these two limitations, the system-level effects can be further improved, i.e., the violation rate can increase around 70\%.

Data Feedback Loops: Model-driven Amplification of Dataset Biases

Rohan Taori,Tatsunori Hashimoto

Datasets scraped from the internet have been critical to large-scale machine learning. Yet, its success puts the utility of future internet-derived datasets at potential risk, as model outputs begin to replace human annotations as a source of supervision. In this work, we formalize a system where interactions with one model are recorded as history and scraped as training data in the future. We then analyze its stability over time by tracking changes to a test-time bias statistic (e.g. gender bias of model predictions). We find that the degree of bias amplification is closely linked to whether the model’s outputs behave like samples from the training distribution, a behavior which we characterize and define as consistent calibration. Experiments in three conditional prediction scenarios – image classification, visual role-labeling, and language generation – demonstrate that models that exhibit a sampling-like behavior are more calibrated and thus more stable. Based on this insight, we propose an intervention to help calibrate and stabilize unstable feedback systems.

****

A 2-parameter Persistence Layer for Learning

Cheng Xin,Soham Mukherjee,Shreyas N. Samaga,Tamal K. Dey

1-parameter persistent homology, a cornerstone in Topological Data Analysis (TDA), studies the evolution of topological features such as cycle basis hidden in data. It has found its application in strengthening the representation power of deep learning models like Graph Neural Networks (GNN). To enrich the representations of topological features, here we propose to study 2-parameter persistence modules induced by bi-filtration functions. In order to incorporate these representations into machine learning models, we introduce a novel vectorization on 2-parameter persistence modules called Generalized Rank Invariant Landscape {\textsc{Gril}}. We show that this vector representation is stable and differentiable with respect to underlying filtration functions and can be easily integrated into machine learning models to augment encoding topological features. We present an algorithm to compute the vectorization and its gradients. We also test our methods on synthetic graph datasets and compare the results with some popular graph neural networks.

****

Is Conditional Generative Modeling all you need for Decision Making?

Anurag Ajay,Yilun Du,Abhi Gupta,Joshua B. Tenenbaum,Tommi S. Jaakkola,Pulkit Agrawal

Recent improvements in conditional generative modeling have made it possible to generate high-quality images from language descriptions alone. We investigate whether these methods can directly address the problem of sequential decision-making. We view decision-making not through the lens of reinforcement learning (RL), but rather through conditional generative modeling. To our surprise, we find that our formulation leads to policies that can outperform existing offline RL approaches across standard benchmarks. By modeling a policy as a return-conditional generative model, we avoid the need for dynamic programming and subsequently eliminate many of the complexities that come with traditional offline RL. We further demonstrate the advantages of modeling policies as conditional generative models by considering two other conditioning variables: constraints and skills. Conditioning on a single constraint or skill during training leads to behaviors at test-time that can satisfy several constraints together or demonstrate a composition of skills. Our results illustrate that conditional generative modeling is a powerful tool for decision-making.

META-STORM: Generalized Fully-Adaptive Variance Reduced SGD for Unbounded Functions

Zijian Liu,Ta Duy Nguyen,Thien Hang Nguyen,Alina Ene,Huy Nguyen

We study the application of variance reduction (VR) techniques to general non-convex stochastic optimization problems. In this setting, the recent work STORM (Cutkosky & Orabona, 2019) overcomes the drawback of having to compute gradients of “mega-batches” that earlier VR methods rely on. There, STORM utilizes recursive momentum to achieve the VR effect and is then later made fully adaptive in STORM+ (Levy et al., 2021), where full-adaptivity removes the requirement for obtaining certain problem-specific parameters such as the smoothness of the objective and bounds on the variance and norm of the stochastic gradients in order to set the step size. However, STORM+ crucially relies on the assumption that the function values are bounded, excluding a large class of useful functions. In this work, we propose META-STORM, a generalized framework of STORM+ that removes this bounded function values assumption while still attaining the optimal convergence rate for non-convex optimization. META-STORM not only maintains full-adaptivity, removing the need to obtain problem specific parameters, but also improves the convergence rate’s dependency on the problem parameters. Furthermore, META-STORM can utilize a large range of parameter settings that subsumes previous methods allowing for more flexibility in a wider range of settings. Finally, we demonstrate the effectiveness of META-STORM through experiments across common deep learning tasks. Our algorithm improves upon the previous work STORM+ and is competitive with widely used algorithms after the addition of per-coordinate update and exponential moving average heuristics.

****

TEMPERA: Test-Time Prompt Editing via Reinforcement Learning

Tianjun Zhang,Xuezhi Wang,Denny Zhou,Dale Schuurmans,Joseph E. Gonzalez

Careful prompt design is critical to the use of large language models in zero-shot or few-shot learning. As a consequence, there is a growing interest in automated methods to design optimal prompts. In this work, we propose Test-time Prompt Editing using Reinforcement learning (TEMPERA). In contrast to prior prompt generation methods, TEMPERA can efficiently leverage prior knowledge, is adaptive to different queries and provides an interpretable prompt for every query. To achieve this, we design a novel action space that allows flexible editing of the initial prompts covering a wide set of commonly-used components like instructions, few-shot exemplars, and verbalizers. The proposed method achieves significant gains compared with recent SoTA approaches like prompt tuning, AutoPrompt, and RLPrompt, across a variety of tasks including sentiment analysis, topic classification, natural language inference, and reading comprehension. Our method achieves 5.33x on average improvement in sample efficiency when compared to the traditional fine-tuning methods.

****

Combining pretrained speech and text encoders for spoken language processing

Karan Singla,Daniel Pressel,Ryan Price,Mahnoosh Mehrabani,Yeon-Jun Kim,Srinivas Bangalore

Spoken Language Processing tasks that extract information from speech signal, have the advantage of using both speech and text modalities. In this paper, we propose to combine pretrained speech and text encoders via cross-attention, and we show the application of the proposed architecture in multiple spoken language processing systems. Our results indicate that it's more efficient to re-purpose previously trained independent modality encoders and learn only cross-attention from scratch. This resultant architecture captures both acoustic and lexical information, and performs text tagging while attending to speech encoder for improved results. We use compact pretrained speech and text encoder which are resource efficient and can be trained on a single consumer GPU card.

****

A Large Scale Sample Complexity Analysis of Neural Policies in the Low-Data Regime

Ezgi Korkmaz

The progress in reinforcement learning algorithm development is at one of its highest points starting from the initial study that enabled sequential decision making from high-dimensional observations. Currently, deep reinforcement learning research has had quite recent breakthroughs from learning without the presence of rewards to learning functioning policies without even knowing the rules of the game. In our paper we focus on the trends currently used in deep reinforcement learning algorithm development in the low-data regime. We theoretically show that the performance profiles of the algorithms developed for the high-data regime do not transfer to the low-data regime in the same order. We conduct extensive experiments in the Arcade Learning Environment and our results demonstrate that the baseline algorithms perform significantly better in the low-data regime compared to the set of algorithms that were initially designed and compared in the large-data region.

****

Evaluating Representations with Readout Model Switching

Yazhe Li,Jorg Bornschein,Marcus Hutter

Although much of the success of Deep Learning builds on learning good representations, a rigorous method to evaluate their quality is lacking. In this paper, we treat the evaluation of representations as a model selection problem and propose to use the Minimum Description Length (MDL) principle to devise an evaluation metric. Contrary to the established practice of limiting the capacity of the readout model, we design a hybrid discrete and continuous-valued model space for the readout models and employ a switching strategy to combine their predictions. The MDL score takes model complexity, as well as data efficiency into account. As a result, the most appropriate model for the specific task and representation w ill be chosen, making it a unified measure for comparison. The proposed metric can be efficiently computed with an online method and we present results for pre-trained vision encoders of various architectures (ResNet and ViT) and objective functions (supervised and self-supervised) on a range of downstream tasks. We compare our methods with accuracy-based approaches and show that the latter are inconsistent when multiple readout models are used. Finally, we discuss important properties revealed by our evaluations such as model scaling, preferred readout model, and data efficiency.

****

Provable Defense Against Geometric Transformations

Rem Yang,Jacob Laurel,Sasa Misailovic,Gagandeep Singh

Geometric image transformations that arise in the real world, such as scaling and rotation, have been shown to easily deceive deep neural networks (DNNs). Hence, training DNNs to be certifiably robust to these perturbations is critical. However, no prior work has been able to incorporate the objective of deterministic certified robustness against geometric transformations into the training procedure, as existing verifiers are exceedingly slow. To address these challenges, we propose the first provable defense for deterministic certified geometric robustness. Our framework leverages a novel GPU-optimized verifier that can certify images between 60$\times$ to 42,600$\times$ faster than existing geometric robustness verifiers, and thus unlike existing works, is fast enough for use in training. Across multiple datasets, our results show that networks trained via our framework consistently achieve state-of-the-art deterministic certified geometric robustness and clean accuracy. Furthermore, for the first time, we verify the geometric robustness of a neural network for the challenging, real-world setting of autonomous driving.

****

Augmentation with Projection: Towards an Effective and Efficient Data Augmentation Paradigm for Distillation

Ziqi Wang,Yuexin Wu,Frederick Liu,Daogao Liu,Le Hou,Hongkun Yu,Jing Li,Heng Ji

Knowledge distillation is one of the primary methods of transferring knowledge from large to small models. However, it requires massive task-specific data, which may not be plausible in many real-world applications. Data augmentation methods such as representation interpolation, token replacement, or augmentation with models are applied to tackle this problem. However, these data augmentation methods either potentially cause shifts in decision boundaries (representation interpolation), are not expressive enough (token replacement), or introduce too much computational overhead (augmentation with models). To this end, we propose AugPro (Augmentation with Projection), an effective and efficient data augmentation method for distillation. Our method builds on top of representation interpolation augmentation methods to maintain the diversity of expressions and converts the augmented data to tokens to avoid shifting decision boundaries. It uses simple operations that come with little computational overhead. The results on multiple GLUE tasks show that our methods can improve distillation performance by a large margin at a low time cost.

Pseudoinverse-Guided Diffusion Models for Inverse Problems

Jiaming Song,Arash Vahdat,Morteza Mardani,Jan Kautz

Diffusion models have become competitive candidates for solving various inverse problems. Models trained for specific inverse problems work well but are limited to their particular use cases, whereas methods that use problem-agnostic models are general but often perform worse empirically. To address this dilemma, we introduce Pseudoinverse-guided Diffusion Models (ΠGDM), an approach that uses problem-agnostic models to close the gap in performance. ΠGDM directly estimates conditional scores from the measurement model of the inverse problem without additional training. It can address inverse problems with noisy, non-linear, or even non-differentiable measurements, in contrast to many existing approaches that are limited to noiseless linear ones. We illustrate the empirical effectiveness of ΠGDM on several image restoration tasks, including super-resolution, inpainting and JPEG restoration. On ImageNet, ΠGDM is competitive with stat e-of-the-art diffusion models trained on specific tasks, and is the first to achieve this with problem-agnostic diffusion models. ΠGDM can also solve a wider set of inverse problems where the measurement processes are composed of several simpler ones.

Autoregressive Diffusion Model for Graph Generation

Lingkai Kong,Jiaming Cui,Haotian Sun,Yuchen Zhuang,B. Aditya Prakash,Chao Zhang

Diffusion-based graph generative models have recently obtained promising results for graph generation. However, existing diffusion-based graph generative models are all one-shot generative models that apply Gaussian diffusion in the dequantized adjacency matrix space. Such a strategy can suffer from difficulty in model training, slow sampling speed, and incapability of incorporating constraints. We propose an \emph{autoregressive diffusion} model for graph generation. Unlike existing methods, we define a node-absorbing diffusion process that operates directly in the discrete graph space. For forward diffusion, we design a \emph{diffusion ordering network}, which learns an optimal node absorbing ordering from graph topology. For reverse generation, we design a \emph{denoising network} that uses the reverse node ordering to efficiently reconstruct the graph by predicting one row of the adjacency matrix at a time. Based on permutation invariance of graph generation, we show that the two networks can be jointly trained by optimizing a simple lower bound of data likelihood. Our experiments on six diverse datasets show that our model achieves better or comparable generation performance with previous state-of-the-art, and meanwhile enjoys fast generation speed.

Self-supervised video pretraining yields strong image representations

Nikhil Parthasarathy,S. M. Ali Eslami,Joao Carreira,Olivier J Henaff

Videos contain far more information than still images, and hold the potential for learning rich representations of the visual world. Yet, pretraining on image datasets has remained the dominant paradigm for learning representations that capture spatial information and previous attempts at video pretraining have fallen short on image understanding tasks. In this work we revisit self-supervised learning of image representations from the dynamic evolution of video frames. To that end, we propose a dataset curation procedure that addresses the domain mismatch between video and image datasets, and develop a contrastive learning framework which handles the complex transformations present in natural videos. This simple paradigm for distilling knowledge from videos to image representations, called VITO, performs surprisingly well on a variety of image-based transfer learning tasks. For the first time, our video-pretrained model closes the gap with ImageNet pretraining on semantic segmentation on PASCAL and ADE20k and object detection on COCO and LVIS, raising the possibility of video-pretraining becoming the new default for learning image representations.

Planning with Sequence Models through Iterative Energy Minimization

Hongyi Chen,Yilun Du,Yiye Chen,Joshua B. Tenenbaum,Patricio A. Vela

Recent works have shown that language modeling can be effectively used to train reinforcement learning (RL) policies. However, the success of applying existing language models to planning, in which we wish to obtain a trajectory of actions to reach some goal, is less straightforward. The typical autoregressive generation procedures of language models preclude sequential refinement of earlier steps, which limits the effectiveness of a predicted plan. In this paper, we suggest an approach towards integrating planning with language models based on the idea of iterative energy minimization, and illustrate how such a procedure leads to improved RL performance across different tasks. We train a masked language model to capture an implicit energy function over trajectories of actions, and formulate planning as finding a trajectory of actions with minimum energy. We illustrate how this procedure enables improved performance over recent approaches across BabyAI and Atari environments. We further demonstrate unique benefits of our iterative optimization procedure, involving new task generalization, test-time constraints adaptation, and the ability to compose plans together. Verifying the Union of Manifolds Hypothesis for Image Data

Bradley CA Brown,Anthony L. Caterini,Brendan Leigh Ross,Jesse C Cresswell,Gabriel Loaiza-Ganem

Deep learning has had tremendous success at learning low-dimensional representations of high-dimensional data. This success would be impossible if there was no hidden low-dimensional structure in data of interest; this existence is posited by the manifold hypothesis, which states that the data lies on an unknown manifold of low intrinsic dimension. In this paper, we argue that this hypothesis does not properly capture the low-dimensional structure typically present in image data. Assuming that data lies on a single manifold implies intrinsic dimension is identical across the entire data space, and does not allow for subregions of this space to have a different number of factors of variation. To address this deficiency, we consider the union of manifolds hypothesis, which states that data lies on a disjoint union of manifolds of varying intrinsic dimensions. We empirically verify this hypothesis on commonly-used image datasets, finding that indeed, observed data lies on a disconnected set and that intrinsic dimension is not constant. We also provide insights into the implications of the union of manifolds hypothesis in deep learning, both supervised and unsupervised, showing that designing models with an inductive bias for this structure improves performance across classification and generative modelling tasks. Our code is available at https://github.com/layer6ai-labs/UoMH.

Last Layer Re-Training is Sufficient for Robustness to Spurious Correlations

Polina Kirichenko,Pavel Izmailov,Andrew Gordon Wilson

Neural network classifiers can largely rely on simple spurious features, such as image backgrounds, to make predictions. However, even in these cases, we show that they still often learn core features associated with the desired attributes of the data, contrary to recent findings. Inspired by this insight, we demonstrate that simple last layer retraining can match or outperform state-of-the-art approaches on spurious correlation benchmarks, but with profoundly lower complexity and computational expenses. Moreover, we show that last layer retraining on large ImageNet-trained models can also significantly reduce reliance on background and texture information, improving robustness to covariate shift, after only minutes of training on a single GPU.

Progressive Data Dropout: An Adaptive Training Strategy for Large-Scale Supervised Learning

David Lee Patrick,Zachary Seligman,Amanda S Fernandez

Common training strategies for deep neural networks are computationally expensive, continuing to redundantly train and evaluate on classes already well-understood by the model. A common strategy to diminish this cost is to reduce data used in training, however this often comes at the expense of the model's accuracy or an additional computational cost in training. We propose progressive data dropout (PDD), an adaptive training strategy which performs class-level data dropout from the training set as the network develops an understanding for each class. Our experiments on large-scale image classification demonstrate PDD reduces the total number of datapoints needed to train the network by a factor of 10, reducing the overall training time without significantly impacting accuracy or modifying the model architecture. We additionally demonstrate improvements via experiments and ablations on computer vision benchmarks, including MNIST, Fashion-MNIST, SVHN, CIFAR, and ImageNet datasets.

Error Sensitivity Modulation based Experience Replay: Mitigating Abrupt Representation Drift in Continual Learning

Fahad Sarfraz,Elahe Arani,Bahram Zonooz

Humans excel at lifelong learning, as the brain has evolved to be robust to distribution shifts and noise in our ever-changing environment. Deep neural networks (DNNs), however, exhibit catastrophic forgetting and the learned representations drift drastically as they encounter a new task. This alludes to a different er ror-based learning mechanism in the brain. Unlike DNNs, where learning scales linearly with the magnitude of the error, the sensitivity to errors in the brain decreases as a function of their magnitude. To this end, we propose "ESMER" which employs a principled mechanism to modulate error sensitivity in a dual-memory rehearsal-based system. Concretely, it maintains a memory of past errors and uses it to modify the learning dynamics so that the model learns more from small consistent errors compared to large sudden errors. We also propose "Error-Sensitive Reservoir Sampling" to maintain episodic memory, which leverages the error history to pre-select low-loss samples as candidates for the buffer, which are better suited for retaining information. Empirical results show that ESMER effectively reduces forgetting and abrupt drift in representations at the task boundary by gradually adapting to the new task while consolidating knowledge. Remarkably, it also enables the model to learn under high levels of label noise, which is ubiquitous in real-world data streams.

Auditing Fairness Online through Interactive Refinement

Pranav Maneriker,Codi Jay Burley,srinivasan parthasarathy

Machine learning algorithms are increasingly being deployed for high-stakes scenarios. A sizeable proportion of currently deployed models make their decisions in a black box manner. Such decision-making procedures are susceptible to intrinsic biases, which has led to a call for accountability in deployed decision systems. In this work, we focus on user-specified accountability of decision-making processes of black box systems. Previous work has formulated this problem as run time fairness monitoring over decision functions. However, formulating appropriate specifications for situation-appropriate fairness metrics is challenging. We construct AVOIR, an automated inference-based optimization system that improves bounds for and generalizes prior work across a wide range of fairness metrics. AVOIR offers an interactive and iterative process for exploring fairness violations aligned with governance and regulatory requirements. Our bounds improve over previous probabilistic guarantees for such fairness grammars in online settings. We also construct a novel visualization mechanism that can be used to investigate the context of reported fairness violations and guide users towards meaningful and compliant fairness specifications. We then conduct case studies with fairness metrics on three different datasets and demonstrate how the visualization and improved optimization can detect fairness violations more efficiently and ameliorate the issues with faulty fairness metric design.

REM: Routing Entropy Minimization for Capsule Networks

Riccardo Renzulli,Enzo Tartaglione,Marco Grangetto

Capsule Networks aim to build an interpretable and biologically-inspired neural network model. One of their main innovations relies on the routing mechanism which extracts a parse tree: its main purpose is to explicitly build relationships between capsules.

However, their true potential has not surfaced yet: these relationships are extremely heterogeneous and difficult to understand, as the intra-class extracted parse trees are very different from each other. A school of thoughts, giving-up on this side, propose less interpretable versions of Capsule Networks without routing.

This paper proposes REM, a technique which minimizes the entropy of the parse tree-like structure. We accomplish this by driving the model parameters distribution towards low entropy configurations, using a pruning mechanism as a proxy.

Thanks to REM, we generate a significantly lower number of parse trees, with essentially no performance loss, showing also that Capsule Networks build stronger and more stable relationships between capsules.

Don’t forget the nullspace! Nullspace occupancy as a mechanism for out of distribution failure

Daksh Idnani,Vivek Madan,Naman Goyal,David J. Schwab,Shanmukha Ramakrishna Vedantam

Out of distribution (OoD) generalization has received considerable interest in r ecent years. In this work, we identify a particular failure mode of OoD generalization for discriminative classifiers that is based on test data (from a new domain) lying in the nullspace of features learnt from source data. We demonstrate the existence of this failure mode across multiple networks trained across RotatedMNIST, PACS, TerraIncognita, DomainNet and ImageNet-R datasets. We then study different choices for characterizing the feature space and show that projecting intermediate representations onto the span of directions that obtain maximum training accuracy provides consistent improvements in OoD performance. Finally, we show that such nullspace behavior also provides an insight into neural networks trained on poisoned data. We hope our work galvanizes interest in the relationship between the nullspace occupancy failure mode and generalization.

****

Variational Classification

Shehzaad Zuzar Dhuliawala,Mrinmaya Sachan,Carl Allen

Classification tasks, ubiquitous across machine learning, are commonly tackled by a suitably designed neural network with a softmax output layer, mapping each data point to a categorical distribution over class labels.
We extend this familiar model from a latent variable perspective to variational classification (VC), analogous to how the variational auto-encoder relates to its deterministic counterpart. We derive a training objective based on the ELBO together with an \textit{adversarial} approach for optimising it.

Within this framework, we identify design choices made implicitly in off-the-shelf softmax functions and can instead include domain-specific assumptions, such as class-conditional latent priors. We demonstrate benefits of the VC model in image classification. We show on several standard datasets, that treating inputs to the softmax layer as latent variables under a mixture of Gaussians prior, improves several desirable aspects of a classifier, such as prediction accuracy, calibration, out-of-domain calibration and adversarial robustness.

ContraNorm: A Contrastive Learning Perspective on Oversmoothing and Beyond

Xiaojun Guo,Yifei Wang,Tianqi Du,Yisen Wang

Oversmoothing is a common phenomenon in a wide range of Graph Neural Networks (GNNs) and Transformers, where performance degenerates as the layer goes deeper. Instead of characterizing oversmoothing from the view of complete collapse in which representations converge to a single point, we dive into a more general perspective dimensional collapse in which representations lie in a narrow cone. Accordingly, inspired by the power of contrastive learning in preventing dimensional collapse, we propose a novel normalization layer ContraNorm. Intuitively, ContraNorm implicitly shatters representations in the embedding space, leading to a more uniform distribution and slighter dimensional collapse. On the theoretical analysis, we prove that ContraNorm can alleviate both complete collapse and dimensional collapse under some conditions. Our proposed normalization layer can be easily inserted into GNNs and Transformers with negligible parameter overhead. Experiments on various real-world datasets verify the effectiveness of our method.

Accelerated Single-Call Methods for Constrained Min-Max Optimization

Yang Cai,Weiqiang Zheng

We study first-order methods for constrained min-max optimization. Existing methods either require two gradient calls or two projections in each iteration, which may be costly in some applications. In this paper, we first show that a variant of the \emph{Optimistic Gradient (OG)} method, a \emph{single-call single-projection} algorithm, has $O(\frac{1}{\sqrt{T}})$ best-iterate convergence rate for inclusion problems with operators that satisfy the weak Minty variation inequality (MVI). Our second result is the first single-call single-projection algorithm -- the \emph{Accelerated Reflected Gradient (ARG)} method that achieves the \emph{optimal $O(\frac{1}{T})$} last-iterate convergence rate for inclusion problems that satisfy negative comonotonicity. Both the weak MVI and negative comonotonicity are well-studied assumptions and capture a rich set of non-convex non-concave min-max optimization problems. Finally, we show that the \emph{Reflected G radient (RG)} method, another \emph{single-call single-projection} algorithm, has $O(\frac{1}{\sqrt{T}})$ last-iterate convergence rate for constrained convex-concave min-max optimization, answering an open problem of [Hsieh et al., 2019]. Our convergence rates hold for standard measures such as the tangent residual and the natural residual.

Towards Interpretable Deep Reinforcement Learning with Human-Friendly Prototypes
Eoin M. Kenny,Mycal Tucker,Julie Shah
Despite recent success of deep learning models in research settings, their application in sensitive domains remains limited because of their opaque decision-making processes. Taking to this challenge, people have proposed various eXplainable AI (XAI) techniques designed to calibrate trust and understandability of black-box models, with the vast majority of work focused on supervised learning. Here, we focus on making an "interpretable-by-design" deep reinforcement learning agent which is forced to use human-friendly prototypes in its decisions, thus making its reasoning process clear. Our proposed method, dubbed Prototype-Wrapper Network (PW-Net), wraps around any neural agent backbone, and results indicate that it does not worsen performance relative to black-box models. Most importantly, we found in a user study that PW-Nets supported better trust calibration and task performance relative to standard interpretability approaches and black-boxes.

****

Distributed Extra-gradient with Optimal Complexity and Communication Guarantees
Ali Ramezani-Kebrya,Kimon Antonakopoulos,Igor Krawczuk,Justin Deschenaux,Volkan Cevher
We consider monotone variational inequality (VI) problems in multi-GPU settings where multiple processors/workers/clients have access to local stochastic dual vectors. This setting includes a broad range of important problems from distributed convex minimization to min-max and games. Extra-gradient, which is a de facto algorithm for monotone VI problems, has not been designed to be communication-efficient. To this end, we propose a quantized generalized extra-gradient (Q-GenX), which is an unbiased and adaptive compression method tailored to solve VIs. We provide an adaptive step-size rule, which adapts to the respective noise profiles at hand and achieve a fast rate of ${\cal O}(1/T)$ under relative noise, and an order-optimal ${\cal O}(1/\sqrt{T})$ under absolute noise and show distributed training accelerates convergence. Finally, we validate our theoretical results by providing real-world experiments and training generative adversarial networks on multiple GPUs.

'I pick you choose': Joint human-algorithm decision making in multi-armed bandits
Kate Donahue,Sreenivas Gollapudi,Kostas Kollias
Online learning in multi-armed bandits has been a rich area of research for decades, resulting in numerous \enquote{no-regret} algorithms that efficiently learn the arm with highest expected reward. However, in many settings the final decision of which arm to pull isn't under the control of the algorithm itself. For example, a driving app typically suggests a subset of routes (arms) to the driver, who ultimately makes the final choice about which to select. Typically, the human also wishes to learn the optimal arm based on historical reward information, but decides which arm to pull based on a potentially different objective function, such as being more or less myopic about exploiting near-term rewards. In this paper, we show when this joint human-algorithm system can achieve good performance. Specifically, we explore multiple possible frameworks for human objectives and give theoretical regret bounds for regret. Finally, we include experimental results exploring how regret varies with the human decision-maker's objective, as well as the number of arms presented.

What Matters In The Structured Pruning of Generative Language Models?
Michael Santacroce,Zixin Wen,yelong shen,Weizhu Chen,Yuanzhi Li

Auto-regressive large language models such as GPT-3 require enormous computational resources to use, leading to huge financial cost and environmental impact. Structured pruning methods traditionally reduce resource usage, however, their application to and efficacy for generative language models is heavily under-explored. We analyze the effects of magnitude, random, and movement (Lagunas et al., 2021) pruning on MLP layers in GPT-like models. We find that movement can under-perform for these models while random pruning nearly matches the best methods. By examining neuron-level redundancy measures, we discover that movement does not select neurons based on how unique they are compared to other neurons, leaving behind excess redundancy. In view of this, we introduce Globally Unique Movement (GUM) to select neurons based on both uniqueness and sensitivity. We then discuss the roles of our techniques on different redundancy metrics through careful comparisons and ablations.

MaxMin-Novelty: Maximizing Novelty via Minimizing the State-Action Values in Deep Reinforcement Learning
Ezgi Korkmaz
Reinforcement learning research has achieved high acceleration in its progress starting from the initial installation of deep neural networks as function approximators to learn policies that make sequential decisions in high-dimensional state representation MDPs. While several consecutive barriers have been broken in deep reinforcement learning research (i.e. learning from high-dimensional states, learning purely via self-play), several others still stand. On this line, the question of how to explore in high-dimensional complex MDPs is a well-understudied and ongoing open problem. To address this, in our paper we propose a unique exploration technique based on maximization of novelty via minimization of the state-action value function (MaxMin Novelty). Our method is theoretically well motivated, and comes with zero computational cost while leading to significant sample efficiency gains in deep reinforcement learning training. We conduct extensive experiments in the Arcade Learning Environment with high-dimensional state representation MDPs. We show that our technique improves the human normalized median scores of Arcade Learning Environment by 248% in the low-data regime.
****

Complete Likelihood Objective for Latent Variable Models
Mikhail Arkhipov,Maria Vikhreva
In this work, we propose an alternative to the Marginal Likelihood (MaL) objective for training latent variable models, Complete Latent Likelihood (CoLLike). We analyze the objectives from the perspective of matching joint distributions. We show that MaL corresponds to a particular KL divergence between some target \emph{joint} distribution and the model joint. Furthermore, the properties of the target joint explain such major malfunctions of MaL as uninformative latents (posterior collapse) and high deviation of the aggregated posterior from the prior. In CoLLike approach, we use a sample from the prior to construct a family of target joint distributions, which properties prevent these drawbacks. We utilize the complete likelihood both to choose the target from this family and to learn the model. We confirm our analysis by experiments with expressive low-dimensional latent variable models, which also indicate that it is possible to achieve high accuracy unsupervised classification using CoLLike objective.
****

The Surprising Effectiveness of Equivariant Models in Domains with Latent Symmetry
Dian Wang,Jung Yeon Park,Neel Sortur,Lawson L.S. Wong,Robin Walters,Robert Platt
Extensive work has demonstrated that equivariant neural networks can significantly improve sample efficiency and generalization by enforcing an inductive bias in the network architecture. These applications typically assume that the domain symmetry is fully described by explicit transformations of the model inputs and outputs. However, many real-life applications contain only latent or partial symmetries which cannot be easily described by simple transformations of the input. In these cases, it is necessary to learn symmetry in the environment instead of imposing it mathematically on the network architecture. We discover, surprising

ly, that imposing equivariance constraints that do not exactly match the domain symmetry is very helpful in learning the true symmetry in the environment. We differentiate between extrinsic and incorrect symmetry constraints and show that while imposing incorrect symmetry can impede the model's performance, imposing extrinsic symmetry can actually improve performance. We demonstrate that an equivariant model can significantly outperform non-equivariant methods on domains with latent symmetries both in supervised learning and in reinforcement learning for robotic manipulation and control problems.

Performance Bounds for Model and Policy Transfer in Hidden-parameter MDPs

Haotian Fu,Jiayu Yao,Omer Gottesman,Finale Doshi-Velez,George Konidaris

In the Hidden-Parameter MDP (HiP-MDP) framework, a family of reinforcement learning tasks is generated by varying hidden parameters specifying the dynamics and reward function for each individual task. HiP-MDP is a natural model for families of tasks in which meta- and lifelong-reinforcement learning approaches can succeed. Given a learned context encoder that infers the hidden parameters from previous experience, most existing algorithms fall into two categories: $\textit{model transfer}$ and $\textit{policy transfer}$, depending on which function the hidden parameters are used to parameterize. We characterize the robustness of model and policy transfer algorithms with respect to hidden parameter estimation error. We first show that the value function of HiP-MDPs is Lipschitz continuous under certain conditions. We then derive regret bounds for both settings through the lens of Lipschitz continuity. Finally, we empirically corroborate our theoretical analysis by experimentally varying the hyper-parameters governing the Lipschitz constants of two continuous control problems; the resulting performance is consistent with our predictions.

Parallel Q-Learning: Scaling Off-policy Reinforcement Learning

Zechu Li,Tao Chen,Zhang-Wei Hong,Anurag Ajay,Pulkit Agrawal

Reinforcement learning algorithms typically require tons of training data, resulting in long training time, especially on challenging tasks. With the recent advance in GPU-based simulation, such as Isaac Gym, data collection speed has been improved thousands of times on a commodity GPU. Most prior works have been using on-policy methods such as PPO to train policies in Isaac Gym due to its simpleness and effectiveness in scaling up. Off-policy methods are usually more sample-efficient but more challenging to be scaled up, resulting in a much longer wall-clock training time in practice. In this work, we presented a novel parallel Q-learning framework that not only gains better sample efficiency but also reduces the training wall-clock time compared to PPO. Different from prior works on distributed off-policy learning, such as Apex, our framework is designed specifically for massively parallel GPU-based simulation and optimized to work on a single workstation. We demonstrate the capability of scaling up Q learning methods to tens of thousands of parallel environments. We also investigate various factors that can affect the policy learning training speed, including the number of parallel environments, exploration schemes, batch size, GPU models, etc.

Emergence of shared sensory-motor graphical language from visual input

Yoann Lemesle,Tristan Karch,Clément Moulin-Frier,Romain Laroche,Pierre-Yves Oudeyer

The framework of Language Games studies the emergence of languages in populations of agents. Recent contributions relying on deep learning methods focused on agents communicating via an idealized communication channel, where utterances produced by a speaker are directly perceived by a listener. This comes in contrast with human communication, which instead relies on a sensory-motor channel, where motor commands produced by the speaker (e.g. vocal or gestural articulators) result in sensory effects perceived by the listener (e.g. audio or visual). Here, we investigate if agents can evolve a shared language when they are equipped with a continuous sensory-motor system to produce and perceive signs, e.g. drawings. To this end, we introduce the Graphical Referential Game (GREG) where a speaker must produce a graphical utterance to name a visual referent object consisting

of combinations of MNIST digits while a listener has to select the corresponding object among distractor referents, given the produced message. The utterances are drawing images produced using dynamical motor primitives combined with a sketching library. To tackle GREG we present CURVES: a multimodal contrastive deep learning mechanism that represents the energy (alignment) between named referents and utterances generated through gradient ascent on the learned energy landscape. We, then, present a set of experiments and metrics based on a systematic compositional dataset to evaluate the resulting language. We show that our method allows the emergence of a shared, graphical language with compositional properties

Composing Task Knowledge With Modular Successor Feature Approximators
Wilka Torrico Carvalho,Angelos Filos,Richard Lewis,Honglak Lee,Satinder Singh
Recently, the Successor Features and Generalized Policy Improvement (SF&GPI) framework has been proposed as a method for learning, composing and transferring predictive knowledge and behavior. SF&GPI works by having an agent learn predictive representations (SFs) that can be combined for transfer to new tasks with GPI. However, to be effective this approach requires state features that are useful to predict, and these state-features are typically hand-designed. In this work, we present a novel neural network architecture, “Modular Successor Feature Approximators” (MSFA), where modules both discover what is useful to predict, and learn their own predictive representations. We show that MSFA is able to better generalize compared to baseline architectures for learning SFs and a modular network that discovers factored state representations.

****

DexDeform: Dexterous Deformable Object Manipulation with Human Demonstrations and Differentiable Physics
Sizhe Li,Zhiao Huang,Tao Chen,Tao Du,Hao Su,Joshua B. Tenenbaum,Chuang Gan
In this work, we aim to learn dexterous manipulation of deformable objects using multi-fingered hands. Reinforcement learning approaches for dexterous rigid object manipulation would struggle in this setting due to the complexity of physics interaction with deformable objects. At the same time, previous trajectory optimization approaches with differentiable physics for deformable manipulation would suffer from local optima caused by the explosion of contact modes from hand-object interactions. To address these challenges, we propose DexDeform, a principled framework that abstracts dexterous manipulation skills from human demonstration, and refines the learned skills with differentiable physics. Concretely, we first collect a small set of human demonstrations using teleoperation. And we then train a skill model using demonstrations for planning over action abstractions in imagination. To explore the goal space, we further apply augmentations to the existing deformable shapes in demonstrations and use a gradient optimizer to refine the actions planned by the skill model. Finally, we adopt the refined trajectories as new demonstrations for finetuning the skill model. To evaluate the effectiveness of our approach, we introduce a suite of six challenging dexterous deformable object manipulation tasks. Compared with baselines, DexDeform is able to better explore and generalize across novel goals unseen in the initial human demonstrations. Additional materials can be found at our project website: https://sites.google.com/view/dexdeform.

NAG-GS: semi-implicit, accelerated and robust stochastic optimizer.
Valentin Leplat,Daniil Merkulov,Aleksandr Katrutsa,Daniel Bershatsky,Ivan Oseledets
Classical machine learning models such as deep neural networks are usually trained by using Stochastic Gradient Descent-based (SGD) algorithms. The classical SGD can be interpreted as a discretization of the stochastic gradient flow. In this paper we propose a novel, robust and accelerated stochastic optimizer that relies on two key elements: (1) an accelerated Nesterov-like Stochastic Differential Equation (SDE) and (2) its semi-implicit Gauss-Seidel type discretization. The convergence and stability of the obtained method, referred to as NAG-GS, are fi

rst studied extensively in the case of the minimization of a quadratic function. This analysis allows us to come up with an optimal step size (or learning rate) in terms of rate of convergence while ensuring the stability of NAG-GS. This is achieved by the careful analysis of the spectral radius of the iteration matrix and the covariance matrix at stationarity with respect to all hyperparameters of our method. We show that NAG-GS is competitive with state-of-the-art methods such as momentum SGD with weight decay and AdamW for the training of machine learning models such as the logistic regression model, the residual networks models on standard computer vision datasets, and Transformers in the frame of the GLUE benchmark.

Loop Unrolled Shallow Equilibrium Regularizer (LUSER) - A Memory-Efficient Inverse Problem Solver

Peimeng Guan,Jihui Jin,Justin Romberg,Mark A. Davenport

In inverse problems we aim to reconstruct some underlying signal of interest from potentially corrupted and often ill-posed measurements. Classical optimization-based techniques proceed by optimizing a data consistency metric together with a regularizer. Current state-of-the-art machine learning approaches draw inspiration from such techniques by unrolling the iterative updates for an optimization-based solver and then learning a regularizer from data. This \emph{loop unrolling} (LU) method has shown tremendous success, but often requires a deep model for the best performance leading to high memory costs during training. Thus, to address the balance between computation cost and network expressiveness, we propose an LU algorithm with shallow equilibrium regularizers (LUSER). These implicit models are as expressive as deeper convolutional networks, but far more memory efficient during training. The proposed method is evaluated on image deblurring, computed tomography (CT), as well as single-coil Magnetic Resonance Imaging (MRI) tasks and shows similar, or even better, performance while requiring up to $8\times$ less computational resources during training when compared against a more typical LU architecture with feedforward convolutional regularizers.

****

Robust Universal Adversarial Perturbations

Changming Xu,Gagandeep Singh

Universal Adversarial Perturbations (UAPs) are imperceptible, image-agnostic vectors that cause deep neural networks (DNNs) to misclassify inputs from a data distribution with high probability. In practical attack scenarios, adversarial perturbations may undergo transformations such as changes in pixel intensity, rotation, etc. while being added to DNN inputs. Existing methods do not create UAPs robust to these real-world transformations, thereby limiting their applicability in attack scenarios. In this work, we introduce and formulate robust UAPs. We build an iterative algorithm using probabilistic robustness bounds and transformations generated by composing arbitrary sub-differentiable transformation functions to construct such robust UAPs. We perform an extensive evaluation on the popular CIFAR-10 and ILSVRC 2012 datasets measuring our UAPs' robustness under a wide range common, real-world transformations such as rotation, contrast changes, etc. Our results show that our method can generate UAPs up to 23% more robust than existing state-of-the-art baselines.

Understanding the Complexity Gains of Contextual Multi-task RL with Curricula

Qiyang Li,Yuexiang Zhai,Yi Ma,Sergey Levine

Reinforcement learning (RL) problems can be challenging without well-shaped rewards. Prior work on provably efficient RL methods generally proposes to address this issue with dedicated exploration strategies, such as novelty-based bonuses. However, another way to tackle this challenge is to reformulate it as a multi-task RL problem, where the task space contains not only the challenging task of interest but also easier tasks that implicitly function as a curriculum. Such a reformulation opens up the possibility of running existing multi-task RL methods as a more efficient alternative to solving a single challenging task from scratch. In this work, we provide a theoretical framework that reformulates a single-task RL problem as a multi-task RL problem defined by a curriculum. Under mild reg ularity conditions on the curriculum, we show that sequentially solving each task in the multi-task RL problem is more computationally efficient than solving the original single-task problem, without any explicit exploration bonuses or other exploration strategies. We also show that our theoretical insights can be translated into an effective practical learning algorithm that can accelerate curriculum learning on simulated robotic goal-reaching tasks.

The Lie Derivative for Measuring Learned Equivariance

Nate Gruver,Marc Anton Finzi,Micah Goldblum,Andrew Gordon Wilson

Equivariance guarantees that a model's predictions capture key symmetries in data. When an image is translated or rotated, an equivariant model's representation of that image will translate or rotate accordingly. The success of convolutional neural networks has historically been tied to translation equivariance directly encoded in their architecture. The rising success of vision transformers, which have no explicit architectural bias towards equivariance, challenges this narrative and suggests that augmentations and training data might also play a significant role in their performance. In order to better understand the role of equivariance in recent vision models, we apply the Lie derivative, a method for measuring equivariance with strong mathematical foundations and minimal hyperparameters. Using the Lie derivative, we study the equivariance properties of hundreds of pretrained models, spanning CNNs, transformers, and Mixer architectures. The scale of our analysis allows us to separate the impact of architecture from other factors like model size or training method. Surprisingly, we find that many violations of equivariance can be linked to spatial aliasing in ubiquitous network layers, such as pointwise non-linearities, and that as models get larger and more accurate they tend to display more equivariance, regardless of architecture. For example, transformers can be more equivariant than convolutional neural networks after training.

Effective passive membership inference attacks in federated learning against overparameterized models

Jiacheng Li,Ninghui Li,Bruno Ribeiro

This work considers the challenge of performing membership inference attacks in a federated learning setting ---for image classification--- where an adversary can only observe the communication between the central node and a single client (a passive white-box attack). Passive attacks are one of the hardest-to-detect attacks, since they can be performed without modifying how the behavior of the central server or its clients, and assumes *no access to private data instances*. The key insight of our method is empirically observing that, near parameters that generalize well in test, the gradient of large overparameterized neural network models statistically behave like high-dimensional independent isotropic random vectors. Using this insight, we devise two attacks that are often little impacted by existing and proposed defenses. Finally, we validated the hypothesis that our attack depends on the overparametrization by showing that increasing the level of overparametrization (without changing the neural network architecture) positively correlates with our attack effectiveness.

Optimizing Bi-Encoder for Named Entity Recognition via Contrastive Learning

Sheng Zhang,Hao Cheng,Jianfeng Gao,Hoifung Poon

We present a bi-encoder framework for named entity recognition (NER), which applies contrastive learning to map candidate text spans and entity types into the same vector representation space. Prior work predominantly approaches NER as sequence labeling or span classification. We instead frame NER as a representation learning problem that maximizes the similarity between the vector representations of an entity mention and its type. This makes it easy to handle nested and flat NER alike, and can better leverage noisy self-supervision signals. A major challenge to this bi-encoder formulation for NER lies in separating non-entity spans from entity mentions. Instead of explicitly labeling all non-entity spans as the same class $\texttt{Outside}$ ($\texttt{O}$) as in most prior methods, we introduce a novel dynamic thresholding loss, learned in conjunction with the standar d contrastive loss. Experiments show that our method performs well in both supervised and distantly supervised settings, for nested and flat NER alike, establishing new state of the art across standard datasets in the general domain (e.g., ACE2004, ACE2005, CoNLL2003) and high-value verticals such as biomedicine (e.g., GENIA, NCBI, BC5CDR, JNLPBA). We release the code at https://github.com/microsoft/binder.

Handling Covariate Shifts in Federated Learning with Generalization Guarantees
Ali Ramezani-Kebrya,Fanghui Liu,Thomas Pethick,Grigorios Chrysos,Volkan Cevher
Covariate shift across clients is a major challenge for federated learning (FL). This work studies the generalization properties of FL under intra-client and inter-client covariate shifts. To this end, we propose Federated Importance-weighteD Empirical risk Minimization (FIDEM) to optimize a global FL model, along with new variants of density ratio matching methods, aiming to handle covariate shifts. These methods trade off some level of privacy for improving the overall generalization performance. We theoretically show that FIDEM achieves smaller generalization error than classical empirical risk minimization under some certain settings. Experimental results demonstrate the superiority of FIDEM over federated averaging (McMahan et al., 2017) and other baselines, which would open the door to study FL under distribution shifts more systematically.

Agree to Disagree: Diversity through Disagreement for Better Transferability
Matteo Pagliardini,Martin Jaggi,François Fleuret,Sai Praneeth Karimireddy
Gradient-based learning algorithms have an implicit \emph{simplicity bias} which in effect can limit the diversity of predictors being sampled by the learning procedure. This behavior can hinder the transferability of trained models by (i) favoring the learning of simpler but spurious features --- present in the training data but absent from the test data --- and (ii) by only leveraging a small subset of predictive features. Such an effect is especially magnified when the test distribution does not exactly match the train distribution---referred to as the Out of Distribution (OOD) generalization problem. However, given only the training data, it is not always possible to apriori assess if a given feature is spurious or transferable. Instead, we advocate for learning an ensemble of models which capture a diverse set of predictive features. Towards this, we propose a new algorithm D-BAT (Diversity-By-disAgreement Training), which enforces agreement among the models on the training data, but disagreement on the OOD data. We show how D-BAT naturally emerges from the notion of generalized discrepancy, as well as demonstrate in multiple experiments how the proposed method can mitigate shortcut-learning, enhance uncertainty and OOD detection, as well as improve transferability.

****

Expected Probabilistic Hierarchies
Marcel Kollovieh,Bertrand Charpentier,Daniel Zügner,Stephan Günnemann
Hierarchical clustering has usually been addressed by discrete optimization using heuristics or continuous optimization of relaxed scores for hierarchies. In this work, we propose to optimize expected scores under a probabilistic model over hierarchies. (1) We show theoretically that the global optimum of the expected Dasgupta cost and Tree-Sampling divergence (TSD), two unsupervised metrics for hierarchical clustering scores, are equal to the optimum of their discrete counterparts contrary to some relaxed scores. (2) We propose Expected Probabilistic Hierarchies (EPH), a probabilistic model to learn hierarchies in data by optimizing expected scores. EPH uses differentiable hierarchy sampling enabling end-to-end gradient-descent based optimizations, and an unbiased subgraph sampling approach to scale to large datasets. (3) We evaluate EPH on synthetic and real-world datasets including vector and graph datasets. EPH outperforms all other approaches on quantitative results and provides meaningful hierarchies in qualitative evaluations.

Taking a Step Back with KCal: Multi-Class Kernel-Based Calibration for Deep Neur al Networks

Zhen Lin,Shubhendu Trivedi,Jimeng Sun

Deep neural network (DNN) classifiers are often overconfident, producing miscalibrated class probabilities. In high-risk applications like healthcare, practitioners require fully calibrated probability predictions for decision-making. That is, conditioned on the prediction vector, every class’ probability should be close to the predicted value. Most existing calibration methods either lack theoretical guarantees for producing calibrated outputs, reduce classification accuracy in the process, or only calibrate the predicted class. This paper proposes a new Kernel-based calibration method called KCal. Unlike existing calibration procedures, KCal does not operate directly on the logits or softmax outputs of the DNN. Instead, KCal learns a metric space on the penultimate-layer latent embedding and generates predictions using kernel density estimates on a calibration set. We first analyze KCal theoretically, showing that it enjoys a provable full calibration guarantee. Then, through extensive experiments across a variety of datasets, we show that KCal consistently outperforms baselines as measured by the calibration error and by proper scoring rules like the Brier Score.

A distinct unsupervised reference model from the environment helps continual learning

Seyyed AmirHossein Ameli Kalkhoran,Mohammadamin Banayeeanzade,Mahdi Samiei,Mahdieh Soleymani Baghshah

The existing continual learning methods are mainly focused on fully-supervised scenarios and are still not able to take advantage of unlabeled data available in the environment. Some recent works tried to investigate semi-supervised continual learning (SSCL) settings in which the unlabeled data are available, but it is only from the same distribution as the labeled data. This assumption is still not general enough for real-world applications and restricts the utilization of unsupervised data. In this work, we introduce Open-Set Semi-Supervised Continual Learning (OSSCL), a more realistic semi-supervised continual learning setting in which out-of-distribution (OoD) unlabeled samples in the environment are assumed to coexist with the in-distribution ones. Under this configuration, we present a model with two distinct parts: (i) the reference network captures general-purpose and task-agnostic knowledge in the environment by using a broad spectrum of unlabeled samples, (ii) the learner network is designed to learn task-specific representations by exploiting supervised samples. The reference model both provides a pivotal representation space and also segregates unlabeled data to exploit them more efficiently. By performing a diverse range of experiments, we show the superior performance of our model compared with other competitors and prove the effectiveness of each component of the proposed model.

The Crossword Puzzle: Simplifying Deep Neural Network Pruning with Fabulous Coordinates

Yicun Duan,Wangkai Jin,Xiangjun Peng

Pruning is a promising technique to shrink the size of Deep Neural Network models with only negligible accuracy overheads. Recent efforts rely on experience-derived metric to guide pruning procedure, which heavily saddles with the effective generalization of pruning methods. We propose The Cross Puzzle, a new method to simplify this procedure by automatically deriving pruning metrics. The key insight behind our method is that: \textit{For Deep Neural Network Models, a Pruning-friendly Distribution of model's weights can be obtained, given a proper Coordinate}. We experimentally confirm the above insight, and denote the new Coordinate as the Fabulous Coordinates. Our quantitative evaluation results show that: the Crossword Puzzle can find a simple yet effective metric, which outperforms the state-of-the-art pruning methods by delivering no accuracy degradation on ResNet-56 (CIFAR-10)/-101 (ImageNet), while the pruning rate is raised to 70\%/50\% for the respective models.

Learning the Visualness of Text Using Large Vision-Language Models

Gaurav Verma,Ryan A. Rossi,Christopher Tensmeyer,Jiuxiang Gu,Ani Nenkova

Visual text evokes an image in a person's mind, while non-visual text fails to do so. A method to automatically detect visual text will unlock the ability to augment text with relevant images, as neural text-to-image generation and retrieval models operate on the implicit assumption that the input text is visual in nature. We curate a dataset of 3,620 English sentences and their visualness scores provided by multiple human annotators. Additionally, we use documents that contain text and visual assets to create a distantly supervised corpus of document text and associated images. We also propose a fine-tuning strategy that adapts large vision-language models like CLIP that assume a one-to-one correspondence between text and image to the task of scoring text visualness from text input alone. Our strategy involves modifying the model's contrastive learning objective to map text identified as non-visual to a common NULL image while matching visual text to their corresponding images in the document. We evaluate the proposed approach on its ability to (i) classify visual and non-visual text accurately, and (ii) attend over words that are identified as visual in psycholinguistic studies. Empirical evaluation indicates that our approach performs better than several heuristics and baseline models for the proposed task. Furthermore, to highlight the importance of modeling the visualness of text, we conduct qualitative analyses of text-to-image generation systems like DALL-E. We release the curated dataset and code.

SemPPL: Predicting Pseudo-Labels for Better Contrastive Representations

Matko Bošnjak,Pierre Harvey Richemond,Nenad Tomasev,Florian Strub,Jacob C Walker,Felix Hill,Lars Holger Buesing,Razvan Pascanu,Charles Blundell,Jovana Mitrovic

Learning from large amounts of unsupervised data and a small amount of supervision is an important open problem in computer vision. We propose a new semi-supervised learning method, Semantic Positives via Pseudo-Labels (SEMPPL), that combines labelled and unlabelled data to learn informative representations. Our method extends self-supervised contrastive learning—where representations are shaped by distinguishing whether two samples represent the same underlying datum (positives) or not (negatives)—with a novel approach to selecting positives. To enrich the set of positives, we leverage the few existing ground-truth labels to predict the missing ones through a k-nearest neighbors classifier by using the learned embeddings of the labelled data. We thus extend the set of positives with datapoints having the same pseudo-label and call these semantic positives. We jointly learn the representation and predict bootstrapped pseudo-labels. This creates a reinforcing cycle. Strong initial representations enable better pseudo-label predictions which then improve the selection of semantic positives and lead to even better representations. SEMPPL outperforms competing semi-supervised methods setting new state-of-the-art performance of 76% and 68.5% top-1accuracy when using a ResNet-50 and training on 10% and 1% of labels on ImageNet, respectively. Furthermore, when using selective kernels, SEMPPL significantly outperforms previous state-of-the-art achieving 72.3% and 78.3% top-1accuracy on ImageNet with 1% and 10% labels, respectively, which improves absolute +7.8% and +6.2% over previous work. SEMPPL also exhibits state-of-the-art performance over larger ResNet models as well as strong robustness, out-of-distribution and transfer performance. We release the checkpoints and the evaluation code at https://github.com/deepmind/semppl.

Differentially Private Adaptive Optimization with Delayed Preconditioners

Tian Li,Manzil Zaheer,Ken Liu,Sashank J. Reddi,Hugh Brendan McMahan,Virginia Smith

Privacy costs may negate the benefits of using adaptive optimizers in differentially private model training. Prior works typically address this issue by using auxiliary information (e.g., public data) to boost the effectiveness of adaptive optimization. In this work, we explore techniques to estimate and efficiently adapt to gradient geometry in private adaptive optimization without auxiliary data. Motivated by the observation that adaptive methods can tolerate stale preconditioners, we propose differentially private adaptive training with delayed preconditioners (DP^2), a simple method that constructs delayed but less noisy precond itioners to better realize the benefits of adaptivity. Theoretically, we provide convergence guarantees for our method for both convex and non-convex problems, and analyze trade-offs between delay and privacy noise reduction. Empirically, we explore DP^2 across several real-world datasets, demonstrating that it can improve convergence speed by as much as 4× relative to non-adaptive baselines and match the performance of state-of-the-art optimization methods that require auxiliary data.

Towards a Mathematics Formalisation Assistant using Large Language Models

Ayush Agrawal,Siddhartha Gadgil,Navin Goyal,Ashvni Narayanan,Anand Tadipatri

Mathematics formalisation is the task of writing mathematics (i.e., definitions, theorem statements, proofs) in natural language, as found in books and papers, into a formal language that can then be checked for correctness by a program. It is a thriving activity today, however formalisation remains cumbersome. In this paper, we explore the abilities of a large language model (Codex) to help with formalisation in the Lean theorem prover. We find that with careful input-dependent prompt selection and postprocessing, Codex is able to formalise short mathematical statements at undergrad level with nearly 75\% accuracy for 120 theorem statements. For proofs quantitative analysis is infeasible and we undertake a detailed case study. We choose a diverse set of 13 theorems at undergrad level with proofs that fit in two-three paragraphs. We show that with a new prompting strategy Codex can formalise these proofs in natural language with at least one out of twelve Codex completion being easy to repair into a complete proof. This is surprising as essentially no aligned data exists for formalised mathematics, particularly for proofs. These results suggest that large language models are a promising avenue towards fully or partially automating formalisation.

FedLite: Improving Communication Efficiency in Federated Split Learning

Jianyu Wang,Hang Qi,Ankit Singh Rawat,Sashank J. Reddi,Sagar M. Waghmare,Felix Yu,Gauri Joshi

In classical federated learning, clients contribute to the overall training by communicating local updates for the underlying model on their private data to a coordinating server. However, updating and communicating the entire model becomes prohibitively expensive when resource-constrained clients collectively aim to train a large machine learning model. Split learning provides a natural solution in such a setting, where only a (small) part of the model is stored and trained on clients while the remaining (large) part of the model only stays at the servers. Unfortunately, the model partitioning employed in split learning significantly increases the communication cost compared to the classical federated learning algorithms. This paper addresses this issue by compressing the additional communication cost associated with split learning via a novel clustering algorithm and a gradient correction technique. An extensive empirical evaluation on standard image and text benchmarks shows that the proposed method can achieve up to 490x communication cost reduction with minimal drop in accuracy, and enables a desirable performance vs. communication trade-off.

Adversarial Policies Beat Professional-Level Go AIs

Tony Tong Wang,Adam Gleave,Nora Belrose,Tom Tseng,Michael D Dennis,Yawen Duan,Viktor Pogrebniak,Sergey Levine,Stuart Russell

We attack the state-of-the-art Go-playing AI system, KataGo, by training an adversarial policy that plays against a frozen KataGo victim. Our attack achieves a >99% win-rate against KataGo without search, and a >80% win-rate when KataGo uses enough search to be near-superhuman. To the best of our knowledge, this is the first successful end-to-end attack against a Go AI playing at the level of a top human professional. Notably, the adversary does not win by learning to play Go better than KataGo---in fact, the adversary is easily beaten by human amateurs. Instead, the adversary wins by tricking KataGo into ending the game prematurely at a point that is favorable to the adversary. Our results demonstrate that even professional-level AI systems may harbor surprising failure modes.

Phenaki: Variable Length Video Generation from Open Domain Textual Descriptions
Ruben Villegas,Mohammad Babaeizadeh,Pieter-Jan Kindermans,Hernan Moraldo,Han Zhang,Mohammad Taghi Saffar,Santiago Castro,Julius Kunze,Dumitru Erhan

We present Phenaki, a model capable of realistic video synthesis given a sequence of textual prompts. Generating videos from text is particularly challenging due to the computational cost, limited quantities of high quality text-video data and variable length of videos. To address these issues, we introduce a new causal model for learning video representation which compresses the video to a small discrete tokens representation. This tokenizer is auto-regressive in time, which allows it to work with video representations of different length.

To generate video tokens from text we are using a bidirectional masked transformer conditioned on pre-computed text tokens. The generated video tokens are subsequently de-tokenized to create the actual video. To address data issues, we demonstrate how joint training on a large corpus of image-text pairs as well as a smaller number of video-text examples can result in generalization beyond what is available in the video datasets. Compared to the previous video generation methods, Phenaki can generate arbitrary long videos conditioned on a sequence of prompts (i.e. time variable text or story) in open domain. To the best of our knowledge, this is the first time a paper studies generating videos from time variable prompts.

Long Range Language Modeling via Gated State Spaces
Harsh Mehta,Ankit Gupta,Ashok Cutkosky,Behnam Neyshabur

State space models have shown to be effective at modeling long range dependencies, specially on sequence classification tasks. In this work we focus on autoregressive sequence modeling over English books, Github source code and ArXiv mathematics articles. Based on recent developments around the effectiveness of gated activation functions, we propose a new layer named \textit{Gated State Space} (GSS) and show that it trains significantly faster than the diagonal version of S4 (i.e. DSS) on TPUs, is fairly competitive with several well-tuned Transformer-based baselines and exhibits zero-shot generalization to longer inputs while being straightforward to implement. Finally, we show that leveraging self-attention to model local dependencies improves the performance of GSS even further.

****

On the (Non-)Robustness of Two-Layer Neural Networks in Different Learning Regimes
Elvis Dohmatob,Alberto Bietti

Neural networks are known to be highly sensitive to adversarial examples. These may arise due to different factors, such as random initialization, or spurious correlations in the learning problem. To better understand these factors, we provide a precise study of the adversarial robustness in different scenarios, from initialization to the end of training in different regimes, as well as intermediate scenarios where initialization still plays a role due to “lazy” training. We consider over-parameterized networks in high dimensions with quadratic targets and infinite samples. Our analysis allows us to identify new tradeoffs between approximation (as measured via test error) and robustness, whereby robustness can only get worse when test error improves, and vice versa. We also show how linearized lazy training
regimes can worsen robustness, due to improperly scaled random initialization. Our theoretical results are illustrated with numerical experiments.

****

Task-customized Masked Autoencoder via Mixture of Cluster-conditional Experts
Zhili LIU,Kai Chen,Jianhua Han,Lanqing HONG,Hang Xu,Zhenguo Li,James Kwok

Masked Autoencoder (MAE) is a prevailing self-supervised learning method that achieves promising results in model pre-training. However, when the various downstream tasks have data distributions different from the pre-training data, the semantically irrelevant pre-training information might result in negative transfer, impeding MAE’s scalability. To address this issue, we propose a novel MAE-based pre-training paradigm, Mixture of Cluster-conditional Experts (MoCE), which can be trained once but provides customized pre-training models for diverse downstr eam tasks. Different from the mixture of experts (MoE), our MoCE trains each expert only with semantically relevant images by using cluster-conditional gates. Thus, each downstream task can be allocated to its customized model pre-trained with data most similar to the downstream data. Experiments on a collection of 11 downstream tasks show that MoCE outperforms the vanilla MAE by 2.45\% on average. It also obtains new state-of-the-art self-supervised learning results on detection and segmentation.

A Deep Dive into Dataset Imbalance and Bias in Face Identification

Valeriia Cherepanova,Steven Reich,Samuel Dooley,Hossein Souri,John P Dickerson,Micah Goldblum,Tom Goldstein

As the deployment of automated face recognition (FR) systems proliferates, bias in these systems is not just an academic question, but a matter of public concern. Media portrayals often center imbalance as the main source of bias, i.e., that FR models perform worse on images of non-white people or women because these demographic groups are underrepresented in training data. Recent academic research paints a more nuanced picture of this relationship. However, previous studies of data imbalance in FR have focused exclusively on the face verification setting, while the face identification setting has been largely ignored, despite being deployed in sensitive applications such as law enforcement. This is an unfortunate omission, as 'imbalance' is a more complex matter in identification; imbalance may arise in not only the training data, but also the testing data, and furthermore may affect the proportion of identities belonging to each demographic group or the number of images belonging to each identity. In this work, we address this gap in the research by thoroughly exploring the effects of each kind of imbalance possible in face identification, and discuss other factors which may impact bias in this setting.

Causally Constrained Data Synthesis For Private Data Release

Varun Chandrasekaran,Darren Edge,Somesh Jha,Lukas Wutschitz,Amit Sharma,Cheng Zhang,Shruti Tople

Data privacy is critical in many decision-making contexts, such as healthcare and finance. A common mechanism is to create differentially private synthetic data using generative models. Such data generation reflects certain statistical properties of the original data, but often has an unacceptable privacy vs. utility trade-off. Since natural data inherently exhibits causal structure, we propose incorporating \emph{causal information} into the training process to favorably navigate the aforementioned trade-off. Under certain assumptions for linear gaussian models and a broader class of models, we theoretically prove that causally informed generative models provide better differential privacy guarantees than their non-causal counterparts. We evaluate our proposal using variational autoencoders, and demonstrate that the trade-off is mitigated through better utility for comparable privacy.

****

Modeling the Data-Generating Process is Necessary for Out-of-Distribution Generalization

Jivat Neet Kaur,Emre Kiciman,Amit Sharma

Recent empirical studies on domain generalization (DG) have shown that DG algorithms that perform well on some distribution shifts fail on others, and no state-of-the-art DG algorithm performs consistently well on all shifts. Moreover, real-world data often has multiple distribution shifts over different attributes; hence we introduce multi-attribute distribution shift datasets and find that the accuracy of existing DG algorithms falls even further. To explain these results, we provide a formal characterization of generalization under multi-attribute shifts using a canonical causal graph. Based on the relationship between spurious attributes and the classification label, we obtain realizations of the canonical causal graph that characterize common distribution shifts and show that each shift entails different independence constraints over observed variables. As a result, we prove that any algorithm based on a single, fixed constraint cannot work well across all shifts, providing theoretical evidence for mixed empirical resul ts on DG algorithms. Based on this insight, we develop Causally Adaptive Constraint Minimization (CACM), an algorithm that uses knowledge about the data-generating process to adaptively identify and apply the correct independence constraints for regularization. Results on fully synthetic, MNIST, small NORB, and Waterbirds datasets, covering binary and multi-valued attributes and labels, show that adaptive dataset-dependent constraints lead to the highest accuracy on unseen domains whereas incorrect constraints fail to do so. Our results demonstrate the importance of modeling the causal relationships inherent in the data-generating process.

Bayes-MIL: A New Probabilistic Perspective on Attention-based Multiple Instance Learning for Whole Slide Images

Yufei CUI,Ziquan Liu,Xiangyu Liu,Xue Liu,Cong Wang,Tei-Wei Kuo,Chun Jason Xue,Antoni B. Chan

Multiple instance learning (MIL) is a popular weakly-supervised learning model on the whole slide image (WSI) for AI-assisted pathology diagnosis. The recent advance in attention-based MIL allows the model to find its region-of-interest (ROI) for interpretation by learning the attention weights for image patches of WSI slides. However, we empirically find that the interpretability of some related methods is either untrustworthy as the principle of MIL is violated or unsatisfactory as the high-attention regions are not consistent with experts' annotations. In this paper, we propose Bayes-MIL to address the problem from a probabilistic perspective. The induced patch-level uncertainty is proposed as a new measure of MIL interpretability, which outperforms previous methods in matching doctors annotations. We design a slide-dependent patch regularizer (SDPR) for the attention, imposing constraints derived from the MIL assumption, on the attention distribution. SDPR explicitly constrains the model to generate correct attention values. The spatial information is further encoded by an approximate convolutional conditional random field (CRF), for better interpretability. Experimental results show Bayes-MIL outperforms the related methods in patch-level and slide-level metrics and provides much better interpretable ROI on several large-scale WSI datasets.

Exploring Connections Between Memorization And Membership Inference

Jihye Choi,Varun Chandrasekaran,Shruti Tople,Somesh Jha

Membership inference (MI) allows privacy adversaries to query trained machine learning models to infer if a particular data sample was used in model training. Prior work has shown that the efficacy of MI is not the same for every sample in the training dataset; they broadly attribute this behavior to various data properties such as distributional difference. However, systematically analyzing the reasons for such disparate behavior has received little attention. In this work, we investigate the cause for such a discrepancy, and observe that the reason is more subtle and fundamental. We first provide empirical insight that an MI adversary is very successful with those samples that are highly $\textit{likely to be memorized}$, irrespective of whether the sample is from the same or a different distribution. Next, we provide a game-based formulation which lower-bounds the advantage of an adversary with the ability to determine if a sample is memorized or not, under certain assumptions made about the efficacy of the model on the memorized samples. Finally, based on our theoretical results, we present a practical instantiation of a highly effective MI attack on memorized samples.

****

Action Matching: A Variational Method for Learning Stochastic Dynamics from Samples

Kirill Neklyudov,Daniel Severo,Alireza Makhzani

Stochastic dynamics are ubiquitous in many fields of science, from the evolution of quantum systems in physics to diffusion-based models in machine learning. Existing methods such as score matching can be used to simulate these physical processes by assuming that the dynamics is a diffusion, which is not always the case. In this work, we propose a method called "Action Matching" that enables us to learn a much broader family of stochastic dynamics. Our method requires access only to samples from different time-steps, makes no explicit assumptions about the underlying dynamics, and can be applied even when samples are uncorrelated (i.e., are not part of a trajectory). Action Matching directly learns an underlying mechanism to move samples in time without modeling the distributions at each time-step. In this work, we showcase how Action Matching can be used for several computer vision tasks such as generative modeling, super-resolution, colorization, and inpainting; and further discuss potential applications in other areas of science.

Pre-train Graph Neural Networks for Brain Network Analysis

Yi Yang,Hejie Cui,Carl Yang

Human brains, controlling behaviors and cognition, are at the center of complex neurobiological systems. Recent studies in neuroscience and neuroimaging analysis have reached a consensus that interactions among brain regions of interest (ROIs) are driving factors for neural development and disorders. Graph neural networks as a powerful tool for analyzing graph-structured data are naturally applied to the analysis of brain networks. However, training of deep learning models including GNNs often requires a significant amount of labeled data. Due to the complicated data acquisition process and restrictions on data sharing, brain network datasets are still small compared to other domains (e.g., molecules, proteins). Moreover, real clinical tasks (e.g., mental disorder analysis) are often conducted on local datasets with even smaller scales and larger noises. To this end, we propose to leverage pre-training to capture the intrinsic brain network structures regardless of specific clinical outcomes. Specifically, we characterize the contributions in this work from two perspectives: (1) We design brain-network-oriented unsupervised pre-training techniques to utilize large-scale brain imaging studies without highly relevant task labels. (2) To facilitate effective knowledge transfer across studies with different ROI systems, we propose to develop a data-driven parcellation atlas mapping pipeline. The proposed pre-training techniques are validated with various GNN models. Extensive experiments demonstrate consistent improvement in performance as well as robustness.

Investigating Multi-task Pretraining and Generalization in Reinforcement Learning

Adrien Ali Taiga,Rishabh Agarwal,Jesse Farebrother,Aaron Courville,Marc G Bellemare

Deep reinforcement learning~(RL) has achieved remarkable successes in complex single-task settings. However, designing RL agents that can learn multiple tasks and leverage prior experience to quickly adapt to a related new task remains challenging. Despite previous attempts to improve on these areas, our understanding of multi-task training and generalization in RL remains limited. To fill this gap, we investigate the generalization capabilities of a popular actor-critic method, IMPALA. Specifically, we build on previous work that has advocated for the use of modes and difficulties of Atari 2600 games as a challenging benchmark for transfer learning in RL. We do so by pretraining an agent on multiple variants of the same Atari game before fine-tuning on the remaining never-before-seen variants. This protocol simplifies the multi-task pretraining phase by limiting negative interference between tasks and allows us to better understand the dynamics of multi-task training and generalization. We find that, given a fixed amount of pretraining data, agents trained with more variations are able to generalize better. Surprisingly, we also observe that this advantage can still be present after fine-tuning for 200M environment frames than when doing zero-shot transfer. This highlights the potential effect of a good learned representation. We also find that, even though small networks have remained popular to solve Atari 2600 games, increasing the capacity of the value and policy network is critical to achieve good performance as we increase the number of pretraining modes and difficulties. Overall, our findings emphasize key points that are essential for efficient multi-task training and generalization in reinforcement learning.

FIT: A Metric for Model Sensitivity

Ben Zandonati,Adrian Alan Pol,Maurizio Pierini,Olya Sirkin,Tal Kopetz

Model compression is vital to the deployment of deep learning on edge devices. Low precision representations, achieved via quantization of weights and activations, can reduce inference time and memory requirements. However, quantifying and predicting the response of a model to the changes associated with this procedure remains challenging. This response is non-linear and heterogeneous throughout the network. Understanding which groups of parameters and activations are more sensitive to quantization than others is a critical stage in maximizing efficiency. For this purpose, we propose FIT. Motivated by an information geometric perspective, FIT combines the Fisher information with a model of quantization. We find that FIT can estimate the final performance of a network without retraining. FIT effectively fuses contributions from both parameter and activation quantization into a single metric. Additionally, FIT is fast to compute when compared to existing methods, demonstrating favourable convergence properties. These properties are validated experimentally across hundreds of quantization configurations, with a focus on layer-wise mixed-precision quantization.

Transfer Learning with Deep Tabular Models

Roman Levin,Valeriia Cherepanova,Avi Schwarzschild,Arpit Bansal,C. Bayan Bruss,Tom Goldstein,Andrew Gordon Wilson,Micah Goldblum

Recent work on deep learning for tabular data demonstrates the strong performance of deep tabular models, often bridging the gap between gradient boosted decision trees and neural networks. Accuracy aside, a major advantage of neural models is that they are easily fine-tuned in new domains and learn reusable features. This property is often exploited in computer vision and natural language applications, where transfer learning is indispensable when task-specific training data is scarce. In this work, we explore the benefits that representation learning provides for knowledge transfer in the tabular domain. We conduct experiments in a realistic medical diagnosis test bed with limited amounts of downstream data and find that transfer learning with deep tabular models provides a definitive advantage over gradient boosted decision tree methods. We further compare the supervised and self-supervised pretraining strategies and provide practical advice on transfer learning with tabular models. Finally, we propose a pseudo-feature method for cases where the upstream and downstream feature sets differ, a tabular-specific problem widespread in real-world applications.

****

An Empirical Study on the Efficacy of Deep Active Learning Techniques

YU LI,Muxi Chen,Yannan Liu,Daojing He,Qiang Xu

Deep Active Learning (DAL) has been advocated as a promising method to reduce labeling costs in supervised learning. However, existing evaluations of DAL methods are based on different settings, and their results are controversial. To tackle this issue, this paper comprehensively evaluates 19 existing DAL methods in a uniform setting, including traditional fully-\underline{s}upervised \underline{a}ctive \underline{l}earning (SAL) strategies and emerging \underline{s}emi-\underline{s}upervised \underline{a}ctive \underline{l}earning (SSAL) techniques. We have several non-trivial findings. First, most SAL methods cannot achieve higher accuracy than random selection. Second, semi-supervised training brings significant performance improvement compared to pure SAL methods. Third, performing data selection in the SSAL setting can achieve a significant and consistent performance improvement, especially with abundant unlabeled data. Our findings produce the following guidance for practitioners: one should (i) apply SSAL as early as possible and (ii) collect more unlabeled data whenever possible, for better model performance. We will release our code upon acceptance.

CrAM: A Compression-Aware Minimizer

Alexandra Peste,Adrian Vladu,Eldar Kurtic,Christoph H Lampert,Dan Alistarh

Deep neural networks (DNNs) often have to be compressed, via pruning and/or quantization, before they can be deployed in practical settings. In this work we propose a new compression-aware minimizer dubbed CrAM that modifies the optimization step in a principled way, in order to produce models whose local loss behavior is stable under compression operations such as pruning. Thus, dense models trained via CrAM should be compressible post-training, in a single step, without significant accuracy loss. Experimental results on standard benchmarks, such as residual networks for ImageNet classification and BERT models for language modelling, show that CrAM produces dense models that can be more accurate than the standard SGD/Adam-based baselines, but which are stable under weight pruning: specifically, we can prune models in one-shot to 70-80% sparsity with almost no accuracy loss, and to 90% with reasonable (~ 1%) accuracy loss, which is competitive with gradual compression methods. Additionally, CrAM can produce sparse models which perform well for transfer learning, and it also works for semi-structured 2:4 pruning patterns supported by GPU hardware. The code for reproducing the results is available at: https://github.com/IST-DASLab/CrAM .

Using Language to Extend to Unseen Domains

Lisa Dunlap,Clara Mohri,Devin Guillory,Han Zhang,Trevor Darrell,Joseph E. Gonzalez,Aditi Raghunathan,Anna Rohrbach

It is expensive to collect training data for every possible domain that a vision model may encounter when deployed. We instead consider how simply $\textit{verbalizing}$ the training domain (e.g.``photos of birds'') as well as domains we want to extend to but do not have data for (e.g.``paintings of birds'') can improve robustness. Using a multimodal model with a joint image and language embedding space, our method $\textit{LADS}$ learns a transformation of the image embeddings from the source domain to each target domain, while preserving task relevant information. Without using any images from the target domain, we show that over the $\textit{extended}$ domain containing both source and target, $\textit{LADS}$ outperforms standard fine-tuning and ensemble approaches over a suite of 4 benchmarks targeting domain adaptation and dataset bias.

Can We Find Nash Equilibria at a Linear Rate in Markov Games?

Zhuoqing Song,Jason D. Lee,Zhuoran Yang

We study decentralized learning in two-player zero-sum discounted Markov games where the goal is to design a policy optimization algorithm for either agent satisfying two properties. First, the player does not need to know the policy of the opponent to update its policy. Second, when both players adopt the algorithm, their joint policy converges to a Nash equilibrium of the game. To this end, we construct a meta-algorithm, dubbed as $\texttt{Homotopy-PO}$, which provably finds a Nash equilibrium at a global linear rate. In particular, $\texttt{Homotopy-PO}$ interweaves two base algorithms $\texttt{Local-Fast}$ and $\texttt{Global-Slow}$ via homotopy continuation. $\texttt{Local-Fast}$ is an algorithm that enjoys local linear convergence while $\texttt{Global-Slow}$ is an algorithm that converges globally but at a slower sublinear rate. By switching between these two base algorithms, $\texttt{Global-Slow}$ essentially serves as a ``guide'' which identifies a benign neighborhood where $\texttt{Local-Fast}$ enjoys fast convergence. However, since the exact size of such a neighborhood is unknown, we apply a doubling trick to switch between these two base algorithms. The switching scheme is delicately designed so that the aggregated performance of the algorithm is driven by $\texttt{Local-Fast}$. Furthermore, we prove that $\texttt{Local-Fast}$ and $\texttt{Global-Slow}$ can both be instantiated by variants of optimistic gradient descent/ascent (OGDA) method, which is of independent interest.

Speeding up Policy Optimization with Vanishing Hypothesis and Variable Mini-Batch Size

Tamás Tardi,Gergo Bogacsovics,Andras Hajdu

Reinforcement learning-based algorithms have been used extensively in recent years due to their flexible nature, good performance, and the increasing number of said algorithms. However, the largest drawback of these techniques remains unsolved, that is, it usually takes a long time for the agents to learn how to solve a given problem. In this work, we outline a novel method that can be used to drastically reduce the training time of current state-of-the-art algorithms like Pr

oximal Policy Optimization (PPO). We evaluate the performance of this approach in a unique environment where we use reinforcement learning to help with a practical astronomical problem: where to place a fixed number of observatory stations in the Solar System to observe space objects (e.g. asteroids) as permanently as possible. That is, the reward in this scenario corresponds to the total coverage of the trajectories of these objects. We apply noisy evaluation for calculating the reward to speed up the training, which technique has already been efficiently applied in stochastic optimization. Namely, we allow the incorporation of some additional noise in the reward function in the form of a hypothesis term and a varying mini-batch size. However, in order to follow the theoretical guidelines, both of them are forced to vanish during training to let the noise converge to zero. Our experimental results show that using this approach we can reduce the training time remarkably, even by 75%.

Understanding Train-Validation Split in Meta-Learning with Neural Networks
Xinzhe Zuo,Zixiang Chen,Huaxiu Yao,Yuan Cao,Quanquan Gu

The goal of meta-learning is to learn a good prior model from a collection of tasks such that the learned prior is able to adapt quickly to new tasks without accessing many data from the new tasks. A common practice in meta-learning is to perform a train-validation split on each task, where the training set is used for adapting the model parameter to that specific task and the validation set is used for learning a prior model that is shared across all tasks. Despite its success and popularity in multitask learning and few-shot learning, the understanding of the train-validation split is still limited, especially when the neural network models are used. In this paper, we study the benefit of train-validation split for classification problems with neural network models trained by gradient descent. We prove that the train-validation split is necessary to learn a good prior model when the noise in the training sample is large, while the train-train method fails. We validate our theory by conducting experiment on both synthetic and real datasets. To the best of our knowledge, this is the first work towards the theoretical understanding of train-validation split in meta-learning with neural networks.

Revisiting Robustness in Graph Machine Learning
Lukas Gosch,Daniel Sturm,Simon Geisler,Stephan Günnemann

Many works show that node-level predictions of Graph Neural Networks (GNNs) are unrobust to small, often termed adversarial, changes to the graph structure. However, because manual inspection of a graph is difficult, it is unclear if the studied perturbations always preserve a core assumption of adversarial examples: that of unchanged semantic content. To address this problem, we introduce a more principled notion of an adversarial graph, which is aware of semantic content change. Using Contextual Stochastic Block Models (CSBMs) and real-world graphs, our results suggest: $i)$ for a majority of nodes the prevalent perturbation models include a large fraction of perturbed graphs violating the unchanged semantics assumption; $ii)$ surprisingly, all assessed GNNs show over-robustness - that is robustness beyond the point of semantic change. We find this to be a complementary phenomenon to adversarial examples and show that including the label-structure of the training graph into the inference process of GNNs significantly reduces over-robustness, while having a positive effect on test accuracy and adversarial robustness. Theoretically, leveraging our new semantics-aware notion of robustness, we prove that there is no robustness-accuracy tradeoff for inductively classifying a newly added node.

Variational Information Pursuit for Interpretable Predictions
Aditya Chattopadhyay,Kwan Ho Ryan Chan,Benjamin David Haeffele,Donald Geman,Rene Vidal

There is a growing interest in the machine learning community in developing predictive algorithms that are interpretable by design. To this end, recent work proposes to sequentially ask interpretable queries about data until a high confidence prediction can be made based on the answers obtained (the history). To promot

e short query-answer chains, a greedy procedure called Information Pursuit (IP) is used, which adaptively chooses queries in order of information gain. Generative models are employed to learn the distribution of query-answers and labels, which is in turn used to estimate the most informative query. However, learning and inference with a full generative model of the data is often intractable for complex tasks. In this work, we propose Variational Information Pursuit (V-IP), a variational characterization of IP which bypasses the need to learn generative models. V-IP is based on finding a query selection strategy and a classifier that minimize the expected cross-entropy between true and predicted labels. We prove that the IP strategy is the optimal solution to this problem. Therefore, instead of learning generative models, we can use our optimal strategy to directly pick the most informative query given any history. We then develop a practical algorithm by defining a finite-dimensional parameterization of our strategy and classifier using deep networks and train them end-to-end using our objective. Empirically, V-IP is 10-100x faster than IP on different Vision and NLP tasks with competitive performance. Moreover, V-IP finds much shorter query chains when compared to reinforcement learning which is typically used in sequential-decision-making problems. Finally, we demonstrate the utility of V-IP on challenging tasks like medical diagnosis where the performance is far superior to the generative modeling approach.

Grammar-Induced Geometry for Data-Efficient Molecular Property Prediction
Minghao Guo,Veronika Thost,Samuel Song,Adithya Balachandran,Payel Das,Jie Chen,Wojciech Matusik
The prediction of molecular properties is a crucial task in the field of material and drug discovery. The potential benefits of using deep learning techniques are reflected in the wealth of recent literature. Still, these techniques are faced with a common challenge in practice: Labeled data are limited by the cost of manual extraction from literature and laborious experimentation. In this work, we propose a data-efficient property predictor by utilizing a learnable hierarchical molecular grammar that can generate molecules from grammar production rules. Such a grammar induces an explicit geometry of the space of molecular graphs, which provides an informative prior on molecular structural similarity. The property prediction is performed using graph neural diffusion over the grammar-induced geometry. On both small and large datasets, our evaluation shows that this approach outperforms a wide spectrum of baselines, including supervised and pre-trained graph neural networks. We include a detailed ablation study and further analysis of our solution, showing its effectiveness in cases with extremely limited data (only ${\sim}100$ samples), and its extension to application in molecular generation.

EF21-P and Friends: Improved Theoretical Communication Complexity for Distributed Optimization with Bidirectional Compression
Kaja Gruntkowska,Alexander Tyurin,Peter Richtárik
The starting point of this paper is the discovery of a novel and simple error-feedback mechanism, which we call EF21-P, for dealing with the error introduced by a contractive compressor. Unlike all prior works on error feedback, where compression and correction operate in the dual space of gradients, our mechanism operates in the primal space of models. While we believe that EF21-P may be of interest in many situations where it is often advantageous to perform model perturbation prior to the computation of the gradient (e.g., randomized smoothing and generalization), in this work we focus our attention on its use as a key building block in the design of communication-efficient distributed optimization methods supporting bidirectional compression. In particular, we employ EF21-P as the mechanism for compressing and subsequently error-correcting the model broadcast by the server to the workers. By combining EF21-P with suitable methods performing worker-to-server compression, we obtain novel methods supporting bidirectional compression and enjoying new state-of-the-art theoretical communication complexity for convex and nonconvex problems. For example, our bounds are the first that manage to decouple the variance/error coming from the workers-to-server and s

erver-to-workers compression, transforming a multiplicative dependence to an additive one. In the convex regime, we obtain the first bounds that match the theoretical communication complexity of gradient descent. Even in this convex regime, our algorithms work with biased gradient estimators, which is non-standard and requires new proof techniques that may be of independent interest. Finally, our theoretical results are corroborated through suitable experiments.

Sparse Upcycling: Training Mixture-of-Experts from Dense Checkpoints

Aran Komatsuzaki,Joan Puigcerver,James Lee-Thorp,Carlos Riquelme Ruiz,Basil Mustafa,Joshua Ainslie,Yi Tay,Mostafa Dehghani,Neil Houlsby

Training large, deep neural networks to convergence can be prohibitively expensive. As a result, often only a small selection of popular, dense models are reused across different contexts and tasks. Increasingly, sparsely activated models, which seek to decouple model size from computation costs, are becoming an attractive alternative to dense models. Although more efficient in terms of quality and computation cost, sparse models remain data-hungry and costly to train from scratch in the large scale regime. In this work, we propose sparse upcycling -- a simple way to reuse sunk training costs by initializing a sparsely activated Mixture-of-Experts model from a dense checkpoint. We show that sparsely upcycled T5 Base, Large, and XL language models and Vision Transformer Base and Large models, respectively, significantly outperform their dense counterparts on SuperGLUE and ImageNet, using only ~50% of the initial dense pretraining sunk cost. The upcycled models also outperform sparse models trained from scratch on 100% of the initial dense pretraining computation budget.

Lossless Adaptation of Pretrained Vision Models For Robotic Manipulation

Mohit Sharma,Claudio Fantacci,Yuxiang Zhou,Skanda Koppula,Nicolas Heess,Jon Scholz,Yusuf Aytar

Recent works have shown that large models pretrained on common visual learning tasks can provide useful representations for a wide range of specialized perception problems, as well as a variety of robotic manipulation tasks. While prior work on robotic manipulation has predominantly used frozen pretrained features, we demonstrate that in robotics this approach can fail to reach optimal performance, and that fine-tuning of the full model can lead to significantly better results. Unfortunately, fine-tuning disrupts the pretrained visual representation, and causes representational drift towards the fine-tuned task thus leading to a loss of the versatility of the original model. We introduce a method for lossless adaptation to address this shortcoming of classical fine-tuning. We demonstrate that appropriate placement of our parameter efficient adapters can significantly reduce the performance gap between frozen pretrained representations and full end-to-end fine-tuning without changes to the original representation and thus preserving original capabilities of the pretrained model. We perform a comprehensive investigation across three major model architectures (ViTs, NFNets, and ResNets), supervised (ImageNet-1K classification) and self-supervised pretrained weights (CLIP, BYOL, Visual MAE) in three manipulation task domains and 35 individual tasks, and demonstrate that our claims are strongly validated in various settings. Please see real world videos at https://sites.google.com/view/robo-adapters

Branch-Train-Merge: Embarrassingly Parallel Training of Expert Language Models

Margaret Li,Suchin Gururangan,Tim Dettmers,Mike Lewis,Tim Althoff,Noah A. Smith,Luke Zettlemoyer

We present Branch-Train-Merge (BTM), a communication-efficient algorithm for embarrassingly parallel training of large language models (LLMs). We show it is possible to independently train subparts of a new class of LLMs on different subsets of the data, eliminating the massive multi-node synchronization currently required to train LLMs. BTM learns a set of independent Expert LMs (ELMs), each specialized to a different textual domain, such as scientific or legal text. These ELMs can be added and removed to update data coverage, ensembled to generalize to new domains, or averaged to collapse back to a single LM for efficient inference. New ELMs are learned by branching from (mixtures of) ELMs in the current se t, further training on new domains, and then merging the resulting models back into the set for future use. Experiments show that BTM improves in- and out-of-domain perplexities as compared to GPT-style Transformer LMs, when controlling for training cost. Through extensive analysis, we show that these results are robust to different ELM initialization schemes, but require expert domain specialization; ensembles with random data splits do not perform well. Our results suggest that aggressive parallelism could be used to efficiently scale larger LMs in future work.

Logical Message Passing Networks with One-hop Inference on Atomic Formulas

Zihao Wang,Yangqiu Song,Ginny Wong,Simon See

Complex Query Answering (CQA) over Knowledge Graphs (KGs) has attracted a lot of attention to potentially support many applications. Given that KGs are usually incomplete, neural models are proposed to answer the logical queries by parameterizing set operators with complex neural networks. However, such methods usually train neural set operators with a large number of entity and relation embeddings from the zero, where whether and how the embeddings or the neural set operators contribute to the performance remains not clear. In this paper, we propose a simple framework for complex query answering that decomposes the KG embeddings from neural set operators. We propose to represent the complex queries into the query graph. On top of the query graph, we propose the Logical Message Passing Neural Network (LMPNN) that connects the local one-hop inferences on atomic formulas to the global logical reasoning for complex query answering. We leverage existing effective KG embeddings to conduct one-hop inferences on atomic formulas, the results of which are regarded as the messages passed in LMPNN. The reasoning process over the overall logical formulas is turned into the forward pass of LMPNN that incrementally aggregates local information to finally predict the answers' embeddings. The complex logical inference across different types of queries will then be learned from training examples based on the LMPNN architecture. Theoretically, our query-graph represenation is more general than the prevailing operator-tree formulation, so our approach applies to a broader range of complex KG queries. Empirically, our approach yields the new state-of-the-art neural CQA model. Our research bridges the gap between complex KG query answering tasks and the long-standing achievements of knowledge graph representation learning. Our implementation can be found at https://github.com/HKUST-KnowComp/LMPNN.

Noise-Robust De-Duplication at Scale

Emily Silcock,Luca D'Amico-Wong,Jinglin Yang,Melissa Dell

Identifying near duplicates within large, noisy text corpora has a myriad of applications that range from de-duplicating training datasets, reducing privacy risk, and evaluating test set leakage, to identifying reproduced news articles and literature within large corpora. Across these diverse applications, the overwhelming majority of work relies on N-grams. Limited efforts have been made to evaluate how well N-gram methods perform, in part because it is unclear how one could create an unbiased evaluation dataset for a massive corpus. This study uses the unique timeliness of historical news wires to create a 27,210 document dataset, with 122,876 positive duplicate pairs, for studying noise-robust de-duplication. The time-sensitivity of news makes comprehensive hand labelling feasible - despite the massive overall size of the corpus - as duplicates occur within a narrow date range. The study then develops and evaluates a range of de-duplication methods: hashing and N-gram overlap (which predominate in the literature), a contrastively trained bi-encoder, and a ``re-rank'' style approach combining a bi- and cross-encoder. The neural approaches significantly outperform hashing and N-gram overlap. We show that the bi-encoder scales well, de-duplicating a 10 million article corpus on a single GPU card in a matter of hours. We also apply our pre-trained model to the RealNews and patent portions of C4 (Colossal Clean Crawled Corpus), illustrating that a neural approach can identify many near duplicates missed by hashing, in the presence of various types of noise. The public release of our NEWS-COPY de-duplication dataset, codebase, and the pre-trained models will facilitate further research and applications.

P2PRISM - Peer to peer learning with individual prism for secure aggregation
Atul Sharma,Wei Chen,Joshua Christian Zhao,Qiang Qiu,Saurabh Bagchi,Somali Chaterji
Federated learning (FL) has made collaboration between nodes possible without explicit sharing of local data. However, it requires the participating nodes to trust the server and its model updates, the server itself being a critical node susceptible to failure and compromise. A loss of trust in the server and a demand to aggregate the model independently for oneself has led decentralized peer-to-peer learning (P2PL) to gain traction lately. In this paper, we highlight the never before exposed vulnerabilities of P2PL towards malicious attacks and how P2PL behaves differently from FL in such a malicious environment. We then present a robust defense - P2PRISM as a secure aggregation protocol for P2PL.

Multi-scale Attention for Diabetic Retinopathy Detection in Retinal Fundus Images
Temitope Ibrahim Amosa,Patrick Sebastian,Lila Iznita Izhar,Fatimat Adeola Adekola,Mardiyyah Adeola Salahudeen
The diagnosis and/or grading of diabetic retinopathy (DR) in the retina fundus has traditionally been done by physicians using manual procedures. However, there has been a significant demand for automated eye diagnostic and grading systems due to the constant rise in the number of persons with diabetes over the past few decades. An excellent diagnostic and predictive value for treatment planning exists with automatic DR grading based on retinal fundus pictures. With the majority of the current automated DR grading systems, it is exceedingly challenging to capture significant features because of the minor changes between severity levels. This paper presents a deep learning-based method for automatically assessing diabetic retinopathy in retina fundus pictures. This paper presents a deep learning-based method for automatically assessing diabetic retinopathy in retina fundus pictures. In order to increase the discriminative ability of the retrieved features, we implement a multi-scale attention mechanism within a deep convolutional neural network architecture in this research. Additionally, we provide a brand-new loss function termed modified grading loss that enhances the training convergence of the suggested strategy by taking into account the distance between various grades of distinct DR categories. The suggested technique is trained, validated, and tested using a dataset about diabetic retinopathy that is openly available. The experimental findings are presented to illustrate how well the suggested strategy competes.

Blessing from Experts: Super Reinforcement Learning in Confounded Environments
Jiayi Wang,Zhengling Qi,Chengchun Shi
We introduce super reinforcement learning in the batch setting, which takes the observed action as input for enhanced policy learning. In the presence of unmeasured confounders, the recommendations from human experts recorded in the observed data allow us to recover certain unobserved information. Including this information in the policy search, the proposed super reinforcement learning will yield a super policy that is guaranteed to outperform both the standard optimal policy and the behavior one (e.g., the expert’s recommendation). Furthermore, to address the issue of unmeasured confounding in finding super-policies, a number of non-parametric identification results are established. Finally, we develop two super-policy learning algorithms and derive their corresponding finite-sample regret guarantees.

****

Reinforcement Learning for Bandits with Continuous Actions and Large Context Spaces
Paul Duckworth,Bruno Lacerda,Katherine Vallis,Nick Hawes
We consider the challenging scenario of contextual bandits with continuous actions and large input ``context'' spaces, e.g. images. We posit that by modifying reinforcement learning (RL) algorithms for continuous control, we can outperform hand-crafted contextual bandit algorithms for continuous actions on standard ben

chmark datasets, i.e. vector contexts. We demonstrate that parametric policy networks outperform recently published tree-based policies in both average regret and costs on held-out samples. Furthermore, in contrast to previous work, we successfully demonstrate that RL algorithms can generalise contextual bandit problems with continuous actions to large context spaces. We obtain state-of-the-art performance using RL and significantly outperform previous methods on image contexts. Lastly, we introduce a new contextual bandits domain with multi-dimensional continuous action space and image context.

Explanation Uncertainty with Decision Boundary Awareness

Davin Hill,Aria Masoomi,Sandesh Ghimire,Max Torop,Jennifer Dy

Post-hoc explanation methods have become increasingly depended upon for understanding black-box classifiers in high-stakes applications, precipitating a need for reliable explanations. While numerous explanation methods have been proposed, recent works have shown that many existing methods can be inconsistent or unstable. In addition, high-performing classifiers are often highly nonlinear and can exhibit complex behavior around the decision boundary, leading to brittle or misleading local explanations. Therefore, there is an impending need to quantify the uncertainty of such explanation methods in order to understand when explanations are trustworthy. We introduce a novel uncertainty quantification method parameterized by a Gaussian Process model, which combines the uncertainty approximation of existing methods with a novel geodesic-based similarity which captures the complexity of the target black-box decision boundary. The proposed framework is highly flexible—it can be used with any black-box classifier and feature attribution method to amortize uncertainty estimates for explanations. We show theoretically that our proposed geodesic-based kernel similarity increases with the complexity of the decision boundary. Empirical results on multiple tabular and image datasets show that our decision boundary-aware uncertainty estimate improves understanding of explanations as compared to existing methods

SARNET: SARCASM VS TRUE-HATE DETECTION NETWORK

Harsh Mittal,Kartikeya Singh Chauhan,Anil Singh Parihar,Kavinder Singh,Ashutosh Pandey

At times hate speech detection classifiers miss the context of a sentence and flag a sarcastic tweet incorrectly. To tackle this problem by emphasising on the context of a tweet we propose SarNet. SarNet is a two-fold deep learning based model which follows a quasi-ternary labelling strategy and contextually classifies a tweet as hate, sarcastic or neither. The first module of SarNet is an ANN-BiLSTM based Pyramid Network used to calculate the hate and sarcastic probabilities of a sentence. The second module of the SarNet is the Nash Equalizer which stems from the concept of game theory and prisoner’s dilemma. It treats hate and sarcasm as two prisoners. A payoff matrix is constructed to calculate the true hate of the tweet. True hate considers the hate part of a tweet excluding the sarcastic part of the tweet. Thus, this gives a true estimate of the hate content in a tweet thereby decreasing the number of sarcastic tweets being falsely flagged as hate. Our proposed model is trained on state-of-the-art hate speech and sarcasm datasets in the English language. The precision, recall and F1 score of our proposed model is 0.93, 0.84 and 0.88 respectively. Comparison with state-of-the-art architectures demonstrated better performance of SarNet by a significant margin.

Learning Portable Skills by Identifying Generalizing Features with an Attention-Based Ensemble

Anita Taosheng De Mello Koch,Zhiyuan Zhou,Akhil Bagaria,Haotian Fu,Cameron Allen,George Konidaris

The ability to rapidly generalize is crucial for reinforcement learning to be practical in real-world tasks. However, generalization is complicated by the fact that, in many settings, some state features reliably support generalization while others do not. We consider the problem of learning generalizable policies and skills (in the form of options) by identifying feature sets that generalize acro ss instances. We propose an attention-ensemble approach, where a collection of minimally overlapping feature masks is learned, each of which individually maximizes performance on the source instance. Subsequent tasks are instantiated using the ensemble, and transfer performance is used to update the estimated probability that each feature set will generalize in the future. We show that our approach leads to fast policy generalization for eight tasks in the Procgen benchmark. We then show its use in learning portable options in Montezuma's Revenge, where it is able to generalize skills learned in the first screen to the remainder of the game.

****

Few-shot Backdoor Attacks via Neural Tangent Kernels
Jonathan Hayase,Sewoong Oh

In a backdoor attack, an attacker injects corrupted examples into the training set. The goal of the attacker is to cause the final trained model to predict the attacker's desired target label when a predefined trigger is added to test inputs. Central to these attacks is the trade-off between the success rate of the attack and the number of corrupted training examples injected. We pose this attack as a novel bilevel optimization problem: construct strong poison examples that maximize the attack success rate of the trained model. We use neural tangent kernels to approximate the training dynamics of the model being attacked and automatically learn strong poison examples. We experiment on subclasses of CIFAR-10 and ImageNet with WideResNet-34 and ConvNeXt architectures on periodic and patch trigger attacks and show that NTBA-designed poisoned examples achieve, for example, an attack success rate of 90% with ten times smaller number of poison examples injected compared to the baseline. We provided an interpretation of the NTBA-designed attacks using the analysis of kernel linear regression. We further demonstrate a vulnerability in overparametrized deep neural networks, which is revealed by the shape of the neural tangent kernel.

Quantitative Universal Approximation Bounds for Deep Belief Networks
Julian Sieber,Johann Gehringer

We show that deep belief networks with binary hidden units can approximate any multivariate probability density under very mild integrability requirements on the parental density of the visible nodes. The approximation is measured in the L^q-norm for $q\in[1,\infty]$ ($q=\infty$ corresponding to the supremum norm) and in Kullback-Leibler divergence. Furthermore, we establish sharp quantitative bounds on the approximation error in terms of the number of hidden units.

Hyperparameter Optimization through Neural Network Partitioning
Bruno Kacper Mlodozeniec,Matthias Reisser,Christos Louizos

Well-tuned hyperparameters are crucial for obtaining good generalization behavior in neural networks. They can enforce appropriate inductive biases, regularize the model and improve performance --- especially in the presence of limited data. In this work, we propose a simple and efficient way for optimizing hyperparameters inspired by the marginal likelihood, an optimization objective that requires no validation data. Our method partitions the training data and a neural network model into K data shards and parameter partitions, respectively. Each partition is associated with and optimized only on specific data shards. Combining these partitions into subnetworks allows us to define the "out-of-training-sample" loss of a subnetwork, i.e., the loss on data shards unseen by the subnetwork, as the objective for hyperparameter optimization. We demonstrate that we can apply this objective to optimize a variety of different hyperparameters in a single training run while being significantly computationally cheaper than alternative methods aiming to optimize the marginal likelihood for neural networks. Lastly, we also focus on optimizing hyperparameters in federated learning, where retraining and cross-validation are particularly challenging.

DiscoBAX - Discovery of optimal intervention sets in genomic experiment design
Clare Lyle,Arash Mehrjou,Pascal Notin,Andrew Jesson,Stefan Bauer,Yarin Gal,Patri

ck Schwab

The discovery of novel therapeutics to cure genetic pathologies relies on the identification of the different genes involved in the underlying disease mechanism. With billions of potential hypotheses to test, an exhaustive exploration of the entire space of potential interventions is impossible in practice. Sample-efficient methods based on active learning or bayesian optimization bear the promise of identifying interesting targets using the least experiments possible. However, genomic perturbation experiments typically rely on proxy outcomes measured in biological model systems that may not completely correlate with the outcome of interventions in humans. In practical experiment design, one aims to find a set of interventions which maximally move a target phenotype via a diverse set of mechanisms in order to reduce the risk of failure in future stages of trials. To that end, we introduce DiscoBAX — a sample-efficient algorithm for the discovery of genetic interventions that maximize the movement of a phenotype in a direction of interest while covering a diverse set of underlying mechanisms. We provide theoretical guarantees on the optimality of the approach under standard assumptions, conduct extensive experiments in synthetic and real-world settings relevant to genomic discovery and demonstrate that DiscoBAX outperforms state-of-the-art active learning and Bayesian optimization methods in this task. Better methods for selecting effective and diverse perturbations in biological systems could enable researchers to potentially discover novel therapeutics for a range of genetically-driven diseases.

How to Enable Uncertainty Estimation in Proximal Policy Optimization

Eugene Bykovets,Yannick Metz,Mennatallah El-Assady,Daniel A. Keim,Joachim M. Buhmann

While deep reinforcement learning (RL) agents have showcased strong results across many domains, a major concern is their inherent opaqueness and the safety of such systems in real-world use cases. To overcome these issues, we need agents that can quantify their uncertainty and detect out-of-distribution (OOD) states. Existing uncertainty estimation techniques, like Monte-Carlo Dropout or Deep Ensembles, have not seen widespread adoption in on-policy deep RL. We posit that this is due to two reasons: concepts like uncertainty and OOD states are not well defined compared to supervised learning, especially for on-policy RL methods. Secondly, available implementations and comparative studies for uncertainty estimation methods in RL have been limited. To overcome the first gap, we propose definitions of uncertainty and OOD for Actor-Critic RL algorithms, namely, proximal policy optimization (PPO), and present possible applicable measures. In particular, we discuss the concepts of value and policy uncertainty. The second point is addressed by implementing different uncertainty estimation methods and comparing them across a number of environments. The OOD detection performance is evaluated via a custom evaluation benchmark of in-distribution (ID) and OOD states for various RL environments. We identify a trade-off between reward and OOD detection performance. To overcome this, we formulate a Pareto optimization problem in which we simultaneously optimize for reward and OOD detection performance. We show experimentally that the recently proposed method of Masksembles strikes a favourable balance among the survey methods, enabling high-quality uncertainty estimation and OOD detection while matching the performance of original RL agents.

Joint-Predictive Representations for Multi-Agent Reinforcement Learning

Mingxiao Feng,Wengang Zhou,Yaodong Yang,Houqiang Li

The recent advances in reinforcement learning have demonstrated the effectiveness of vision-based self-supervised learning (SSL). However, the main efforts on this direction have been paid on single-agent setting, making multi-agent reinforcement learning~(MARL) lags thus far. There are two significant obstacles that prevent applying off-the-shelf SSL approaches with MARL on a partially observable multi-agent system : (a) each agent only gets a partial observation, and (b) previous SSL approaches only take consistent temporal representations into account, while ignoring the characterization that captures the interaction and fusion among agents. In this paper, we propose \textbf{M}ulti-\textbf{A}gent \textbf{Jo

}int-Predictive \textbf{R}epresentations~(MAJOR), a novel framework to explore self-supervised learning on cooperative MARL. Specifically, we treat the latent representations of local observations of all agents as the sequence of masked contexts of the global state, and we then learn effective representations by predicting the future latent representations for each agent with the help of the agent-level information interactions in a joint transition model. We have conducted extensive experiments on wide-range MARL environments, including both vision-based and state-based scenarios, and show that our proposed MAJOR achieves superior asymptotic performance and sample efficiency against other state-of-the-art methods.

Symmetries, Flat Minima and the Conserved Quantities of Gradient Flow

Bo Zhao,Iordan Ganev,Robin Walters,Rose Yu,Nima Dehmamy

Empirical studies of the loss landscape of deep networks have revealed that many local minima are connected through low-loss valleys. Yet, little is known about the theoretical origin of such valleys. We present a general framework for finding continuous symmetries in the parameter space, which carve out low-loss valleys. Our framework uses equivariances of the activation functions and can be applied to different layer architectures. To generalize this framework to nonlinear neural networks, we introduce a novel set of nonlinear, data-dependent symmetries. These symmetries can transform a trained model such that it performs similarly on new samples, which allows ensemble building that improves robustness under certain adversarial attacks. We then show that conserved quantities associated with linear symmetries can be used to define coordinates along low-loss valleys. The conserved quantities help reveal that using common initialization methods, gradient flow only explores a small part of the global minimum. By relating conserved quantities to convergence rate and sharpness of the minimum, we provide insights on how initialization impacts convergence and generalizability.

DP-SGD-LF: Improving Utility under Differentially Private Learning via Layer Freezing

Qiaoyue Tang,Mathias Lécuyer

Differentially Private SGD (DP-SGD) is a widely known substitute for SGD to train deep learning models with privacy guarantees. However, privacy guarantees come at cost in model utility. The key DP-SGD steps responsible for this utility cost are per-sample gradient clipping, which introduces bias, and adding noise to the aggregated (clipped) gradients, which increases the variance of model updates. Inspired by the observation that different layers in a neural network often converge at different rates following a bottom-up pattern, we incorporate layer freezing into DP-SGD to increase model utility at fixed privacy budget. Through theoretical analysis and empirical evidence we show that layer freezing improves model utility, by reducing both the bias and variance introduced by gradient clipping and noising. These improvements in turn lead to better model accuracy, and empirically generalize over multiple datasets, models, and privacy budgets.

Explainability as statistical inference

Hugo Henri Joseph Senetaire,Damien Garreau,Jes Frellsen,Pierre-Alexandre Mattei

A wide variety of model explanation approaches have been proposed in recent years, all guided by very different rationales and heuristics. In this paper, we take a new route and cast interpretability as a statistical inference problem. We propose a general deep probabilistic model designed to produce interpretable predictions. The model’s parameters can be learned via maximum likelihood, and the method can be adapted to any predictor network architecture, and any type of prediction problem. Our method is a case of amortized interpretability models, where a neural network is used as a selector to allow for fast interpretation at inference time. Several popular interpretability methods are shown to be particular cases of regularised maximum likelihood for our general model. We propose new datasets with ground truth selection which allow for the evaluation of the features importance map. Using these datasets, we show experimentally that using multip

le imputation provides more reasonable interpretation.

Concept-based Explanations for Out-of-Distribution Detectors
Jihye Choi,Jayaram Raghuram,Ryan Feng,Jiefeng Chen,Somesh Jha,Atul Prakash
Out-of-distribution (OOD) detection plays a crucial role in ensuring the safe deployment of deep neural network (DNN) classifiers.
While a myriad of methods have focused on improving the performance of OOD detectors, a critical gap remains in interpreting their decisions.
We help bridge this gap by providing explanations for OOD detectors based on learned high-level concepts.
We first propose two new metrics for assessing the effectiveness of a particular set of concepts for explaining OOD detectors: 1) $\textit{detection completeness}$, which quantifies the sufficiency of concepts for explaining an OOD-detector's decisions, and 2) $\textit{concept separability}$, which captures the distributional separation between in-distribution and OOD data in the concept space.
Based on these metrics, we propose a framework for learning a set of concepts that satisfy the desired properties of detection completeness and concept separability, and demonstrate the framework's effectiveness in providing concept-based explanations for diverse OOD detection techniques.
We also show how to identify prominent concepts that contribute to the detection results via a modified Shapley value-based importance score.

FaDIn: Fast Discretized Inference for Hawkes Processes with General Parametric Kernels
Guillaume Staerman,Cédric Allain,Alexandre Gramfort,Thomas Moreau
Temporal point processes (TPP) are a natural tool for modeling event-based data. Among all TPP models, Hawkes processes have proven to be the most widely used, mainly due to their simplicity and computational ease when considering exponential or non-parametric kernels. Although non-parametric kernels are an option, such models require large datasets. While exponential kernels are more data efficient and relevant for certain applications where events immediately trigger more events, they are ill-suited for applications where latencies need to be estimated, such as in neuroscience. This work aims to offer an efficient solution to TPP inference using general parametric kernels with finite support. The developed solution consists of a fast L2 gradient-based solver leveraging a discretized version of the events. After supporting the use of discretization theoretically, the statistical and computational efficiency of the novel approach is demonstrated through various numerical experiments. Finally, the effectiveness of the method is evaluated by modeling the occurrence of stimuli-induced patterns from brain signals recorded with magnetoencephalography (MEG). Given the use of general parametric kernels, results show that the proposed approach leads to a more plausible estimation of pattern latency compared to the state-of-the-art.

Summarization Programs: Interpretable Abstractive Summarization with Neural Modular Trees
Swarnadeep Saha,Shiyue Zhang,Peter Hase,Mohit Bansal
Current abstractive summarization models either suffer from a lack of clear interpretability or provide incomplete rationales by only highlighting parts of the source document. To this end, we propose the Summarization Program (SP), an interpretable modular framework consisting of an (ordered) list of binary trees, each encoding the step-by-step generative process of an abstractive summary sentence from the source document. A Summarization Program contains one root node per summary sentence, and a distinct tree connects each summary sentence (root node) to the document sentences (leaf nodes) from which it is derived, with the connecting nodes containing intermediate generated sentences. Edges represent different modular operations involved in summarization such as sentence fusion, compression, and paraphrasing. We first propose an efficient best-first search method over neural modules, SP-Search that identifies SPs for human summaries by directly optimizing for ROUGE scores. Next, using these programs as automatic supervisio

n, we propose seq2seq models that generate Summarization Programs, which are then executed to obtain final summaries. We demonstrate that SP-Search effectively represents the generative process behind human summaries using modules that are typically faithful to their intended behavior. We also conduct a simulation study to show that Summarization Programs improve the interpretability of summarization models by allowing humans to better simulate model reasoning. Summarization Programs constitute a promising step toward interpretable and modular abstractive summarization, a complex task previously addressed primarily through blackbox end-to-end neural systems.

Planning with Large Language Models for Code Generation

Shun Zhang,Zhenfang Chen,Yikang Shen,Mingyu Ding,Joshua B. Tenenbaum,Chuang Gan

Existing large language model-based code generation pipelines typically use beam search or sampling algorithms during the decoding process. Although the programs they generate achieve high token-matching-based scores, they often fail to compile or generate incorrect outputs. The main reason is that conventional Transformer decoding algorithms may not be the best choice for code generation. In this work, we propose a novel Transformer decoding algorithm, Planning-Guided Transformer Decoding (PG-TD), that uses a planning algorithm to do lookahead search and guide the Transformer to generate better programs. Specifically, instead of simply optimizing the likelihood of the generated sequences, the Transformer makes use of a planner that generates candidate programs and tests them on public test cases. The Transformer can therefore make more informed decisions and generate tokens that will eventually lead to higher-quality programs. We also design a mechanism that shares information between the Transformer and the planner to make our algorithm computationally efficient. We empirically evaluate our framework with several large language models as backbones on public coding challenge benchmarks, showing that 1) it can generate programs that consistently achieve higher performance compared with competing baseline methods; 2) it enables controllable code generation, such as concise codes and highly-commented codes by optimizing modified objective.

Unleash Model Capacity for Universal Dense Retrieval by Task Specialty Optimization

Wenzheng Zhang,Chenyan Xiong,Karl Stratos,Arnold Overwijk

Universal dense retrieval, with one unified representation space to empower various retrieval scenarios, has many appealing advantages in simplicity, efficiency, and potential to break echo chambers with cross-scenario information access. However, standard multi-task trained dense retrievers often fail to meet the accuracy of scenario-specific models. In this paper, we analyze the multi-task learning in universal retrieval and show that the model capacity is not the main bottleneck. It is the optimization failed to fully utilize the network parameters to capture task-specific signals. This motivated our development of TACO-DR, which conducts multi-task learning for universal retrieval with TAsk speCialty Optimization. TACO-DR dynamically adjusts the learning rate for each parameter regrading each task based on its task-specific sensitivity, to encourage parameters to better capture task specific signals. On the KILT benchmark, TACO-DR outperforms various multi-task learning methods and achieves better overall accuracy than single-task models. Our analysis shows that TACO-DR better utilizes the model capacity with more task-specific parameters. Our code and model checkpoints will be open-sourced.

Training Equilibria in Reinforcement Learning

Lauro Langosco,David Krueger,Adam Gleave

In partially observable environments, reinforcement learning algorithms such as policy gradient and Q-learning may have multiple equilibria---policies that are stable under further training---and can converge to policies that are strictly suboptimal.

Prior work blames insufficient exploration, but suboptimal equilibria can arise despite full exploration and other favorable circumstances like a flexible polic

y parametrization.
We show theoretically that the core problem is that in partially observed environments, an agent's past actions induce a distribution on hidden states.
Equipping the policy with memory helps it model the hidden state and leads to convergence to a higher reward equilibrium, \emph{even when there exists a memoryless optimal policy}.
Experiments show that
policies with insufficient memory tend to learn to use the environment as auxiliary memory,and parameter noise helps policies escape suboptimal equilibria.

Hebbian Deep Learning Without Feedback
Adrien Journé,Hector Garcia Rodriguez,Qinghai Guo,Timoleon Moraitis
Recent approximations to backpropagation (BP) have mitigated many of BP's computational inefficiencies and incompatibilities with biology, but important limitations still remain. Moreover, the approximations significantly decrease accuracy in benchmarks, suggesting that an entirely different approach may be more fruitful. Here, grounded on recent theory for Hebbian learning in soft winner-take-all networks, we present multilayer SoftHebb, i.e. an algorithm that trains deep neural networks, without any feedback, target, or error signals. As a result, it achieves efficiency by avoiding weight transport, non-local plasticity, time-locking of layer updates, iterative equilibria, and (self-) supervisory or other feedback signals – which were necessary in other approaches. Its increased efficiency and biological compatibility do not trade off accuracy compared to state-of-the-art bio-plausible learning, but rather improve it. With up to five hidden layers and an added linear classifier, accuracies on MNIST, CIFAR-10, STL-10, and ImageNet, respectively reach 99.4%, 80.3%, 76.2%, and 27.3%. In conclusion, SoftHebb shows with a radically different approach from BP that Deep Learning over few layers may be plausible in the brain and increases the accuracy of bio-plausible machine learning. Code is available at https://github.com/NeuromorphicComputing/SoftHebb.

A Simulation-based Framework for Robust Federated Learning to Training-time Attacks
Wanyun Xie,Thomas Pethick,Ali Ramezani-Kebrya,Volkan Cevher
Well-known robust aggregation schemes in federated learning (FL) are shown to be vulnerable to an informed adversary who can tailor training-time attacks [Fang et al., Xie et al.]. We frame robust distributed learning problem as a game between a server and an adversary that is able to optimize strong training-time attacks. We introduce RobustTailor, a simulation-based framework that prevents the adversary from being omniscient. The simulated game we propose enjoys theoretical guarantees through a regret analysis. RobustTailor improves robustness to training-time attacks significantly while preserving almost the same privacy guarantees as standard robust aggregation schemes in FL. Empirical results under challenging attacks show that RobustTailor performs similar to an upper bound with perfect knowledge of honest clients.

Key Design Choices for Double-transfer in Source-free Unsupervised Domain Adaptation
Andrea Maracani,Raffaello Camoriano,Elisa Maiettini,Davide Talon,Lorenzo Rosasco,Lorenzo Natale
Fine-tuning and Domain Adaptation emerged as effective strategies for efficiently transferring deep learning models to new target tasks. However, target domain labels are not accessible in many real-world scenarios. This led to the development of Unsupervised Domain Adaptation (UDA) methods, which only employ unlabeled target samples. Furthermore, efficiency and privacy requirements may also prevent the use of source domain data during the adaptation stage. This particularly challenging setting, known as Source-free Unsupervised Domain Adaptation (SF-UDA), is still understudied. In this paper, we systematically analyze the impact of the main design choices in SF-UDA through a large-scale empirical study on 500 models and 74 domain pairs. We identify the normalization approach, pre-training

strategy, and backbone architecture as the most critical factors. Based on our observations, we propose recipes to best tackle SF-UDA scenarios. Moreover, we show that SF-UDA performs competitively also beyond standard benchmarks and backbone architectures, performing on par with UDA at a fraction of the data and computational cost. Experimental data and code will be released upon acceptance.

PALM: Preference-based Adversarial Manipulation against Deep Reinforcement Learning

Fengshuo Bai,Runze Liu,Yaodong Yang,Yali Du

To improve the robustness of DRL agents, it is important to study their vulnerability under adversarial attacks that would lead to extreme behaviors desired by adversaries. Preference-based RL (PbRL) aims for learning desired behaviors with human preferences. In this paper, we propose PALM, a preference-based adversarial manipulation method against DRL agents which adopts human preferences to perform targeted attacks with the assistance of an intention policy and a weighting function. The intention policy is trained based on the PbRL framework to guide the adversarial policy to mitigate restrictions of the victim policy during exploration, and the weighting function learns weight assignment to improve the performance of the adversarial policy. Theoretical analysis demonstrates that PALM converges to critical points under some mild conditions. Empirical results on a few manipulation tasks of Meta-world show that PALM exceeds the performance of state-of-the-art adversarial attack methods under the targeted setting. Additionally, we show the vulnerability of the offline RL agents by fooling them into behaving as human desires on several Mujoco tasks. Our code and videos are available in https://sites.google.com/view/palm-adversarial-attack.

Equivariance-aware Architectural Optimization of Neural Networks

Kaitlin Maile,Dennis George Wilson,Patrick Forré

Incorporating equivariance to symmetry groups as a constraint during neural network training can improve performance and generalization for tasks exhibiting those symmetries, but such symmetries are often not perfectly nor explicitly present. This motivates algorithmically optimizing the architectural constraints imposed by equivariance. We propose the equivariance relaxation morphism, which preserves functionality while reparameterizing a group equivariant layer to operate with equivariance constraints on a subgroup, as well as the $[G]$-mixed equivariant layer, which mixes layers constrained to different groups to enable within-layer equivariance optimization. We further present evolutionary and differentiable neural architecture search (NAS) algorithms that utilize these mechanisms respectively for equivariance-aware architectural optimization. Experiments across a variety of datasets show the benefit of dynamically constrained equivariance to find effective architectures with approximate equivariance.

Unsupervised Non-Parametric Signal Separation Using Bayesian Neural Networks

Alexander V Belikov,Alessandro Montanari,Emmanuel Simon Moulin

Bayesian neural networks (BNN) take the best from two worlds: the one of flexible and scalable neural networks and the one of probabilistic graphical models, the latter allowing for probabilistic interpretation of inference results.

We make one extra step towards unification of these two domains and render BNN as an elementary unit of abstraction in the framework of probabilistic modeling, which allows us to promote well-known distributions to distribution fields.

We use transformations to obtain field versions of several popular distributions and demonstrate the utility of our approach on the problem of signal/background separation.

Starting from prior knowledge that a certain region of space contains predominantly one of the components, in an unsupervised and non-parametric manner, we recover the representation of both previously unseen components as well as their proportions.

SPIDER: Searching Personalized Neural Architecture for Federated Learning

Erum Mushtaq,Chaoyang He,Jie Ding,Salman Avestimehr

Federated learning (FL) is an efficient learning framework that assists distributed machine learning when data cannot be shared with a centralized server. Recent advancements in FL use predefined architecture-based learning for all the clients. However, given that clients' data are invisible to the server and data distributions are non-identical across clients, a predefined architecture discovered in a centralized setting may not be an optimal solution for all the clientsin FL. Motivated by this challenge, we introduce SPIDER, an algorithmic framework that aims to Search Personalized neural architecture for feDERated learning. SPIDER is designed based on two unique features: (1) alternately optimizing one architecture-homogeneous global model (Supernet) in a generic FL manner and one architecture-heterogeneous local model that is connected to the global model by weight-sharing-based regularization (2) achieving architecture-heterogeneous local model by an operation-level perturbation based neural architecture search method. Experimental results demonstrate that SPIDER outperforms other state-of-the-art personalization methods with much fewer times of hyperparameter tuning.
****
On Gradient Descent Convergence beyond the Edge of Stability
Lei Chen,Joan Bruna
Gradient Descent (GD) is a powerful workhorse of modern machine learning thanks to its scalability and efficiency in high-dimensional spaces. Its ability to find local minimisers is only guaranteed for losses with Lipschitz gradients, where it can be seen as a `bona-fide' discretisation of an underlying gradient flow. Yet, many ML setups involving overparametrised models do not fall into this problem class, which has motivated research beyond the so-called ``Edge of Stability'' (EoS), where the step-size crosses the admissibility threshold inversely proportional to the Lipschitz constant above. Perhaps surprisingly, GD has been empirically observed to still converge regardless of local instability and oscillatory behavior.

The incipient theoretical analysis of this phenomena has mainly focused in the overparametrised regime, where the effect of choosing a large learning rate may be associated to a `Sharpness-Minimisation' implicit regularisation within the manifold of minimisers, under appropriate asymptotic limits. In contrast, in this work we directly examine the conditions for such unstable convergence, focusing on simple, yet representative, learning problems. Specifically, we characterize a local condition involving third-order derivatives that stabilizes oscillations of GD above the EoS, and leverage such property in a teacher-student setting, under population loss. Finally, focusing on Matrix Factorization, we establish a non-asymptotic `Local Implicit Bias' of GD above the EoS, whereby quasi-symmetric initializations converge to symmetric solutions --- where sharpness is minimum amongst all minimisers.

Synaptic Dynamics Realize First-order Adaptive Learning and Weight Symmetry
Yukun Yang,Peng Li
Gradient-based first-order adaptive optimization methods such as the Adam optimizer are prevalent in training artificial networks, achieving the state-of-the-art results. This work attempts to answer the question whether it is viable for biological neural systems to adopt such optimization methods. To this end, we demonstrate a realization of the Adam optimizer using biologically-plausible mechanisms in synapses. The proposed learning rule has clear biological correspondence, runs continuously in time, and achieves performance to comparable Adam's. In addition, we present a new approach, inspired by the predisposition property of synapses observed in neuroscience, to circumvent the biological implausibility of the weight transport problem in backpropagation (BP). With only local information and no separate training phases, this method establishes and maintains weight symmetry in the forward and backward signaling paths, and is applicable to the proposed biologically plausible Adam learning rule. The aforementioned mechanisms may shed light on the way in which biological synaptic dynamics facilitate learning.
****

FedAvg Converges to Zero Training Loss Linearly: The Power of Overparameterized Multi-Layer Neural Networks
Bingqing Song,Prashant Khanduri,Xinwei Zhang,Jinfeng Yi,Mingyi Hong
Federated Learning (FL) is a distributed learning paradigm that allows multiple clients to learn a joint model by utilizing privately held data at each client. Significant research efforts have been devoted to develop advanced algorithms that deal with the situation where the data at individual clients have different distributions (i.e., the data heterogeneity issue). In this work, we show that data heterogeneity can be dealt from a different perspective. That is, by utilizing a certain overparameterized multi-layer neural network at each client, even the vanilla FedAvg (a.k.a. the Local SGD) algorithm can accurately optimize the training problem. Specifically, when each client has a neural network with one wide layer of size N (where N is the number of total training samples), followed by layers of smaller widths, FedAvg converges linearly to a solution that achieves (almost) zero training loss, without requiring any assumptions on the data distributions at each client. To our knowledge, this is the first work that demonstrates such resilience to data heterogeneity
for FedAvg when trained on multi-layer neural networks. Our experiments also confirm that, neural network of large size can achieve better and more stable performance for FL problems.

Robust Graph Representation Learning via Predictive Coding
Billy Byiringiro,Tommaso Salvatori,Thomas Lukasiewicz
Graph neural networks have recently shown outstanding results in diverse types of tasks in machine learning, providing interdisciplinary state-of-the-art performance on structured data. However, they have been proved to be vulnerable to imperceptible adversarial attacks and shown to be unfit for out-of-distribution generalisation.
Here, we address this problem by introducing a novel message-passing scheme based on the theory of predictive coding, an energy-based alternative to back-propagation that has its roots in neuroscience.
As both graph convolution and predictive coding can be seen as low-pass filtering mechanisms, we postulate that predictive coding adds a second efficient filter to the messaging passing process which enhances the robustness of the learned representation. Through an extensive set of experiments, we show that the proposed model attains comparable performance to its graph convolution network counterpart, delivering strictly better performance on inductive tasks. Most importantly, we show that the energy minimization enhances the robustness of the produced presentation and can be leveraged to further calibrate our models and provide representations that are more robust against advanced graph adversarial attacks.

****
Accelerating Hamiltonian Monte Carlo via Chebyshev Integration Time
Jun-Kun Wang,Andre Wibisono
Hamiltonian Monte Carlo (HMC) is a popular method in sampling. While there are quite a few works of studying this method on various aspects, an interesting question is how to choose its integration time to achieve acceleration. In this work, we consider accelerating the process of sampling from a distribution $\pi(x) \propto \exp(-f(x))$ via HMC via time-varying integration time. When the potential f is L-smooth and m-strongly convex, i.e. for sampling from a log-smooth and strongly log-concave target distribution π, it is known that under a constant integration time, the number of iterations that ideal HMC takes to get an ϵ Wasserstein-2 distance to the target π is $O(\kappa \log \frac{1}{\epsilon})$, where $\kappa := \frac{L}{m}$ is the condition number. We propose a scheme of time-varying integration time based on the roots of Chebyshev polynomials. We show that in the case of quadratic potential f, i.e. when the target π is a Gaussian distribution, ideal HMC with this choice of integration time only takes $O(\sqrt{\kappa} \log \frac{1}{\epsilon})$ number of iterations to reach Wasserstein-2 distance less than ϵ; this improvement on the dependence on condition number is akin to acceleration in optimization. The desi

gn and analysis of HMC with the proposed integration time is built on the tools of Chebyshev polynomials. Experiments find the advantage of adopting our scheme of time-varying integration time even for sampling from distributions with smooth strongly convex potentials that are not quadratic.

Multi-Hypothesis 3D human pose estimation metrics favor miscalibrated distributions

Pawe■ A. Pierzchlewicz,R. James Cotton,Mohammad Bashiri,Fabian H. Sinz

Due to depth ambiguities and occlusions, lifting 2D poses to 3D is a highly ill-posed problem. Well-calibrated distributions of possible poses can make these ambiguities explicit and preserve the resulting uncertainty for downstream tasks. This study shows that previous attempts, which account for these ambiguities via multiple hypotheses generation, produce miscalibrated distributions. We identify that miscalibration can be attributed to the use of sample-based metrics such as $\operatorname{minMPJPE}$. In a series of simulations, we show that minimizing $\operatorname{minMPJPE}$, as commonly done, should converge to the correct mean prediction. However, it fails to correctly capture the uncertainty, thus resulting in a miscalibrated distribution. To mitigate this problem, we propose an accurate and well-calibrated model called Conditional Graph Normalizing Flow (cGNFs). Our model is structured such that a single cGNF can estimate both conditional and marginal densities within the same model - effectively solving a zero-shot density estimation problem. We evaluate cGNF on the Human 3.6M dataset and show that cGNF provides a well-calibrated distribution estimate while being close to state-of-the-art in terms of overall $\operatorname{minMPJPE}$. Furthermore, cGNF outperforms previous methods on occluded joints while it remains well-calibrated.

Learning to Abstain from Uninformative Data

Yikai Zhang,Songzhu Zheng,Mina Dalirrooyfard,Pengxiang Wu,Anderson Schneider,Yuriy Nevmyvaka,Chao Chen

Learning and decision making in domains with naturally high noise-to-signal ratios – such as Finance or Healthcare – can be challenging yet extremely important. In this paper, we study a problem of learning and decision making under a general noisy generative process. The distribution has a significant proportion of uninformative data with high noise in label, while part of the data contains useful information represented by low label noise. This dichotomy is present during both training and inference, which requires the proper handling of uninformative data at testing time. We propose a novel approach to learn under these conditions via a loss inspired by the selective learning theory. By minimizing the loss, the model is guaranteed to make a near-optimal decision by distinguishing informative data from the uninformative data and making predictions. We build upon the strength of our theoretical guarantees by describing an iterative algorithm, which jointly optimizes both a predictor and a selector, and evaluate its empirical performance under a variety of settings.

Order Matters: Agent-by-agent Policy Optimization

Xihuai Wang,Zheng Tian,Ziyu Wan,Ying Wen,Jun Wang,Weinan Zhang

While multi-agent trust region algorithms have achieved great success empirically in solving coordination tasks, most of them, however, suffer from a non-stationarity problem since agents update their policies simultaneously. In contrast, a sequential scheme that updates policies agent-by-agent provides another perspective and shows strong performance. However, sample inefficiency and lack of monotonic improvement guarantees for each agent are still the two significant challenges for the sequential scheme. In this paper, we propose the \textbf{A}gent-by-\textbf{a}gent \textbf{P}olicy \textbf{O}ptimization (A2PO) algorithm to improve the sample efficiency and retain the guarantees of monotonic improvement for each agent during training. We justify the tightness of the monotonic improvement bound compared with other trust region algorithms. From the perspective of sequentially updating agents, we further consider the effect of agent updating order and extend the theory of non-stationarity into the sequential update scheme. To evaluate A2PO, we conduct a comprehensive empirical study on four benchmarks: StarCraftII, Multi-agent MuJoCo, Multi-agent Particle Environment, and Google Research Football full game scenarios. A2PO consistently outperforms strong baselines.

AQuaMaM: An Autoregressive, Quaternion Manifold Model for Rapidly Estimating Complex SO(3) Distributions

Michael A. Alcorn

Accurately modeling complex, multimodal distributions is necessary for optimal decision-making, but doing so for rotations in three-dimensions, i.e., the SO(3) group, is challenging due to the curvature of the rotation manifold. The recently described implicit-PDF (IPDF) is a simple, elegant, and effective approach for learning arbitrary distributions on SO(3) up to a given precision. However, inference with IPDF requires N forward passes through the network's final multilayer perceptron—where N places an upper bound on the likelihood that can be calculated by the model—which is prohibitively slow for those without the computational resources necessary to parallelize the queries. In this paper, I introduce AQuaMaM, a neural network capable of both learning complex distributions on the rotation manifold and calculating exact likelihoods for query rotations in a single forward pass. Specifically, AQuaMaM autoregressively models the projected components of unit quaternions as a mixture of uniform distributions that partition their geometrically-restricted domain of values. On an "infinite" toy dataset with ambiguous viewpoints, AQuaMaM rapidly converges to a sampling distribution closely matching the true data distribution. In contrast, the sampling distribution for IPDF dramatically diverges from the true data distribution, despite IPDF approaching its theoretical minimum evaluation loss during training. On a constructed dataset of 500,000 renders of a die in different rotations, an AQuaMaM model trained from scratch reaches a log-likelihood 14% higher than an IPDF model using a pretrained ResNet-50. Further, compared to IPDF, AQuaMaM uses 24% fewer parameters, has a prediction throughput 52$\times$ faster on a single GPU, and converges in a similar amount of time during training.

****

Conformal Prediction is Robust to Label Noise

Bat-Sheva Einbinder,Stephen Bates,Anastasios Nikolas Angelopoulos,Asaf Gendler,Yaniv Romano

We study the robustness of conformal prediction—a powerful tool for uncertainty quantification—to label noise. Our analysis tackles both regression and classification problems, characterizing when and how it is possible to construct uncertainty sets that correctly cover the unobserved noiseless ground truth labels. Through stylized theoretical examples and practical experiments, we argue that naïve conformal prediction covers the noiseless ground truth label unless the noise distribution is adversarially designed. This leads us to believe that correcting for label noise is unnecessary except for pathological data distributions or noise sources. In such cases, we can also correct for noise of bounded size in the conformal prediction algorithm in order to ensure correct coverage of the ground truth labels without score or data regularity.

Φ-DVAE: Learning Physically Interpretable Representations with Nonlinear Filtering

Alex John Glyn-Davies,Connor Duffin,Omer Deniz Akyildiz,Mark Girolami

Incorporating unstructured data into physical models is a challenging problem that is emerging in data assimilation. Traditional approaches focus on well-defined observation operators whose functional forms are typically assumed to be known. This prevents these methods from achieving a consistent model-data synthesis in configurations where the mapping from data-space to model-space is unknown. To address these shortcomings, in this paper we develop a physics-informed dynamical variational autoencoder (Φ-DVAE) for embedding diverse data streams into time-evolving physical systems described by differential equations. Our approach combines a standard (possibly nonlinear) filter for the latent state-space mod el and a VAE, to embed the unstructured data stream into the latent dynamical system. A variational Bayesian framework is used for the joint estimation of the embedding, latent states, and unknown system parameters. To demonstrate the method, we look at three examples: video datasets generated by the advection and Korteweg-de Vries partial differential equations, and a velocity field generated by the Lorenz-63 system. Comparisons with relevant baselines show that the Φ-DVAE provides a data efficient dynamics encoding methodology that is competitive with standard approaches, with the added benefit of incorporating a physically interpretable latent space.

Revisiting Structured Dropout

Yiren Zhao,Oluwatomisin Dada,Xitong Gao,Robert D. Mullins

Large neural networks are often overparameterised and prone to overfitting, Dropout is a widely used regularization technique to combat overfitting and improve model generalization. However, unstructured Dropout is not always effective for specific network architectures and this has led to the formation of multiple structured Dropout approaches to improve model performance and, sometimes, reduce the computational resources required for inferencing. In this work we revisit structured Dropout comparing different Dropout approaches on natural language processing and computer vision tasks for multiple state-of-the-art networks. Additionally, we devise an approach to structured Dropout we call \textbf{\emph{ProbDropBlock}} which drops contiguous blocks from feature maps with a probability given by the normalized feature salience values. We find that with a simple scheduling strategy the proposed approach to structured Dropout consistently improved model performance compared to baselines and other Dropout approaches on a diverse range of tasks and models. In particular, we show \textbf{\emph{ProbDropBlock}} improves RoBERTa finetuning on MNLI by 0.22%, and training of ResNet50 on ImageNet by 0.28%.

****

Flatter, Faster: Scaling Momentum for Optimal Speedup of SGD

Aditya Cowsik,Tankut Can,Paolo Glorioso

Commonly used optimization algorithms often show a trade-off between good generalization and fast training times. For instance, stochastic gradient descent (SGD) tends to have good generalization; however, adaptive gradient methods have superior training times. Momentum can help accelerate training with SGD, but so far there has been no principled way to select the momentum hyperparameter. Here we study implicit bias arising from the interplay between SGD with label noise and momentum in the training of overparameterized neural networks. We find that scaling the momentum hyperparameter $1-\beta$ with the learning rate to the power of $2/3$ maximally accelerates training, without sacrificing generalization. To analytically derive this result we develop an architecture-independent framework, where the main assumption is the existence of a degenerate manifold of global minimizers, as is natural in overparameterized models. Training dynamics display the emergence of two characteristic timescales that are well-separated for generic values of the hyperparameters. The maximum acceleration of training is reached when these two timescales meet, which in turn determines the scaling limit we propose. We perform experiments, including matrix sensing and ResNet on CIFAR10, which provide evidence for the robustness of these results.

Learning implicit hidden Markov models using neural likelihood-free inference

Sanmitra Ghosh,Paul Birrell,Daniela De Angelis

Likelihood-free inference methods for implicit models based on neural conditional density estimation were shown to drastically reduce the simulation burden in comparison to classical methods such as ABC. However, when applied in the context of any latent variable model, such as a Hidden Markov model (HMM), these methods are designed to only estimate the parameters rather than the joint posterior distribution of both the parameters and the hidden states. Naive application of these methods to a HMM, ignoring the inference of this joint posterior distribution, will result in overestimation of uncertainty of the posterior predictive. We propose a postprocessing step that can rectify this problem. Our approach relie s on learning directly the intractable posterior distribution of the hidden states, using an autoregressive-flow, by exploiting the Markov property. Upon evaluating our approach on some intractable HMMs, we found that the quality of the estimates retrieved using our postprocessing is comparable to what can be achieved using a computationally expensive particle-filtering which additionally requires a tractable data distribution.

Brain Signal Generation and Data Augmentation with a Single-Step Diffusion Probabilistic Model

Szabolcs Torma,Dr. Luca Szegletes

Brain-computer interfaces based on deep learning rely on large amounts of high-quality data. Finding publicly available brain signal datasets that meet all requirements is a challenge. However, brain signals synthesized with generative models may provide a solution to this problem. Our work builds on diffusion probabilistic models (DPMs) and aims to generate brain signals that have the properties needed to develop further classification models based on deep learning. We show that our DPM can generate high-quality event-related potentials (ERPs) and motor imagery (MI) signals. Furthermore, with the progressive distillation of the model, subject-specific data can be produced in a one-step reverse process. We augment publicly available datasets and demonstrate the impact of the generated signals on a deep learning classification model. DPMs are versatile models, and this work shows that brain signal processing is one of many other tasks in which these models can be useful.

Know Your Boundaries: The Advantage of Explicit Behavior Cloning in Offline RL

Wonjoon Goo,Scott Niekum

We introduce an offline reinforcement learning (RL) algorithm that explicitly clones a behavior policy to constrain value learning. In offline RL, it is often important to prevent a policy from selecting unobserved actions, since the consequence of these actions cannot be presumed without additional information about the environment. One straightforward way to implement such a constraint is to explicitly model a given data distribution via behavior cloning and directly force a policy not to select uncertain actions. However, many offline RL methods instantiate the constraint indirectly---for example, pessimistic value estimation---due to a concern about errors when modeling a potentially complex behavior policy. In this work, we argue that it is not only viable but beneficial to explicitly model the behavior policy for offline RL because the constraint can be realized in a stable way with the trained model. We first suggest a theoretical framework that allows us to incorporate behavior-cloned models into value-based offline RL methods, enjoying the strength of both explicit behavior cloning and value learning. Then, we propose a practical method utilizing a score-based generative model for behavior cloning. With the proposed method, we show state-of-the-art performance on several datasets within the D4RL and Robomimic benchmarks and achieve competitive performance across all datasets tested.

On the Convergence of AdaGrad(Norm) on $\mathbb{R}^d$: Beyond Convexity, Non-Asymptotic Rate and Acceleration

Zijian Liu,Ta Duy Nguyen,Alina Ene,Huy Nguyen

Existing analysis of AdaGrad and other adaptive methods for smooth convex optimization is typically for functions with bounded domain diameter. In unconstrained problems, previous works guarantee an asymptotic convergence rate without an explicit constant factor that holds true for the entire function class. Furthermore, in the stochastic setting, only a modified version of AdaGrad, different from the one commonly used in practice, in which the latest gradient is not used to update the stepsize, has been analyzed. Our paper aims at bridging these gaps and developing a deeper understanding of AdaGrad and its variants in the standard setting of smooth convex functions as well as the more general setting of quasar convex functions. First, we demonstrate new techniques to explicitly bound the convergence rate of the vanilla AdaGrad for unconstrained problems in both deterministic and stochastic settings. Second, we propose a variant of AdaGrad for wh ich we can show the convergence of the last iterate, instead of the average iterate. Finally, we give new accelerated adaptive algorithms and their convergence guarantee in the deterministic setting with explicit dependency on the problem parameters, improving upon the asymptotic rate shown in previous works.

Bounded Attacks and Robustness in Image Transform Domains

Mohamed-Hicham LEGHETTAS,Markus Püschel

Classical image transformation such as the discrete cosine transform (DCT) and the discrete wavelet transforms (DWTs) provide semantically meaningful representations of images. In this paper we propose a general method for adversarial attacks in such transform domains that, in contrast to prior work, obey the L^∞ constraint in the pixel domain. The key idea is to replace the standard attack based on projections with the barrier method. Experiments with DCT and DWTs produce adversarial examples that are significantly more similar to the original than with prior attacks. Further, through adversarial training we show that robustness against our attacks transfers to robustness against a broad class of common image perturbations.

SP2 : A Second Order Stochastic Polyak Method

Shuang Li,William Joseph Swartworth,Martin Taká■,Deanna Needell,Robert M. Gower

Recently the SP (Stochastic Polyak step size) method has emerged as a competitive adaptive method for setting the step sizes of SGD. SP can be interpreted as a method specialized to interpolated models, since it solves the interpolation equations. SP solves these equation by using local linearizations of the model. We take a step further and develop a method for solving the interpolation equations that uses the local second-order approximation of the model. Our resulting method SP2 uses Hessian-vector products to speed-up the convergence of SP. Furthermore, and rather uniquely among second-order methods, the design of SP2 in no way relies on positive definite Hessian matrices or convexity of the objective function. We show SP2 is competitive both in experiments and in theory.

We show SP2 is very competitive on matrix completion, non-convex test problems and logistic regression. We also provide a convergence theory on sums-of-quadratics.

Multi-Objective GFlowNets

Moksh Jain,Sharath Chandra Raparthy,Alex Hernández-García,Jarrid Rector-Brooks,Yoshua Bengio,Santiago Miret,Emmanuel Bengio

In many applications of machine learning, like drug discovery and material design, the goal is to generate candidates that simultaneously maximize a set of objectives. As these objectives are often conflicting, there is no single candidate that simultaneously maximizes all objectives, but rather a set of Pareto-optimal candidates where one objective cannot be improved without worsening another. Moreover, these objectives, when considered in practice are often under-specified, making diversity of candidates a key consideration. The existing multi-objective optimization methods focus predominantly on covering the Pareto front, failing the capture diversity in the space of candidates. Motivated by the success of GFlowNets for generation of diverse candidates in a single objective setting, in this paper we consider Multi-Objective GFlowNets (MOGFNs). MOGFNs consist of a Conditional GFlowNet which models a family of single-objective sub-problems derived by decomposing the multi-objective optimization problem. Our work is the first to empirically demonstrate conditional GFlowNets. Through a series of experiments on synthetic tasks and real-world domains, we empirically demonstrate that MOGFNs outperform existing methods in terms of Hypervolume, R2-distance and candidate diversity. We also demonstrate the effectiveness of MOGFNs over existing methods in active learning settings. Finally, we supplement our empirical results with a careful analysis of each component of MOGFNs.

Making Better Decision by Directly Planning in Continuous Control

Jinhua Zhu,Yue Wang,Lijun Wu,Tao Qin,Wengang Zhou,Tie-Yan Liu,Houqiang Li

By properly utilizing the learned environment model, model-based reinforcement l earning methods can improve the sample efficiency for decision-making problems. Beyond using the learned environment model to train a policy, the success of MCTS-based methods shows that directly incorporating the learned environment model as a planner to make decisions might be more effective. However, when action space is of high dimension and continuous, directly planning according to the learned model is costly and non-trivial. Because of two challenges: (1) the infinite number of candidate actions and (2) the temporal dependency between actions in different timesteps. To address these challenges, inspired by Differential Dynamic Programming (DDP) in optimal control theory, we design a novel Policy Optimization with Model Planning (POMP) algorithm, which incorporates a carefully designed Deep Differential Dynamic Programming (D3P) planner into the model-based RL framework. In D3P planner, (1) to effectively plan in the continuous action space, we construct a locally quadratic programming problem that uses a gradient-based optimization process to replace search. (2) To take the temporal dependency of actions at different timesteps into account, we leverage the updated and latest actions of previous timesteps (i.e., step $1, \cdots, h-1$) to update the action of the current step (i.e., step h), instead of updating all actions simultaneously. We theoretically prove the convergence rate for our D3P planner and analyze the effect of the feedback term. In practice, to effectively apply the neural network based D3P planner in reinforcement learning, we leverage the policy network to initialize the action sequence and keep the action update conservative in the planning process. Experiments demonstrate that POMP consistently improves sample efficiency on widely used continuous control tasks. Our code is released at https://github.com/POMP-D3P/POMP-D3P.

Large language models are not zero-shot communicators

Laura Eline Ruis,Akbir Khan,Stella Biderman,Sara Hooker,Tim Rocktäschel,Edward Grefenstette

The recent success of large language models (LLMs) has drawn heavy attention and investment in their use as conversational and embodied systems. Despite widespread use of LLMs as conversational agents, evaluations of performance fail to capture a crucial aspect of communication: interpreting language in context. Humans interpret language using beliefs, prior knowledge about the world, and more. For example, we intuitively understand the response "I wore gloves" to the question "Did you leave fingerprints?" as meaning "No". To investigate whether LLMs have the ability to make this type of inference, known as an implicature, we design a simple task and evaluate a set of models. We find that despite only evaluating on utterances that require a binary inference (yes or no), most perform close to random. Models adapted to be "aligned with human intent" via reinforcement learning perform much better, but still leave a significant gap with human performance. This gap is even more pronounced for context-heavy utterances. We present our findings as the starting gun for further research into evaluating how LLMs interpret language in context, in order to drive the development of more pragmatic and useful models of human discourse.

Data dependent frequency sensitivity of convolutional neural networks

Charles Godfrey,Elise Bishoff,Myles McKay,Davis Brown,Grayson Jorgenson,Henry Kvinge,Eleanor Byler

It is widely acknowledged that trained convolutional neural networks (CNNs) have different levels of sensitivity to signals of different frequency. In particular, a number of empirical studies have documented CNNs sensitivity to low-frequency signals. In this work we show with theory and experiments that this observed sensitivity is a consequence of the frequency distribution of natural images, which is known to have most of its power concentrated in low-to-mid frequencies. Our theoretical analysis relies on representations of the layers of a CNN in frequency space, an idea that has previously been used to accelerate computations and study implicit bias of network training algorithms, but to the best of our knowledge has not been applied in the domain of model robustness.

****

Is end-to-end learning enough for fitness activity recognition?

Antoine Mercier,Guillaume Berger,Sunny Panchal,Florian Dietrichkeit,Cornelius Böhm,Ingo Bax,Roland Memisevic

End-to-end learning has taken hold of many computer vision tasks, in particular, related to still images, with task-specific optimization yielding very strong performance. Nevertheless, human-centric action recognition is still largely dominated by hand-crafted pipelines, and only individual components are replaced by neural networks that typically operate on individual frames. As a testbed to study the relevance of such pipelines, we present a new fully annotated video dataset of fitness activities. Any recognition capabilities in this domain are almost exclusively a function of human poses and their temporal dynamics, so pose-based solutions should perform well. We show that, with this labelled data, end-to-end learning on raw pixels can compete with state-of-the-art action recognition pipelines based on pose estimation. We also show that end-to-end learning can support temporally fine-grained tasks such as real-time repetition counting.

****

Efficient Exploration using Model-Based Quality-Diversity with Gradients

Bryan Lim,Manon Flageat,Antoine Cully

Exploration is a key challenge in Reinforcement Learning, especially in long-horizon, deceptive and sparse-reward environments. For such applications, population-based approaches have proven effective. Methods such as Quality-Diversity deals with this by encouraging novel solutions and producing a diversity of behaviours. However, these methods are driven by either undirected sampling (i.e. mutations) or use approximated gradients (i.e. Evolution Strategies) in the parameter space, which makes them highly sample-inefficient. In this paper, we propose a model-based Quality-Diversity approach, relying on gradients and learning in imagination. Our approach optimizes all members of a population simultaneously to maintain both performance and diversity efficiently by leveraging the effectiveness of QD algorithms as good data generators to train deep models. We demonstrate that it maintains the divergent search capabilities of population-based approaches while significantly improving their sample efficiency (5 times faster) and quality of solutions (2 times more performant).

****

HiT-MDP: Learning the SMDP option framework on MDPs with Hidden Temporal Embeddings

Chang Li,Dongjin Song,Dacheng Tao

The standard option framework is developed on the Semi-Markov Decision Process (SMDP) which is unstable to optimize and sample inefficient. To this end, we propose the Hidden Temporal MDP (HiT-MDP) and prove that the option-induced HiT-MDP is homomorphic equivalent to the option-induced SMDP. A novel transformer-based framework is introduced to learn options' embedding vectors (rather than conventional option tuples) on HiT-MDPs. We then derive a stable and sample efficient option discovering method under the maximum-entropy policy gradient framework. Extensive experiments on challenging Mujoco environments demonstrate HiT-MDP's efficiency and effectiveness: under widely used configurations, HiT-MDP achieves competitive, if not better, performance compared to the state-of-the-art baselines on all finite horizon and transfer learning environments. Moreover, HiT-MDP significantly outperforms all baselines on infinite horizon environments while exhibiting smaller variance, faster convergence, and better interpretability. Our work potentially sheds light on the theoretical ground of extending the option framework into a large-scale foundation model.

Improved Group Robustness via Classifier Retraining on Independent Splits

Thien Hang Nguyen,Hongyang Ryan Zhang,Huy Nguyen

Deep neural networks learned by minimizing the average risk can achieve strong average performance, but their performance for a subgroup may degrade, if the subgroup is underrepresented in the overall data population. Group distributionally robust optimization (Sagawa et al., 2020a, GDRO) is a standard baseline for learning models with strong worst-group performance. However, GDRO requires group labels for every example during training and can be prone to overfitting, often requiring careful model capacity control via regularization or early stopping. Wh en only a limited amount of group labels is available, Just Train Twice (Liu et al., 2021, JTT) is a popular approach which infers a pseudo-group-label for every unlabeled example. The process of inferring pseudo labels can be highly sensitive during model selection. To alleviate overfitting for GDRO and the pseudo labeling process for JTT, we propose a new method via classifier retraining on independent splits (of the training data). We find that using a novel sample splitting procedure achieves robust worst-group performance in the fine-tuning step. When evaluated on benchmark image and text classification tasks, our approach consistently reduces the requirement of group labels and hyperparameter search during training. Experimental results confirm that our approach performs favorably compared with existing methods (including GDRO and JTT) when either group labels are available during training or are only available during validation.

(Certified!!) Adversarial Robustness for Free!

Nicholas Carlini,Florian Tramer,Krishnamurthy Dj Dvijotham,Leslie Rice,Mingjie Sun,J Zico Kolter

In this paper we show how to achieve state-of-the-art certified adversarial robustness to 2-norm bounded perturbations by relying exclusively on off-the-shelf pretrained models. To do so, we instantiate the denoised smoothing approach of Salman et al. by combining a pretrained denoising diffusion probabilistic model and a standard high-accuracy classifier. This allows us to certify 71% accuracy on ImageNet under adversarial perturbations constrained to be within a 2-norm of 0.5, an improvement of 14 percentage points over the prior certified SoTA using any approach, or an improvement of 30 percentage points over denoised smoothing. We obtain these results using only pretrained diffusion models and image classifiers, without requiring any fine tuning or retraining of model parameters.

URVoice: An Akl-Toussaint/ Graham- Sklansky Approach towards Convex Hull Computation for Sign Language Interpretation

Madhumitha V,Santhi Natarajan,Bharathi Malarkeddy A

We present URVoice, a vocalizer for the communication impaired, based on the Indian Sign Language Notations. Contemporary psychological theories consider language and speech as devices to understand complex psychological processes and deliver them as cultural products of ideas and communication. Sign and gesture language, offering an intelligent co-ordination of eye-and-hand and ear-and-mouth, has evolved as an intelligent manifestation of speech for the impaired. However, they have very limited modality and iconicity in accommodating a greater range of linguistically relevant meanings. URVoice is an Augmentative and Alternative Communication (AAC) device, which currently features a pipeline of forward communication from signer to collocutor with a novel approach shouldered on convex hull using vision-based approach. The solution achieves real time translation of gesture to text/voice using convex hull as the computational geometry, which follows Akl-Toussaint heuristic and Graham-Sklansky scan algorithms. The results are weighed against our other solutions based on conventional Machine Learning and Deep Learning approaches. A futuristic version of URVoice, with voice translated to sign language gestures, will be a complete solution for effectively bridging the cognitive and communication gap between the impaired and the abled lot.

Gaussian-Bernoulli RBMs Without Tears

Renjie Liao,Simon Kornblith,Mengye Ren,David J. Fleet,Geoffrey Hinton

We revisit the challenging problem of training Gaussian-Bernoulli restricted Boltzmann machines (GRBMs), introducing two innovations. We propose a novel Gibbs-Langevin sampling algorithm that outperforms existing methods like Gibbs sampling.

We propose a modified contrastive divergence (CD) algorithm so that one can generate images with GRBMs starting from noise.

This enables direct comparison of GRBMs with deep generative models, improving evaluation protocols in the RBM literature.

Moreover, we show that modified CD and gradient clipping are enough to robustly train GRBMs with large learning rates, thus removing the necessity of various tr

icks in the literature.
Experiments on Gaussian Mixtures, MNIST, FashionMNIST, and CelebA show GRBMs can generate good samples, despite their single-hidden-layer architecture.

Efficient Conditionally Invariant Representation Learning

Roman Pogodin,Namrata Deka,Yazhe Li,Danica J. Sutherland,Victor Veitch,Arthur Gretton

We introduce the Conditional Independence Regression CovariancE (CIRCE), a measure of conditional independence for multivariate continuous-valued variables. CIRCE applies as a regularizer in settings where we wish to learn neural features $\varphi(X)$ of data X to estimate a target Y, while being conditionally independent of a distractor Z given Y. Both Z and Y are assumed to be continuous-valued but relatively low dimensional, whereas X and its features may be complex and high dimensional. Relevant settings include domain-invariant learning, fairness, and causal learning. The procedure requires just a single ridge regression from Y to kernelized features of Z, which can be done in advance. It is then only necessary to enforce independence of $\varphi(X)$ from residuals of this regression, which is possible with attractive estimation properties and consistency guarantees. By contrast, earlier measures of conditional feature dependence require multiple regressions for each step of feature learning, resulting in more severe bias and variance, and greater computational cost. When sufficiently rich features are used, we establish that CIRCE is zero if and only if $\varphi(X) \perp \!\!\! \perp Z \mid Y$. In experiments, we show superior performance to previous methods on challenging benchmarks, including learning conditionally invariant image features. Code for image data experiments is available at github.com/namratadeka/circe.

Heterogeneous Neuronal and Synaptic Dynamics for Spike-Efficient Unsupervised Learning: Theory and Design Principles

Biswadeep Chakraborty,Saibal Mukhopadhyay

This paper shows that the heterogeneity in neuronal and synaptic dynamics reduces the spiking activity of a Recurrent Spiking Neural Network (RSNN) while improving prediction performance, enabling spike-efficient (unsupervised) learning.
We analytically show that the diversity in neurons' integration/relaxation dynamics improves an RSNN's ability to learn more distinct input patterns (higher memory capacity), leading to improved classification and prediction performance. We further prove that heterogeneous Spike-Timing-Dependent-Plasticity (STDP) dynamics of synapses reduce spiking activity but preserve memory capacity. The analytical results motivate Heterogeneous RSNN design using Bayesian optimization to determine heterogeneity in neurons and synapses to improve $\mathcal{E}$, defined as the ratio of spiking activity and memory capacity. The empirical results on time series classification and prediction tasks show that optimized HRSNN increases performance and reduces spiking activity compared to a homogeneous RSNN.

MMVAE+: Enhancing the Generative Quality of Multimodal VAEs without Compromises

Emanuele Palumbo,Imant Daunhawer,Julia E Vogt

Multimodal VAEs have recently gained attention as efficient models for weakly-supervised generative learning with multiple modalities. However, all existing variants of multimodal VAEs are affected by a non-trivial trade-off between generative quality and generative coherence. In particular mixture-based models achieve good coherence only at the expense of sample diversity and a resulting lack of generative quality. We present a novel variant of the mixture-of-experts multimodal variational autoencoder that improves its generative quality, while maintaining high semantic coherence. We model shared and modality-specific information in separate latent subspaces, proposing an objective that overcomes certain dependencies on hyperparameters that arise for existing approaches with the same latent space structure. Compared to these existing approaches, we show increased robustness with respect to changes in the design of the latent space, in terms of the capacity allocated to modality-specific subspaces. We show that our model achieves both good generative coherence and high generative quality in challenging experiments, including more complex multimodal datasets than those used in previous works.

A probabilistic framework for task-aligned intra- and inter-area neural manifold estimation

Edoardo Balzani,Jean-Paul G Noel,Pedro Herrero-Vidal,Dora E Angelaki,Cristina Savin

Latent manifolds provide a compact characterization of neural population activity and of shared co-variability across brain areas. Nonetheless, existing statistical tools for extracting neural manifolds face limitations in terms of interpretability of latents with respect to task variables, and can be hard to apply to datasets with no trial repeats. Here we propose a novel probabilistic framework that allows for interpretable partitioning of population variability within and across areas in the context of naturalistic behavior. Our approach for task aligned manifold estimation (TAME-GP) explicitly partitions variability into private and shared sources which can themselves be subdivided in task-relevant and task irrelevant components, uses a realistic Poisson noise model, and introduces temporal smoothing of latent trajectories in the form of a Gaussian Process prior. This TAME-GP graphical model allows for robust estimation of task-relevant variability in local population responses, and of shared co-variability between brain areas. We demonstrate the efficiency of our estimator on within model and biologically motivated simulated data. We also apply it to several datasets of neural population recordings during behavior. Overall, our results demonstrate the capacity of TAME-GP to capture meaningful intra- and inter-area neural variability with single trial resolution.

Applying Second Order Optimization to Deep Transformers with Parameter-Efficient Tuning

Ning Ding,Qiaosen Wang,Yulin Chen,Pengjun Xie,Zhiyuan Liu,Hai-Tao Zheng,Maosong Sun

Despite the theoretical superiority in convergence issues, second-order optimizers are generally not among the top choices for training large-scale neural networks due to their high computational and memory cost. Nevertheless, introduced in recent progress of parameter-efficient tuning is a new paradigm that large-scale pre-trained models (PTMs) can be adapted to specific tasks by optimizing a tiny proportion of parameters, which might hopefully change the game. We associate this new paradigm with the computational tractability of second-order optimizers and succeed in applying them to large PTMs that are from hundreds of millions to billions in scale. Beyond verifying their tractability, we further investigate the stability-influencing factors in the optimization process and propose accordingly a Newton-step-clipping approach in which we clip the update tensors rather than the gradients. This approach stabilizes the convergence by gating the magnitude of Newton steps along the optimization trajectories through the rugged landscapes of deep transformers.

We conduct extensive experiments across different downstream tasks, demonstrating that, when equipped with our Newton-step-clipping strategy, second-order optimizers, especially Kronecker-factored curvature approximation (K-FAC), can attain comparable and even superior results and faster convergence to those state-of-the-art bars implemented with AdamW. Furthermore, we scale the model up to 3 billion parameters and validate the tractability and effectiveness of our method. This work is not only the first successful application of second-order optimization on such large-scale models but also sheds light on the possibility of further optimization-wise analysis on large-scale models in the future.

****

Density Sketches for Sampling and Estimation

Aditya Desai,Benjamin Coleman,Anshumali Shrivastava

There has been an exponential increase in the data generated worldwide. Insights into this data led by machine learning (ML) have given rise to exciting applications such as recommendation engines, conversational agents, and so on. Often, data for these applications is generated at a rate faster than ML pipelines can c

onsume it. In this paper, we propose Density Sketches(DS) - a cheap and practical approach to reducing data redundancy in a streaming fashion. DS creates a succinct online summary of data distribution. While DS does not store the samples from the stream, we can sample unseen data on the fly from DS to use for downstream learning tasks. In this sense, DS can replace actual data in many machine learning pipelines analogous to generative models. Importantly, unlike generative models, which do not have statistical guarantees, the sampling distribution of DS asymptotically converges to underlying unknown density distribution.

Mask-tuning: Towards Improving Pre-trained Language Models' Generalization
Somayeh Ghanbarzadeh,Hamid Palangi,Yan Huang,Radames Cruz Moreno,Hamed Khanpour

Pre-trained language models have the known generalization problem. This issue emerges from the pre-trained language models' learning process that heavily relies on spurious correlations, which work for the majority of training examples but do not hold in general. As a consequence, the models' performance drops substantially on out-of-distribution datasets. Previous studies proposed various solutions, including data augmentation and learning process improvement. In this paper, we present Mask-tuning, an approach that alleviates the impact of spurious correlations on the fine-tuning learning process. To achieve this goal, Mask-tuning integrates masked language training into the fine-tuning learning process. In this case, Mask-tuning perturbs the linguistic relation of downstream tasks' training examples and computes masked language training loss. Then, the perturbed examples are fed into fine-tuning process to be classified based on their ground-truth label and compute the fine-tuning training loss. Afterward, Mask-tuning loss -- a weighted aggregation of masked language model training loss and fine-tuning loss-- updates the masked language model and fine-tuning through training iterations. Extensive experiments show that Mask-tuning consistently improves the pre-trained language models' generalization on out-of-distribution datasets and enhances their performance on in-distribution datasets. The source code and pre-trained models will be available on the author's GitHub page.

Meta-Learning via Classifier(-free) Guidance
Elvis Nava,Seijin Kobayashi,Yifei Yin,Robert K. Katzschmann,Benjamin F Grewe

State-of-the-art meta-learning techniques do not optimize for zero-shot adaptation to unseen tasks, a setting in which humans excel. On the contrary, meta-learning algorithms learn hyperparameters and weight initializations that explicitly optimize for few-shot learning performance. In this work, we take inspiration from recent advances in generative modeling and language-conditioned image synthesis to propose meta-learning techniques that use natural language guidance to achieve higher zero-shot performance compared to the state-of-the-art. We do so by recasting the meta-learning problem as a multi-modal generative modeling problem: given a task, we consider its adapted neural network weights and its natural language description as equivalent multi-modal task representations. We first train an unconditional generative hypernetwork model to produce neural network weights; then we train a second "guidance" model that, given a natural language task description, traverses the hypernetwork latent space to find high-performance task-adapted weights in a zero-shot manner. We explore two alternative approaches for latent space guidance: "HyperCLIP"-based classifier guidance and a conditional Hypernetwork Latent Diffusion Model ("HyperLDM"), which we show to benefit from the classifier-free guidance technique common in image generation. Finally, we demonstrate that our approaches outperform existing meta-learning methods with zero-shot learning experiments on our Meta-VQA dataset, which we specifically constructed to reflect the multi-modal meta-learning setting.
****

Tiered Pruning for Efficient Differentialble Inference-Aware Neural Architecture Search
Slawomir Kierat,Mateusz Sieniawski,Denys Fridman,Chenhan D. Yu,Szymon Migacz,Pawel Morkisz,Alex Fit-Florea

We propose three novel pruning techniques to improve the cost and results of inference-aware Differentiable Neural Architecture Search (DNAS). First, we introdu ce $\textbf{Prunode}$, a stochastic bi-path building block for DNAS, which can search over inner hidden dimensions with $\mathcal{O}(1)$ memory and compute complexity. Second, we present an algorithm for pruning blocks within a stochastic layer of the SuperNet during the search. Third, we describe a novel technique for pruning unnecessary stochastic layers during the search. The optimized models resulting from the search are called PruNet and establishes a new state-of-the-art Pareto frontier for NVIDIA V100 in terms of inference latency for ImageNet Top-1 image classification accuracy. PruNet as a backbone also outperforms GPUNet and EfficientNet on the COCO object detection task on inference latency relative to mean Average Precision (mAP).

****

MyoDex: Generalizable Representations for Dexterous Physiological Manipulation
Vittorio Caggiano,Sudeep Dasari,Vikash Kumar

The complexity of human dexterity has attracted attention from multiple fields. Still, much is to be understood about how hand manipulation behaviors emerge. In this work we aim at learning dexterous manipulation behaviors with a physiologically realistic hand model: MyoHand. In contrast to prior works demonstrating isolated postural and force control, here we demonstrate musculoskeletal agents (MyoDex) exhibiting contact-rich dynamic dexterous manipulation behaviors in simulation. Furthermore, to demonstrate generalization, we show that a single MyoDex agent can be trained to solve up-to 14 different contact-rich tasks. Aligned with human development, simultaneous learning of multiple tasks imparts physiological coordinated muscle contractions i.e., muscle synergies, that are not only shared amongst those in-domain tasks but are also effective in out-of-domain tasks. By leveraging these pre-trained manipulation synergies, we show generalization to 14 additional previously unsolved tasks. While physiological behaviors with large muscle groups (such as legged-locomotion, arm-reaching, etc), have been demonstrated before, to the best of our knowledge nimble behaviors of this complexity with smaller muscle groups are being demonstrated for the first time.

****

Do We Really Need Labels for Backdoor Defense?
Zidi Xiong,Dongxian Wu,Yifei Wang,Yisen Wang

Since training a model from scratch always requires massive computational resources recently, it has become popular to download pre-trained backbones from third-party platforms and deploy them in various downstream tasks. While providing some convenience, it also introduces potential security risks like backdoor attacks, which lead to target misclassification for any input image with a specifically defined trigger (i.e., backdoored examples). Current backdoor defense methods always rely on clean labeled data, which indicates that safely deploying the pre-trained model in downstream tasks still demands these costly or hard-to-obtain labels. In this paper, we focus on how to purify a backdoored backbone with only unlabeled data. To evoke the backdoor patterns without labels, we propose to leverage the unsupervised contrastive loss to search for backdoors in the feature space. Surprisingly, we find that we can mimic backdoored examples with adversarial examples crafted by contrastive loss, and erase them with adversarial finetuning. Thus, we name our method as Contrastive Backdoor Defense (CBD). Against several backdoored backbones from both supervised and self-supervised learning, extensive experiments demonstrate our unsupervised method achieves comparable or even better defense compared to these supervised backdoor defense methods. Thus, our method allows practitioners to safely deploy pre-trained backbones on downstream tasks without extra labeling costs.

Metadata Archaeology: Unearthing Data Subsets by Leveraging Training Dynamics
Shoaib Ahmed Siddiqui,Nitarshan Rajkumar,Tegan Maharaj,David Krueger,Sara Hooker

Modern machine learning research relies on relatively few carefully curated data sets. Even in these datasets, and typically in `untidy' or raw data, practitioners are faced with significant issues of data quality and diversity which can be prohibitively labor intensive to address. Existing methods for dealing with these challenges tend to make strong assumptions about the particular issues at play, and often require a priori knowledge or metadata such as domain labels. Our wo rk is orthogonal to these methods: we instead focus on providing a unified and efficient framework for Metadata Archaeology -- uncovering and inferring metadata of examples in a dataset. We curate different subsets of data that might exist in a dataset (e.g. mislabeled, atypical, or out-of-distribution examples) using simple transformations, and leverage differences in learning dynamics between these probe suites to infer metadata of interest. Our method is on par with far more sophisticated mitigation methods across different tasks: identifying and correcting mislabeled examples, classifying minority-group samples, prioritizing points relevant for training and enabling scalable human auditing of relevant examples.

Single SMPC Invocation DPHelmet: Differentially Private Distributed Learning on a Large Scale

Moritz Kirschte,Sebastian Meiser,Saman Ardalan,Esfandiar Mohammadi

Distributing machine learning predictors enables the collection of large-scale datasets while leaving sensitive raw data at trustworthy sites. We introduce a learning technique that is scalable to a large number of users, satisfies Differential Privacy, and is applicable to non-trivial tasks, such as CIFAR-10. For a large number of participants, communication cost is one of the main challenges. We achieve a low communication cost by requiring only a single invocation of an efficient secure multiparty summation protocol. By relying on state-of-the-art feature extractors, we are able to utilize differentially private convex learners for non-trivial tasks such as CIFAR-10. Convex learners have proven to have a strong utility-private tradeoff. Our experimental results show that for $1{,}000$ users with 50 data points each, our scheme outperforms state-of-the-art scalable distributed learning methods (differentially private federated learning, short DP-FL) while requiring around 500 times fewer communication costs: For CIFAR-10, we achieve a classification accuracy of $67.3\,\%$ for an $\varepsilon = 0.59$ while DP-FL achieves $57.6\,\%$. We also show the learnability properties convergence and uniform stability.

Re-Benchmarking Out-of-Distribution Detection in Deep Neural Networks

Jinling Gao,Haoyue Bai,Lin Zhu,Nanyang Ye

Out-of-distribution (OOD) detection is a key challenge for making machine learning models robust in the real world, where we want models to be aware of uncertainty outside their training data distribution. Despite the rapid development of existing OOD detection algorithms, their experimental settings are usually inconsistent, e.g., datasets, evaluation metrics, model selection, implementation choices. In this paper, we aim to understand OOD detection fundamentally and provide a comprehensive benchmarking of the current state of the art OOD detection methods in a consistent and realistic evaluation setting. This benchmarking contains a serious of datasets split, model selection criteria and OOD detection algorithms. This experimental framework can be easily extended to new algorithms, datasets, and model selection criteria. We conduct extensive experiments on this benchmark and find that the threshold of OOD detection algorithms are not consistent over different datasets and model selection criteria.

Towards Antisymmetric Neural Ansatz Separation

Aaron Zweig,Joan Bruna

We study separations between two fundamental models (or \emph{Ansätze}) of antisymmetric functions, that is, functions f of the form $f(x_{\sigma(1)}, \ldots, x_{\sigma(N)}) = \text{sign}(\sigma)f(x_1, \ldots, x_N)$, where σ is any permutation.
These arise in the context of quantum chemistry, and are the basic modeling tool for wavefunctions of Fermionic systems.
Specifically, we consider two popular antisymmetric Ansätze: the Slater representation, which leverages the alternating structure of determinants, and the Jastrow ansatz, which augments Slater determinants with a product by an arbitrary symmetric function. We construct an antisymmetric function that can be more efficiently expressed in Jastrow form, yet provably cannot be approximated by Slater de

terminants unless there are exponentially (in N^2) many terms. This represents the first explicit quantitative separation between these two Ansätze.

Multi-instance Interactive Segmentation with Self-Supervised Transformer
Xavier Jiménez,Jaonary Rabarisoa,Valentin Belissen,Quoc Cuong PHAM
The rise of Vision Transformers (ViT) combined with better self-supervised learning pre-tasks has taken representation learning to the next level, beating supervised results on ImageNet. In particular, self-attention mechanism of ViT allows to easily visualize semantic information learned by the network. Following revealing of attention maps of DINO, many tried to leverage its representations for unsupervised segmentation. Despite very promising results for basic images with a single clear object in a simple background, representation of ViT are not able to segment images, with several classes and object instance, in an unsupervised fashion yet. In this paper, we propose SALT: Semi-supervised Segmentation with Self-supervised Attention Layers in Transformers, an interactive algorithm for multi-class/multi-instance segmentation. We follow previous works path and take it a step further by discriminating between different objects, using sparse human help to select said objects. We show that remarkable results are achieved with very sparse labels. Different pre-tasks are compared, and we show that self-supervised ones are more robust for panoptic segmentation, and overall achieve very similar performance. Evaluation is carried out on Pascal VOC 2007 and COCO-panoptic. Performance is evaluated for extreme conditions such as very noisy, and sparse interactions going to as little as one interaction per class.

Spurious Features in Continual Learning
Timothee LESORT
Continual Learning (CL) is the research field addressing learning without forgetting when the data distribution is not static.

This paper studies spurious features' influence on continual learning algorithms.

We show that continual learning algorithms solve tasks by selecting features that are not generalizable.

Our experiments highlight that continual learning algorithms face two related problems: (1) spurious features (SP) and (2) local spurious features (LSP). The first one is due to a covariate shift between training and testing data, while the second is due to the limited access to data at each training step.

We study (1) through a consistent set of continual learning experiments varying spurious correlation amount and data distribution support.

We show that (2) is a major cause of performance decrease in continual learning along with catastrophic forgetting.

This paper presents a different way of understanding performance decrease in continual learning by highlighting the influence of (local) spurious features in algorithms capabilities.

Time Series Subsequence Anomaly Detection via Graph Neural Networks
Weiqi Chen,Zhiqiang Zhou,Qingsong Wen,Liang Sun
Time series subsequence anomaly detection is an important task in a large variety of real-world applications ranging from health monitoring to AIOps, and is challenging due to complicated underlying temporal dynamics and unpredictable anomalous patterns. Firstly, how to effectively learn the temporal dependency in time series remains a challenge. Secondly, diverse and complicated anomalous subsequences as well as the lack of labels make accurate detection difficult. For example, the popular subsequence anomaly detection algorithm---time series discord---fails to handle recurring anomalies. Thirdly, many existing algorithms require a proper subsequence length for effective detection, which is difficult or impossible in practice. In this paper, we present a novel approach to subsequence anomaly detection which combines practical heuristics of time series discords and temporal relationships with deep neural networks. By performing length selection considering multi-scale information and incorporating prior knowledge using graph neural networks, our method can adaptively learn the appropriate subsequence l

ength as well as integrated representations from both priors and raw data favorable to anomaly detection. In particular, our graph incorporates both semantic and temporal relationships between subsequences. The experimental results demonstrate the effectiveness of the proposed algorithm, which achieves superior performance on multiple time series anomaly benchmarks in comparison with state-of-the-art algorithms.

Aligning Model and Macaque Inferior Temporal Cortex Representations Improves Model-to-Human Behavioral Alignment and Adversarial Robustness

Joel Dapello,Kohitij Kar,Martin Schrimpf,Robert Baldwin Geary,Michael Ferguson,David Daniel Cox,James J. DiCarlo

While some state-of-the-art artificial neural network systems in computer vision are strikingly accurate models of the corresponding primate visual processing, there are still many discrepancies between these models and the behavior of primates on object recognition tasks. Many current models suffer from extreme sensitivity to adversarial attacks and often do not align well with the image-by-image behavioral error patterns observed in humans. Previous research has provided strong evidence that primate object recognition behavior can be very accurately predicted by neural population activity in the inferior temporal (IT) cortex, a brain area in the late stages of the visual processing hierarchy. Therefore, here we directly test whether making the late stage representations of models more similar to that of macaque IT produces new models that exhibit more robust, primate-like behavior. We conducted chronic, large-scale multi-electrode recordings across the IT cortex in six non-human primates (rhesus macaques). We then use these data to fine-tune (end-to-end) the model "IT" representations such that they are more aligned with the biological IT representations, while preserving accuracy on object recognition tasks. We generate a cohort of models with a range of IT similarity scores validated on held-out animals across two image sets with distinct statistics. Across a battery of optimization conditions, we observed a strong correlation between the models' IT-likeness and alignment with human behavior, as well as an increase in its adversarial robustness. We further assessed the limitations of this approach and find that the improvements in behavioral alignment and adversarial robustness generalize across different image statistics, but not to object categories outside of those covered in our IT training set. Taken together, our results demonstrate that building models that are more aligned with the primate brain leads to more robust and human-like behavior, and call for larger neural data-sets to further augment these gains.

On the Expressive Power of Geometric Graph Neural Networks

Chaitanya K. Joshi,Cristian Bodnar,Simon V Mathis,Taco Cohen,Pietro Lio

The expressive power of Graph Neural Networks (GNNs) has been studied extensively through the lens of the Weisfeiler-Leman (WL) graph isomorphism test. Yet, many graphs arising in real-world applications come embedded in Euclidean space with an additional notion of geometric isomorphism, which is not covered by the WL framework. In this work, we propose a geometric version of the WL test (GWL) for discriminating geometric graphs while respecting the underlying physical symmetries: permutation, rotation, reflection, and translation. We use GWL to characterise the expressive power of GNNs that are invariant or equivariant to physical symmetries by studying the classes of geometric graphs that can or cannot be distinguished by these architectures. This allows us to formalise the advantages equivariant GNN layers have over their invariant counterparts in the Geometric Deep Learning blueprint. Finally, we connect our discrimination-based perspective with the universal approximation properties of geometric GNNs and prove they are two sides of the same coin.

Fusion over the Grassmann Manifold for Incomplete-Data Clustering

Jeremy Scott Johnson,Huanran Li,Chun Gan,Zheng Lu,Matthew Malloy,Daniel L. Pimentel-Alarcón

This paper presents a new paradigm to cluster incomplete vectors using subspaces as proxies to exploit the geometry of the Grassmannian. We leverage this new pe

rspective to develop an algorithm to cluster and complete data in a union of subspaces via a fusion penalty formulation. Our approach does not require prior knowledge of the number of subspaces, is naturally suited to handle noise, and only requires an upper bound on the subspaces’ dimensions. In developing our model, we present local convergence guarantees. We describe clustering, completion, model selection, and sketching techniques that can be used in practice, and complement our analysis with synthetic and real-data experiments.

Off Policy Average Reward Actor Critic with Deterministic Policy Search
Naman Saxena,Subhojyoti Khastagir,Shishir N Y,Shalabh Bhatnagar
The average reward criterion is relatively less explored as most existing works in the Reinforcement Learning literature consider the discounted reward criterion. There are few recent works that present on-policy average reward actor-critic algorithms, but average reward off-policy actor-critic is relatively less explored. In this paper, we present both on-policy and off-policy deterministic policy gradient theorems for the average reward performance criterion. Using these theorems, we also present an Average Reward Off-Policy Deep Deterministic Policy Gradient (ARO-DDPG) Algorithm. We show a finite time analysis of the resulting three-timescale stochastic approximation scheme and obtain an ϵ-optimal stationary policy with a sample complexity of $\Omega(\epsilon^{-2.5})$. We compare the average reward performance of our proposed algorithm and observe better empirical performance compared to state-of-the-art on-policy average reward actor-critic algorithms over MuJoCo based environments.

Why Did This Model Forecast This Future? Information-Theoretic Temporal Saliency for Counterfactual Explanations of Probabilistic Forecasts
Chirag Raman,Hayley Hung,Marco Loog
Probabilistic forecasting of multivariate time series is significant to several research domains where multiple futures exist for a single observed sequence. Identifying the observations on which a well-performing model bases its forecasts can enable domain experts to form data-driven hypotheses about the causal relationships between features. Consequently, we begin by revisiting the question: what constitutes a causal explanation? One hurdle in the landscape of explainable artificial intelligence is that what constitutes an explanation is not well-grounded. We build upon Miller's framework of explanations derived from research in multiple social science disciplines, and establish a conceptual link between counterfactual reasoning and saliency-based explanation techniques. However, the complication is a lack of a consistent and principled notion of saliency. Also, commonly derived saliency maps may be inconsistent with the data generation process and the underlying model. We therefore leverage a unifying definition of information-theoretic saliency grounded in preattentive human visual cognition and extend it to forecasting settings. In contrast to existing methods that require either explicit training of the saliency mechanism or access to the internal parameters of the underlying model, we obtain a closed-form solution for the resulting saliency map for commonly used density functions in probabilistic forecasting. To empirically evaluate our explainability framework in a principled manner, we construct a synthetic dataset of conversation dynamics and demonstrate that our method recovers the true salient timesteps for a forecast given a well-performing underlying model.
****

CLMIU: Commonsense Learning in Multimodal Image Understanding.
Sergio Sanchez Santiesteban,Muhammad Awais,Sara Atito,Yi-Zhe Song,Josef Kittler
The problem of automatically describing the content of an image through accurate and meaningful captions has been attracting considerable attention among computer vision researchers. Recently, Transformers have been applied to image captioning to encode cross-modal information, in conjunction with Convolutional Neural Networks, which provide image region descriptions in terms of embeddings and object labels as input. However, the generated captions sometimes fail to capture the intentions, relationships, and abstract concepts that rely on general or commonsense knowledge. In this work we propose a novel network design, combining the

strengths of Transformer models with graph-based models conveying external (common sense) knowledge. Our proposed architecture is a pure vision transformer-based image captioning model, with sequences of image patches used directly as input, without extracting any regional features. In particular, unlike the prior work, our architecture incorporates a knowledge-augmented encoder with a Transformer backbone to inject the external knowledge extracted from a knowledge graph. Furthermore, the bidirectional training on a vision-language corpus of image-text pairs, using modality specific self-supervised learning objectives, achieves promising results compared to the state-of-the-art. Our method has been trained from scratch on a small dataset, achieving a 3.8%, 2.7%, 3.2% and 6.3% improvement in BLEU@4, Meteor, Rouge and Cider scores respectively. We also reported competitive results on the NoCaps dataset, showing that the model generalizes to unseen object categories.

In-Situ Text-Only Adaptation of Speech Models with Low-Overhead Speech Imputations

Ashish Mittal,Sunita Sarawagi,Preethi Jyothi

Fast and accurate adaptation of automatic speech recognition (ASR) systems using only text data in the target domain is a problem of long-standing practical relevance. Text-only adaptation was easy in traditional cascaded ASR systems with completely decoupled acoustic and language models. Recently, the RNNTransducer (RNN-T) has emerged as a default ASR model because of its high accuracy, low latency, and capability of supporting streaming input. However text-only adaptation of the RNN-T model is significantly more challenging due to its tight integration of acoustic and language models and end-to-end training. Existing recent approaches for text-only adaptation of RNN-Ts, either entail significant modification to the network or introduce high latency during decoding. We propose a new approach (TOLSTOI) that imputes speech representations internal to a baseline RNN-T, starting from text-only inputs, and performs in-situ adaptation that results in higher adaptation accuracy without any runtime overheads during decoding. Our imputation model is a function of the labeled data and trained parameters of the ASR model, and that we show, is more effective in controlling catastrophic forgetting compared to existing methods. We establish the effectiveness of TOLSTOI using three target domains and two ASR models of varying complexity. We yield up to 35% relative reduction in word error rate with text-only adaptation while forgetting the least compared to existing adaptation approaches. Our method is easy to implement and can be harnessed on existing RNN-T models without requiring ASR model training from scratch.

Rethinking Uniformity in Self-Supervised Representation Learning

Xianghong Fang,Jian Li,Xiangchu Feng,Benyou Wang

Self-supervised representation learning has achieved great success in many machine learning tasks. While many research efforts focus on learning better representations by preventing the model from the \emph{collapse} problem, less attention has been drawn to analyzing the collapse degrees of representations. In this paper, we present a formal study of collapse analysis via the \emph{uniformity} metric, which measures how uniformly learned representations distribute on the surface of the unit hypersphere. We fundamentally find that \textit{representation that obeys zero-mean isotropic Gaussian distribution is with the ideal uniformity} since its l_2-normalized form uniformly distributes on the surface of the unit hypersphere. Therefore, we propose to use the Wasserstein distance between the distribution of learned representations and the ideal distribution as a quantifiable metric of \emph{uniformity}. Moreover, we design five desirable constraints for ideal uniformity metrics, based on which we find that the proposed uniformity metric satisfies all constraints while the existing one does not. Synthetic experiments also demonstrate the proposed uniformity metric is capable to deal with the dimensional collapse while the existing one is insensitive. Furthermore, we impose the proposed \emph{uniformity} metric as an auxiliary loss term for various existing self-supervised methods, which consistently improves the downstream performance.

Proposal-Contrastive Pretraining for Object Detection from Fewer Data

Quentin Bouniot,Romaric Audigier,Angelique Loesch,Amaury Habrard

The use of pretrained deep neural networks represents an attractive way to achieve strong results with few data available. When specialized in dense problems such as object detection, learning local rather than global information in images has proven to be more efficient. However, for unsupervised pretraining, the popular contrastive learning requires a large batch size and, therefore, a lot of resources. To address this problem, we are interested in transformer-based object detectors that have recently gained traction in the community with good performance and with the particularity of generating many diverse object proposals.

In this work, we present Proposal Selection Contrast (ProSeCo), a novel unsupervised overall pretraining approach that leverages this property. ProSeCo uses the large number of object proposals generated by the detector for contrastive learning, which allows the use of a smaller batch size, combined with object-level features to learn local information in the images. To improve the effectiveness of the contrastive loss, we introduce the object location information in the selection of positive examples to take into account multiple overlapping object proposals. When reusing pretrained backbone, we advocate for consistency in learning local information between the backbone and the detection head.

We show that our method outperforms state of the art in unsupervised pretraining for object detection on standard and novel benchmarks in learning with fewer data.

****

SkillS: Adaptive Skill Sequencing for Efficient Temporally-Extended Exploration

Giulia Vezzani,Dhruva Tirumala,Markus Wulfmeier,Dushyant Rao,Abbas Abdolmaleki,Ben Moran,Tuomas Haarnoja,Jan Humplik,Roland Hafner,Michael Neunert,Claudio Fantacci,Tim Hertweck,Thomas Lampe,Fereshteh Sadeghi,Nicolas Heess,Martin Riedmiller

The ability to effectively reuse prior knowledge is a key requirement when building general and flexible Reinforcement Learning (RL) agents.

Skill reuse is one of the most common approaches, but current methods have considerable limitations. For example, fine-tuning an existing policy frequently fails, as the policy can degrade rapidly early in training, particularly in sparse reward tasks. In a similar vein, distillation of expert behavior can lead to poor results when given sub-optimal experts.

We compare several common approaches for skill transfer on multiple domains and in several different transfer settings, including under changes in task and system dynamics. We identify how existing methods can fail and introduce an alternative approach which sidesteps some of these problems.

Our approach learns to sequence existing temporally-abstract skills for exploration but learns the final policy directly from the raw experience. This conceptual split enables rapid adaptation and thus efficient data collection but without constraining the final solution. Our approach significantly outperforms many classical methods across a suite of evaluation tasks and we use a broad set of ablations to highlight the importance of different components of our method.

****

Bridging between Pool- and Stream-Based Active Learning with Temporal Data Coherence

Sebastian Schmidt,Stephan Günnemann

Active learning (AL) reduces the amount of labeled data needed for training a machine learning model by choosing intelligently which instances to label. Classic pool-based AL needs all data to be present in a datacenter, which can be challenging with the increasing amounts of data needed in deep learning. However, AL on mobile devices and robots like autonomous cars can filter the data from perception sensor streams before it ever reaches the datacenter. In our work, we investigate AL for such image streams and propose a new concept exploiting their temporal properties. We define three methods using a pseudo uncertainty based on loss learning (Yoo & Kweon, 2019). The first considers the temporal change of uncertainty and requires 5% less labeled data than the vanilla approach. It is

extended by the change in latent space in the second method. The third method, temporal distance loss stream (TDLS), combines both with submodular optimization . In our evaluation on an extension of the public Audi Autonomous Driving Dataset (Geyer et al., 2020) we outperform state-of-the-art approaches by using 1% fewer labels. Additionally, we compare our stream-based approaches with existing approaches for AL in a pool-based scenario. Our experiments show that, although pool-based AL has access to more data, our stream-based AL approaches need 0.5% fewer labels.
****

Scaling Laws For Deep Learning Based Image Reconstruction

Tobit Klug,Reinhard Heckel

Deep neural networks trained end-to-end to map a measurement of a (noisy) image to a clean image perform excellent for a variety of linear inverse problems.
Current methods are only trained on a few hundreds or thousands of images as opposed to the millions of examples deep networks are trained on in other domains.
In this work, we study whether major performance gains are expected from scaling up the training set size.
We consider image denoising, accelerated magnetic resonance imaging, and super-resolution and empirically determine the reconstruction quality as a function of training set size, while simultaneously scaling the network size.
For all three tasks we find that an initially steep power-law scaling slows significantly already at moderate training set sizes.
Interpolating those scaling laws suggests that even training on millions of images would not significantly improve performance.
To understand the expected behavior, we analytically characterize the performance of a linear estimator learned with early stopped gradient descent.
The result formalizes the intuition that once the error induced by learning the signal model is small relative to the error floor, more training examples do not improve performance.
****

Robust Exploration via Clustering-based Online Density Estimation

Alaa Saade,Steven Kapturowski,Daniele Calandriello,Charles Blundell,Michal Valko,Pablo Sprechmann,Bilal Piot

Intrinsic motivation is a critical ingredient in reinforcement learning to enable progress when rewards are sparse. However, many existing approaches that measure the novelty of observations are brittle, or rely on restrictive assumptions about the environment which limit generality. We propose to decompose the exploration problem into two orthogonal sub-problems: (i) finding the right representation (metric) for exploration (ii) estimating densities in this representation space.

To address (ii), we introduce Robust Exploration via Clustering-based Online Density Estimation (RECODE), a non-parametric method that estimates visitation counts for clusters of states that are similar according to the metric induced by any arbitrary representation learning technique. We adapt classical clustering algorithms to design a new type of memory that allows RECODE to keep track of the history of interactions over thousands of episodes, thus effectively tracking global visitation counts. This is in contrast to existing non-parametric approaches, that can only store the recent history, typically the current episode.

The generality of RECODE allows us to easily address (i) by leveraging both off-the-shelf and novel representation learning techniques. In particular, we introduce a novel generalization of the action-prediction representation that leverages multi-step predictions and that we find to be better suited to a suite of challenging 3D-exploration tasks in DM-HARD-8. We show experimentally that our approach can work with a variety of RL agents, and obtain state-of-the-art performance on Atari and DM-HARD-8.
****

Meta Learning to Bridge Vision and Language Models for Multimodal Few-Shot Learning

Ivona Najdenkoska,Xiantong Zhen,Marcel Worring

Multimodal few-shot learning is challenging due to the large domain gap between vision and language modalities. Existing methods are trying to communicate visual concepts as prompts to frozen language models, but rely on hand-engineered task induction to reduce the hypothesis space. To make the whole process learnable, we introduce a multimodal meta-learning approach. Specifically, our approach decomposes the training of the model into a set of related multimodal few-shot tasks. We define a meta-mapper network, acting as a meta-learner, to efficiently bridge frozen large-scale vision and language models and leverage their already learned capacity. By updating the learnable parameters only of the meta-mapper, it learns to accrue shared meta-knowledge among these tasks. Thus, it can rapidly adapt to newly presented samples with only a few gradient updates. Importantly, it induces the task in a completely data-driven manner, with no need for a hand-engineered task induction. We evaluate our approach on recently proposed multimodal few-shot benchmarks, measuring how rapidly the model can bind novel visual concepts to words and answer visual questions by observing only a limited set of labeled examples. The experimental results show that our meta-learning approach outperforms the baseline across multiple datasets and various training settings while being computationally more efficient.

****

DLP: Data-Driven Label-Poisoning Backdoor Attack

Xun Xian,Xuan Bi,Mingyi Hong,Jie Ding

Backdoor attacks, which aim to disrupt or paralyze classifiers on specific tasks, are becoming an emerging concern in several learning scenarios, e.g., Machine Learning as a Service (MLaaS). Various backdoor attacks have been introduced in the literature, including perturbation-based methods, which modify a subset of training data; and clean-sample methods, which relabel only a proportion of training samples. Indeed, clean-sample attacks can be particularly stealthy since they never require modifying the samples at the training and test stages. However, the state-of-the-art clean-sample attack of relabelling training data based on their semantic meanings could be ineffective and inefficient in test performances due to heuristic selections of semantic patterns. In this work, we introduce a new type of clean-sample backdoor attack, named as DLP backdoor attack, allowing attackers to backdoor effectively, as measured by test performances, for an arbitrary backdoor sample size. The critical component of DLP is a data-driven backdoor scoring mechanism embedding in a multi-task formulation, which enables attackers to simultaneously perform well on the normal learning tasks and the backdoor tasks. Systematic empirical evaluations show the superior performance of the proposed DLP to state-of-the-art clean-sample attacks.

****

AlphaFold Distillation for Improved Inverse Protein Folding

Igor Melnyk,Aurelie Lozano,Payel Das,Vijil Chenthamarakshan

Inverse protein folding, i.e., designing sequences that fold into a given three-dimensional structure, is one of the fundamental design challenges in bio-engineering and drug discovery. Traditionally, inverse folding mainly involves learning from sequences that have an experimentally resolved structure. However, the known structures cover only a tiny space of the protein sequences, imposing limitations on the model learning. Recently proposed forward folding models, e.g., AlphaFold, offer unprecedented opportunity for accurate estimation of the structure given a protein sequence. Naturally, incorporating a forward folding model as a component of an inverse folding approach offers the potential of significantly improving the inverse folding, as the folding model can provide a feedback on any generated sequence in the form of the predicted protein structure or a structural confidence metric. However, at present, these forward folding models are still prohibitively slow to be a part of the model optimization loop during training. In this work, we propose to perform knowledge distillation on the folding model's confidence metrics, e.g., pTM or pLDDT scores, to obtain a smaller, faster and end-to-end differentiable distilled model, which then can be included as part of the structure consistency regularized inverse folding model training. Moreover, our regularization technique is general enough and can be applied in oth er design tasks, e.g., sequence-based protein infilling. Extensive experiments show a clear benefit of our method over the non-regularized baselines. E.g., in inverse folding design problems we observe up to 3% improvement in sequence recovery and up to 45% improvement in protein diversity, while still preserving structural consistency of the generated sequences.

****

Convexifying Transformers: Improving optimization and understanding of transformer networks

Tolga Ergen,Behnam Neyshabur,Harsh Mehta

Understanding the fundamental mechanism behind the success of transformer networks is still an open problem in the deep learning literature. Although their remarkable performance has been mostly attributed to the self-attention mechanism, the literature still lacks a solid analysis of these networks and interpretation of the functions learned by them. To this end, we study the training problem of attention/transformer networks and introduce a novel convex analytic approach to improve the understanding and optimization of these networks. Particularly, we first introduce a convex alternative to the self-attention mechanism and reformulate the regularized training problem of attention/transformer networks. Then, we cast the reformulation as a convex optimization problem that is interpretable and easier to optimize. Moreover, as a byproduct of our convex analysis, we reveal an implicit regularization mechanism, which promotes sparsity across tokens. Therefore, we not only improve the optimization of attention/transformer networks but also provide a solid theoretical understanding of the functions learned by them. We also demonstrate the effectiveness of our theory through several numerical experiments.

Unsupervised Model-based Pre-training for Data-efficient Control from Pixels

Sai Rajeswar,Pietro Mazzaglia,Tim Verbelen,Alexandre Piché,Bart Dhoedt,Aaron Courville,Alexandre Lacoste

Controlling artificial agents from visual sensory data is an arduous task. Reinforcement learning (RL) algorithms can succeed in this but require large amounts of interactions between the agent and the environment. To alleviate the issue, unsupervised RL proposes to employ self-supervised interaction and learning, for adapting faster to future tasks. Yet, whether current unsupervised strategies improve generalization capabilities is still unclear, especially in visual control settings. In this work, we design an unsupervised RL strategy for data-efficient visual control. First, we show that world models pre-trained with data collected using unsupervised RL can facilitate adaptation for future tasks. Then, we analyze several design choices to adapt faster, effectively reusing the agents' pre-trained components, and planning in imagination, with our hybrid planner, which we dub Dyna-MPC. By combining the findings of a large-scale empirical study, we establish an approach that strongly improves performance on the Unsupervised RL Benchmark, requiring 20$\times$ less data to match the performance of supervised methods. The approach also demonstrates robust performance on the Real-Word RL benchmark, hinting that the approach generalizes to noisy environments.

****

A Cognitive-inspired Multi-Module Architecture for Continual Learning

Shruthi Gowda,Bahram Zonooz,Elahe Arani

Artificial neural networks (ANNs) exhibit a narrow scope of expertise on stationary independent data. However, data in the real world is continuous and dynamic, and ANNs must adapt to novel scenarios while also retaining the learned knowledge to become lifelong learners. The ability of humans to excel at these tasks can be attributed to multiple factors ranging from cognitive computational structures, cognitive biases, and the multi-memory systems in the brain. We incorporate key concepts from each of these to design a cognitive-inspired continual learning method. Cognitive Continual Learner (CCL) includes multiple modules, implicit and explicit knowledge representation dichotomy, inductive bias, and a multi-memory system. CCL shows improvement across all continual learning settings and also exhibits reduced task recency bias. To test versatility of continual learning methods on a challenging distribution shift, we introduce a novel domain-increm

ental dataset Domain^{2}IL. In addition to improved performance on existing benchmarks, CCL also demonstrates superior performance on this dataset.
****

Shuffled Transformers for Blind Training

Hengyuan Xu,Liyao Xiang,Hangyu Ye,Dixi Yao,Pengzhi Chu

Conventional split learning faces the challenge of preserving training data and model privacy as a part of the training is beyond the data owner's control. We tackle this problem by introducing blind training, i.e., training without being aware of the data or the model, realized by shuffled Transformers. This is attributed to our intriguing findings that the inputs and the model weights of the Transformer encoder blocks, the backbone of Transformer, can be shuffled without degrading the model performance. We not only have proven the shuffling invariance property in theory, but also designs a privacy-preserving split learning framework following the property, with little modification to the original Transformer architecture. We carry out verification of the properties through experiments, and also show our proposed framework successfully defends privacy attacks to split learning with superiority.
****

Non-Gaussian Process Regression

Yaman Kindap,Simon J. Godsill

Standard GPs offer a flexible modelling tool for well-behaved processes. However, deviations from Gaussianity are expected to appear in real world datasets, with structural outliers and shocks routinely observed. In these cases GPs can fail to model uncertainty adequately and may over-smooth inferences. Here we extend the GP framework into a new class of time-changed GPs that allow for straightforward modelling of heavy-tailed non-Gaussian behaviours, while retaining a tractable conditional GP structure through an infinite mixture of non-homogeneous GPs representation. The conditional GP structure is obtained by conditioning the observations on a latent transformed input space and the random evolution of the latent transformation is modelled using a Lévy process which allows Bayesian inference in both the posterior predictive density and the latent transformation function. We present Markov chain Monte Carlo inference procedures for this model and demonstrate the potential benefits compared to a standard GP.
****

ImageNet-X: Understanding Model Mistakes with Factor of Variation Annotations

Badr Youbi Idrissi,Diane Bouchacourt,Randall Balestriero,Ivan Evtimov,Caner Hazirbas,Nicolas Ballas,Pascal Vincent,Michal Drozdzal,David Lopez-Paz,Mark Ibrahim

Deep learning vision systems are widely deployed across applications where reliability is critical. However, even today's best models can fail to recognize an object when its pose, lighting, or background varies. While existing benchmarks surface examples challenging for models, they do not explain why such mistakes arise. To address this need, we introduce ImageNet-X—a set of sixteen human annotations of factors such as pose, background, or lighting the entire ImageNet-1k validation set as well as a random subset of 12k training images. Equipped with ImageNet-X, we investigate 2,200 current recognition models and study the types of mistakes as a function of model’s (1) architecture, e.g. transformer vs. convolutional, (2) learning paradigm, e.g. supervised vs. self-supervised, and (3) training procedures, e.g., data augmentation. Regardless of these choices, we find models have consistent failure modes across ImageNet-X categories. We also find that while data augmentation can improve robustness to certain factors, they induce spill-over effects to other factors. For example, color-jitter augmentation improves robustness to color and brightness, but surprisingly hurts robustness to pose. Together, these insights suggest to advance the robustness of modern vision models, future research should focus on collecting additional data and understanding data augmentation schemes. Along with these insights, we release a toolkit based on ImageNet-X to spur further study into the mistakes image recognition systems make.

Hardware-aware compression with Random Operation Access Specific Tile (ROAST) hashing

Aditya Desai,Keren Zhou,Anshumali Shrivastava

Advancements in deep learning are often associated with increasing model sizes. Training and deploying large models require sophisticated hardware and incur significantly higher costs. Thus, model compression is a widely explored approach to solving the problem. However, SOTA techniques fall short in one or more desirable aspects of compression - for instance, pruning does not reduce memory for training, quantization can only provide up to $32\times$ compression, HashedNet is cache-inefficient, etc. This paper proposes a model-agnostic, cache-friendly, and hardware-aware model compression approach: Random Operation Access Specific Tile (ROAST) hashing. ROAST collapses the parameters by clubbing them through a lightweight mapping. While clubbing these parameters, ROAST utilizes cache hierarchies by aligning the memory access pattern with the parameter access pattern. ROAST is up to $\sim 25 \times$ faster to train and $\sim 50 \times$ faster to infer than the popular parameter sharing method HashedNet. Additionally, ROAST introduces global weight sharing, which is empirically and theoretically superior to local weight sharing in HashedNet, and can be of independent interest. With ROAST, we can efficiently train and deploy the model using a much smaller memory footprint ($\sim 10 \times - 100 \times$ lesser) in text and image classification tasks

SoftZoo: A Soft Robot Co-design Benchmark For Locomotion In Diverse Environments

Tsun-Hsuan Wang,Pingchuan Ma,Andrew Everett Spielberg,Zhou Xian,Hao Zhang,Joshua B. Tenenbaum,Daniela Rus,Chuang Gan

While significant research progress has been made in robot learning for control, unique challenges arise when simultaneously co-optimizing morphology. Existing work has typically been tailored for particular environments or representations. In order to more fully understand inherent design and performance tradeoffs and accelerate the development of new breeds of soft robots, a comprehensive virtual platform — with well-established tasks, environments, and evaluation metrics — is needed. In this work, we introduce SoftZoo, a soft robot co-design platform for locomotion in diverse environments. SoftZoo supports an extensive, naturally-inspired material set, including the ability to simulate environments such as flat ground, desert, wetland, clay, ice, snow, shallow water, and ocean. Further, it provides a variety of tasks relevant for soft robotics, including fast locomotion, agile turning, and path following, as well as differentiable design representations for morphology and control. Combined, these elements form a feature-rich platform for analysis and development of soft robot co-design algorithms. We benchmark prevalent representations and co-design algorithms, and shed light on 1) the interplay between environment, morphology, and behavior (2) the importance of design space representations 3) the ambiguity in muscle formation and controller synthesis and 4) the value of differentiable physics. We envision that SoftZoo will serve as a standard platform and template an approach toward the development of novel representations and algorithms for co-designing soft robots’ behavioral and morphological intelligence. Demos are available on our project page.

Smooth Mathematical Functions from Compact Neural Networks

INGI HONG

This is paper for the smooth function approximation by neural networks (NN). Mathematical or physical functions can be replaced by NN models through regression. In this study, we get NNs that generate highly accurate and highly smooth function, which only comprised of a few weight parameters, through discussing a few topics about regression. First, we reinterpret inside of NNs for regression; consequently, we propose a new activation function--integrated sigmoid linear unit (ISLU). Then special charateristics of metadata for regression, which is different from other data like image or sound, is discussed for improving the performance of neural networks. Finally, the one of a simple hierarchical NN that generate models substituting mathematical function is presented, and the new batch concept ``meta-batch" which improves the performance of NN several times more is introduced. The new activation function, meta-batch method, features of numerical data, meta-augmentation with metaparameters, and a structure of NN generating a compact multi-layer perceptron(MLP) are essential in this study.

Self-Supervised Learning of Maximum Manifold Capacity Representations

Thomas Edward Yerxa,Yilun Kuang,Eero P Simoncelli,SueYeon Chung

Self-supervised Learning (SSL) has recently emerged as a successful strategy for learning useful representations of images without relying on hand-assigned labels. Many such methods aim to learn a function that maps distinct views of the same scene or object to nearby points in the representation space. These methods are often justified by showing that they optimize an objective that is an approximation of (or correlated with) the mutual information between representations of different views. Here, we recast the problem from the perspective of manifold capacity, a recently developed measure for evaluating the quality of a representation. Specifically, we develop a contrastive learning framework that aims to maximize the number of linearly separable object manifolds, yielding a Maximum Manifold Capacity Representation (MMCR). We apply this method to unlabeled images, each augmented by a set of basic transformations, and find that it learns meaningful features using the standard linear evaluation protocol. Specifically, we find that MMCRs support performance on object recognition comparable to recently developed SSL frameworks, while providing more robustness to adversarial attacks. Finally, empirical analysis reveals the means by which compression of object manifolds gives rise to class separability.

TOWARDS AN OBJECTIVE EVALUATION OF THE TRUSTWORTHINESS OF CLASSIFIERS

Manish Chandra,Debasis Ganguly

With the widespread deployment of AI models in applications that impact human lives, research on model trustworthiness has become increasingly important, as a result of which model effectiveness alone (measured, e.g., with accuracy, F1, etc.) should not be the only criteria to evaluate predictive models; additionally the trustworthiness of these models should also be factored in. It has been argued that the features deemed important by a black-box model should be aligned with the human perception of the data, which in turn, should contribute to increasing the trustworthiness of a model. Existing research in XAI evaluates such alignments with user studies - the limitations being that these studies are subjective, difficult to reproduce, and consumes a large amount of time to conduct. We propose an evaluation framework, which provides a quantitative measure for trustworthiness of a black-box model, and hence, we are able to provide a fair comparison between a number of different black-box models. Our framework is applicable to both text and images, and our experiment results show that a model with a higher accuracy does not necessarily exhibit better trustworthiness.

Fine-grain Inference on Out-of-Distribution Data with Hierarchical Classification

Randolph Linderman,Jingyang Zhang,Nathan Inkawhich,Hai Li,Yiran Chen

Machine learning methods must be trusted to make appropriate decisions in real-world environments, even when faced with out-of-distribution (OOD) samples. Many current approaches simply aim to detect OOD examples and alert the user when an unrecognized input is given. However, when the OOD sample significantly overlaps with the training data, a binary anomaly detection is not interpretable or explainable, and provides little information to the user. We propose a new model for OOD detection that makes predictions at varying levels of granularity—as the inputs become more ambiguous, the model predictions become coarser and more conservative. Consider an animal classifier that encounters an unknown bird species and a car. Both cases are OOD, but the user gains more information if the classifier recognizes that its uncertainty over the particular species is too large and predicts “bird” instead of detecting it as OOD. Furthermore, we diagnose the classifier’s performance at each level of the hierarchy improving the explainabilit y and interpretability of the model’s predictions. We demonstrate the effectiveness of hierarchical classifiers for both fine- and coarse-grained OOD tasks.

ResGrad: Residual Denoising Diffusion Probabilistic Models for Text to Speech

Zehua Chen,Yihan Wu,Yichong Leng,Jiawei Chen,Haohe Liu,Xu Tan,Yang Cui,Ke Wang,Lei He,sheng zhao,Jiang Bian,Danilo Mandic

Denoising Diffusion Probabilistic Models (DDPMs) are emerging in text-to-speech (TTS) synthesis because of their strong capability of generating high-fidelity samples. However, their iterative refinement process in high-dimensional data space results in slow inference speed, which restricts their application in real-time systems. Previous works have explored speeding up by minimizing the number of inference steps but at the cost of sample quality. In this work, to improve the inference speed for DDPM-based TTS model while achieving high sample quality, we propose ResGrad, a lightweight diffusion model which learns to refine the output spectrogram of an existing TTS model (e.g., FastSpeech 2) by predicting the residual between the model output and the corresponding ground-truth speech. ResGrad has several advantages: 1) Compare with other acceleration methods for DDPM which need to synthesize speech from scratch, ResGrad reduces the complexity of task by changing the generation target from ground-truth mel-spectrogram to the residual, resulting into a more lightweight model and thus a smaller real-time factor. 2) ResGrad is employed in the inference process of the existing TTS model in a plug-and-play way, without re-training this model. We verify ResGrad on the single-speaker dataset LJSpeech and two more challenging datasets with multiple speakers (LibriTTS) and high sampling rate (VCTK). Experimental results show that in comparison with other speed-up methods of DDPMs: 1) ResGrad achieves better sample quality with the same inference speed measured by real-time factor; 2) with similar speech quality, ResGrad synthesizes speech faster than baseline methods by more than 10 times. Audio samples are available at \url{https://resgrad1.github.io/}.

The Adversarial Regulation of the Temporal Difference Loss Costs More Than Expected

Ezgi Korkmaz

Deep reinforcement learning research has enabled reaching significant performance levels for sequential decision making in MDPs with highly complex observations and state dynamics with the aid of deep neural networks. However, this aid came with a cost that is inherent to deep neural networks which have increased sensitivities towards indistinguishable peculiarly crafted non-robust directions. To alleviate these sensitivities several studies suggested techniques to cope with this problem via explicitly regulating the temporal difference loss for the worst-case sensitivity. In our study, we show that these worst-case regularization techniques come with a cost that intriguingly causes inconsistencies and overestimations in the state-action value functions. Furthermore, our results essentially demonstrate that vanilla trained deep reinforcement learning policies have more accurate and consistent estimates for the state-action values. We believe our results reveal foundational intrinsic properties of the adversarial training techniques and demonstrate the need to rethink the approach to robustness in deep reinforcement learning.

Beyond Link Prediction: On Pre-Training Knowledge Graph Embeddings

Daniel Ruffinelli,Rainer Gemulla

Knowledge graph embeddings (KGE) models provide low-dimensional representations of the entities and relations in a knowledge graph (KG). Most prior work focused on training and evaluating KGE models for the task of link prediction; the question of whether or not KGE models provide useful representations more generally remains largely open. In this work, we explore the suitability of KGE models (i) for more general graph-structure prediction tasks and (ii) for downstream tasks such as entity classification. For (i), we found that commonly trained KGE models often perform poorly at structural tasks other than link prediction. Based on this observation, we propose a more general multi-task training approach, which includes additional self-supervised tasks such as neighborhood prediction or domain prediction. In our experiments, these multi-task KGE models showed significantly better overall performance for structural prediction tasks. For (ii), we investigate whether KGE models provide useful features for a variety of downstream tasks. Here we view KGE models as a form of self-supervised pre-training and study the impact of both model training and model selection on downstream task performance. We found that multi-task pre-training can (but does not always) significantly improve performance and that KGE models can (but do not always) compete with or even outperform task-specific GNNs trained in a supervised fashion. Our work suggests that more research is needed on how to pre-train KGE models and on their suitability for downstream applications.

Masked Siamese ConvNets: Towards an Effective Masking Strategy for General-purpose Siamese Networks

Li Jing,Jiachen Zhu,Yann LeCun

Siamese Networks are a popular self-supervised learning framework that learns useful representation without human supervision by encouraging representations to be invariant to distortions. Existing methods heavily rely on hand-crafted augmentations, which are not easily adapted to new domains. To explore a general-purpose or domain-agnostic siamese network, we investigate using masking as augmentations in siamese networks. Recently, masking for siamese networks has only been shown useful with transformer architectures, e.g. MSN and data2vec. In this work, we identify the underlying problems of masking for siamese networks with arbitrary backbones, including ConvNets. We propose an effective and general-purpose masking strategy and demonstrate its effectiveness on various siamese network frameworks. Our method generally improves siamese networks' performances in the few-shot image classification, and object detection tasks.

Canary in a Coalmine: Better Membership Inference with Ensembled Adversarial Queries

Yuxin Wen,Arpit Bansal,Hamid Kazemi,Eitan Borgnia,Micah Goldblum,Jonas Geiping,Tom Goldstein

As industrial applications are increasingly automated by machine learning models, enforcing personal data ownership and intellectual property rights requires tracing training data back to their rightful owners. Membership inference algorithms approach this problem by using statistical techniques to discern whether a target sample was included in a model's training set. However, existing methods only utilize the unaltered target sample or simple augmentations of the target to compute statistics. Such a sparse sampling of the model's behavior carries little information, leading to poor inference capabilities. In this work, we use adversarial tools to directly optimize for queries that are discriminative and diverse. Our improvements achieve significantly more accurate membership inference than existing methods, especially in offline scenarios and in the low false-positive regime which is critical in legal settings.

Maximum Entropy Information Bottleneck for Confidence-aware Stochastic Embedding

Sungtae An,Nataraj Jammalamadaka,Eunji Chong

Stochastic embedding has several advantages over deterministic embedding, such as the capability of associating uncertainty with the resulting embedding and robustness to noisy data. This is especially useful when the input data has ambiguity (e.g., blurriness or corruption) which often happens with in-the-wild settings. Many existing methods for stochastic embedding are limited by the assumption that the embedding follows a standard normal distribution under the variational information bottleneck principle. We present a different variational approach to stochastic embedding in which maximum entropy acts as the bottleneck, which we call "Maximum Entropy Information Bottleneck" or MEIB. We show that models trained with the MEIB objective outperform existing methods in terms of regularization, perturbation robustness, probabilistic contrastive learning, and risk-controlled recognition performance.

Reprogramming Large Pretrained Language Models for Antibody Sequence Infilling
Igor Melnyk,Vijil Chenthamarakshan,Pin-Yu Chen,Payel Das,Amit Dhurandhar,Inkit Padhi,Devleena Das
Antibodies comprise the most versatile class of binding molecules, with numerous applications in biomedicine. Therapeutic antibody development requires designing novel and diverse sequences with improved properties, while maintaining the structural consistency. Computational design of antibodies involves unusual challenges relative to designing other classes of proteins, as antibodies comprise multiple long, variable, and unstructured loops at the complementarity-determining region (CDR) that determine the antigen binding affinity and specificity of an antibody. Recently, deep language models and graph neural networks have shown impressive success in antibody sequence generation. Since only a limited number of antibody structures are known, training a model using this limited data can lead to degraded performance, particularly lacking diversity in the generated samples. To address such issues, we leverage the method of Model Reprogramming (MR) here, which focuses on repurposing pretrained machine learning models for target domain tasks with scarce data, where it may be difficult to train a high-performing model from scratch. Prior works in MR have primarily focused on classification-based tasks. We extend the capabilities of reprogramming beyond classification tasks, and towards a more complex problem of antibody sequence generation. Specifically, we introduce Reprogramming for Protein Sequence Infilling, a framework in which pretrained natural language models are repurposed for protein sequence infilling via reprogramming, to infill protein sequence templates as a method of novel protein generation. For variable CDR sequence design, we formulate the task as text infilling that uses the constant region of an antibody as the sequence template. Results on antibody design benchmarks show that our reprogrammed model on low resourced antibody sequence dataset provides highly diverse CDR sequences, up to more than a two-fold increase of diversity over the baselines, without losing structural integrity and naturalness. The performance benefit of the reprogrammed model learning only from antibody sequences is more evident for longer CDR design or for multiple loop infilling at once, compared to existing graph-based models that require additional structural information. The generated sequences also demonstrate enhanced antigen binding specificity or virus neutralization ability.
****
Using semantic distance for diverse and sample efficient genetic programming
David Saxton,Chrisantha Fernando
Evolutionary methods, such as genetic programming, search a space of programs to find those with good fitness, often using mutations that manipulate the syntactic structure of programs without being aware of how they affect the semantics. For applications where the semantics are highly sensitive to small syntactic mutations, or where fitness evaluation is expensive, this can make learning programs intractable.

We introduce a mutation operator that yields mutated programs that are semantically far from previously evaluated programs, while still being semantically close to their parent. For function regression, this leads to an algorithm that is one to two orders of magnitude more sample efficient than other gradient-free methods, such as genetic programming, or learning the weights of a neural network using evolutionary strategies.

We show how this method can be applied to learning architecture-specific and general purpose neural network optimizers, and to reinforcement learning loss functions. The learnt components are simple, interpretable, high performance, and contain novel features not seen before such as weight growth.
****
Semi-parametric Prompt-Generation for Model Editing
Harshavardhan Kamarthi,Yen-Chang Hsu,Yilin Shen,Hongxia Jin
Large Language models are used in various downstream tasks with great success. However, changing specific knowledge or beliefs of a model (a.k.a. model editing)

efficiently to revise inaccurate predictions while not affecting all other cases is still challenging. Most previous methods compute gradients to change the model. These strategies generally work, paying the cost of high computing and memory complexity. The semi-parametric strategy has recently shown its effectiveness in alleviating the complexity via introducing memory to store the edits of knowledge. However, the memory does not have a proper mechanism to be utilized by a large pre-trained language model, limiting its generalizability to more complicated model editing scenarios. This work proposes a prompt generation mechanism to bridge
the gap. Our method encodes the edits as prefix prompts for language models, then has the large pre-trained language model perform inference with the prompts. In other words, the model is edited by prompts without changing model parameters. Our method, SEPROG, significantly outperforms state-of-art methods by up to 20% on entailed edit benchmarks and provides up to 30% better performance over gradient-based methods on non-entailed benchmarks. These advantages are achieved with much less computation and memory consumption, proving prompt generation’s great potential in model editing problems.

Improved Learning-augmented Algorithms for k-means and k-medians Clustering
Thy Dinh Nguyen,Anamay Chaturvedi,Huy Nguyen
We consider the problem of clustering in the learning-augmented setting. We are given a data set in d-dimensional Euclidean space, and a label for each data point given by a predictor indicating what subsets of points should be clustered together. This setting captures situations where we have access to some auxiliary information about the data set relevant for our clustering objective, for instance the labels output by a neural network. Following prior work, we assume that there are at most an $\alpha \in (0,c)$ for some $c<1$ fraction of false positives and false negatives in each predicted cluster, in the absence of which the labels would attain the optimal clustering cost OPT. For a dataset of size m, we propose a deterministic k-means algorithm that produces centers with an improved bound on the clustering cost compared to the previous randomized state-of-the-art algorithm while preserving the $O(d m \log m)$ runtime. Furthermore, our algorithm works even when the predictions are not very accurate, i.e., our cost bound holds for α up to $1/2$, an improvement from α being at most $1/7$ in previous work. For the k-medians problem we again improve upon prior work by achieving a biquadratic improvement in the dependence of the approximation factor on the accuracy parameter α to get a cost of $(1+O(\alpha))\mathrm{OPT}$, while requiring essentially just $O(md \log^3 m/\alpha)$ runtime.

Neural Implicit Shape Editing using Boundary Sensitivity
Arturs Berzins,Moritz Ibing,Leif Kobbelt
Neural fields are receiving increased attention as a geometric representation due to their ability to compactly store detailed and smooth shapes and easily undergo topological changes. Compared to classic geometry representations, however, neural representations do not allow the user to exert intuitive control over the shape. Motivated by this, we leverage boundary sensitivity to express how perturbations in parameters move the shape boundary. This allows us to interpret the effect of each learnable parameter and study achievable deformations. With this, we perform geometric editing: finding a parameter update that best approximates a globally prescribed deformation. Prescribing the deformation only locally allows the rest of the shape to change according to some prior, such as semantics or deformation rigidity. Our method is agnostic to the model and its training and updates the NN in-place. Furthermore, we show how boundary sensitivity helps to optimize and constrain objectives (such as surface area and volume), which are difficult to compute without first converting to another representation, such as a mesh.

****

Amortised Invariance Learning for Contrastive Self-Supervision
Ruchika Chavhan,Jan Stuehmer,Calum Heggan,Mehrdad Yaghoobi,Timothy Hospedales

Contrastive self-supervised learning methods famously produce high quality transferable representations by learning invariances to different data augmentations. Invariances established during pre-training can be interpreted as strong inductive biases. However these may or may not be helpful, depending on if they match the invariance requirements of downstream tasks or not. This has led to several attempts to learn task-specific invariances during pre-training, however, these methods are highly compute intensive and tedious to train. We introduce the notion of amortized invariance learning for contrastive self supervision. In the pre-training stage, we parameterize the feature extractor by differentiable invariance hyper-parameters that control the invariances encoded by the representation. Then, for any downstream task, both linear readout and task-specific invariance requirements can be efficiently and effectively learned by gradient-descent. We evaluate the notion of amortized invariances for contrastive learning over two different modalities: vision and audio, on two widely-used contrastive learning methods in vision: SimCLR and MoCo-v2 with popular architectures like ResNets and Vision Transformers, and SimCLR with ResNet-18 for audio. We show that our amortized features provide a reliable way to learn diverse downstream tasks with different invariance requirements, while using a single feature and avoiding task-specific pre-training. This provides an exciting perspective that opens up new horizons in the field of general purpose representation learning.

DIFFUSION GENERATIVE MODELS ON SO(3)

Yesukhei Jagvaral,Francois Lanusse,Rachel Mandelbaum

Diffusion-based generative models represent the current state-of-the-art for image generation. However, standard diffusion models are based on Euclidean geometry and do not translate directly to manifold-valued data. In this work, we develop extensions of both score-based generative models (SGMs) and Denoising Diffusion Probabilistic Models (DDPMs) to the Lie group of 3D rotations, SO(3). SO(3) is of particular interest in many disciplines such as robotics, biochemistry and astronomy/planetary science. Contrary to more general Riemannian manifolds, SO(3) admits a tractable solution to heat diffusion, and allows us to implement efficient training of Diffusion models. We apply both SO(3) DDPMs and SGMs to synthetic densities on SO(3) and demonstrate state-of-the-art results.

****

Certifiably Robust Transformers with 1-Lipschitz Self-Attention

Xiaojun Xu,Linyi Li,Yu Cheng,Subhabrata Mukherjee,Ahmed Hassan Awadallah,Bo Li

Recent works have shown that neural networks with Lipschitz constraints will lead to high adversarial robustness. In this work, we propose the first One-Lipschitz Self-Attention (OLSA) mechanism for Transformer models. In particular, we first orthogonalize all the linear operations in the self-attention mechanism. We then bound the overall Lipschitz constant by aggregating the Lipschitz of each element in the softmax with weighted sum. Based on the proposed self-attention mechanism, we construct an OLSA Transformer to achieve model deterministic certified robustness. We evaluate our model on multiple natural language processing (NLP) tasks and show that it outperforms existing certification on Transformers, especially for models with multiple layers. As an example, for 3-layer Transformers we achieve an ■2 deterministic certified robustness radius of 1.733 and 0.979 on the word embedding space for the Yelp and SST dataset, while the existing SOTA certification baseline of the same embedding space can only achieve 0.061 and 0.110. In addition, our certification is significantly more efficient than previous works, since we only need the output logits and Lipschitz constant for certification. We also fine-tune our OLSA Transformer as a downstream classifier of a pre-trained BERT model and show that it achieves significantly higher certified robustness on BERT embedding space compared with previous works (e.g. from 0.071 to 0.368 on the QQP datasets).

Revisiting Populations in multi-agent Communication

Paul Michel,Mathieu Rita,Kory Wallace Mathewson,Olivier Tieleman,Angeliki Lazaridou

Despite evidence from cognitive sciences that larger groups of speakers tend to develop more structured languages in human communication, scaling up to populations has failed to yield significant benefits in emergent multi-agent communication. In this paper we advocate for an alternate population-level training paradigm for referential games based on the idea of "partitioning" the agents into sender-receiver pairs and limiting co-adaptation across pairs. We show that this results in optimizing a different objective at the population level, where agents maximize (1) their respective "internal" communication accuracy and (2) some measure of alignment between agents. In experiments, we find that this leads to the emergence of languages that are significantly more compositional. Moreover, when agents are trained in populations that are not fully connected (ie. not all agent pairs interact at training time), this approach reduces multi-linguality and improves zero-shot communication with new agents (ie. agents are able to communicate successfully with other agents outside their training partners).

****

Univariate vs Multivariate Time Series Forecasting with Transformers
William Michael John Murphy,Ke Chen

Multivariate time series forecasting is a challenging problem and a number of Transformer-based long-term time series forecasting models have been developed to tackle it. These models, however, are impeded by the additional information available in multivariate forecasting. In this paper we propose a simple univariate setting as an alternative method for producing multivariate forecasts. The univariate model is trained on each individual dimension of the time series. This single model is then used to forecast each dimension of the multivariate forecast in turn. A comparative study shows that our setting outperforms state-of-the-art Transformers in the multivariate setting in benchmark datasets. To investigate why, we set three hypotheses and verify them via an empirical study, which leads to a criterion for when our univariate setting is likely to lead to better performance and reveals flaws in the current multivariate Transformers for long-term time series forecasting.

Sequential Gradient Coding For Straggler Mitigation
Nikhil Krishnan Muralee Krishnan,MohammadReza Ebrahimi,Ashish J Khisti

In distributed computing, slower nodes (stragglers) usually become a bottleneck. Gradient Coding (GC), introduced by Tandon et al., is an efficient technique that uses principles of error-correcting codes to distribute gradient computation in the presence of stragglers. In this paper, we consider the distributed computation of a sequence of gradients $\{g(1),g(2),\ldots,g(J)\}$, where processing of each gradient $g(t)$ starts in round-t and finishes by round-$(t+T)$. Here $T\geq 0$ denotes a delay parameter. For the GC scheme, coding is only across computing nodes and this results in a solution where $T=0$. On the other hand, having $T>0$ allows for designing schemes which exploit the temporal dimension as well. In this work, we propose two schemes that demonstrate improved performance compared to GC. Our first scheme combines GC with selective repetition of previously unfinished tasks and achieves improved straggler mitigation. In our second scheme, which constitutes our main contribution, we apply GC to a subset of the tasks and repetition for the remainder of the tasks. We then multiplex these two classes of tasks across workers and rounds in an adaptive manner, based on past straggler patterns. Using theoretical analysis, we demonstrate that our second scheme achieves significant reduction in the computational load. In our experiments, we study a practical setting of concurrently training multiple neural networks over an AWS Lambda cluster involving 256 worker nodes, where our framework naturally applies. We demonstrate that the latter scheme can yield a 16\% improvement in runtime over the baseline GC scheme, in the presence of naturally occurring, non-simulated stragglers.

TTN: A Domain-Shift Aware Batch Normalization in Test-Time Adaptation
Hyesu Lim,Byeonggeun Kim,Jaegul Choo,Sungha Choi

This paper proposes a novel batch normalization strategy for test-time adaptation. Recent test-time adaptation methods heavily rely on the modified batch normal ization, i.e., transductive batch normalization (TBN), which calculates the mean and the variance from the current test batch rather than using the running mean and variance obtained from the source data, i.e., conventional batch normalization (CBN). Adopting TBN that employs test batch statistics mitigates the performance degradation caused by the domain shift. However, re-estimating normalization statistics using test data depends on impractical assumptions that a test batch should be large enough and be drawn from i.i.d. stream, and we observed that the previous methods with TBN show critical performance drop without the assumptions. In this paper, we identify that CBN and TBN are in a trade-off relationship and present a new test-time normalization (TTN) method that interpolates the statistics by adjusting the importance between CBN and TBN according to the domain-shift sensitivity of each BN layer. Our proposed TTN improves model robustness to shifted domains across a wide range of batch sizes and in various realistic evaluation scenarios. TTN is widely applicable to other test-time adaptation methods that rely on updating model parameters via backpropagation. We demonstrate that adopting TTN further improves their performance and achieves state-of-the-art performance in various standard benchmarks.

Choreographer: Learning and Adapting Skills in Imagination

Pietro Mazzaglia,Tim Verbelen,Bart Dhoedt,Alexandre Lacoste,Sai Rajeswar

Unsupervised skill learning aims to learn a rich repertoire of behaviors without external supervision, providing artificial agents with the ability to control and influence the environment. However, without appropriate knowledge and exploration, skills may provide control only over a restricted area of the environment, limiting their applicability. Furthermore, it is unclear how to leverage the learned skill behaviors for adapting to downstream tasks in a data-efficient manner. We present Choreographer, a model-based agent that exploits its world model to learn and adapt skills in imagination. Our method decouples the exploration and skill learning processes, being able to discover skills in the latent state space of the model. During adaptation, the agent uses a meta-controller to evaluate and adapt the learned skills efficiently by deploying them in parallel in imagination. Choreographer is able to learn skills both from offline data, and by collecting data simultaneously with an exploration policy. The skills can be used to effectively adapt to downstream tasks, as we show in the URL benchmark, where we outperform previous approaches from both pixels and states inputs. The skills also explore the environment thoroughly, finding sparse rewards more frequently, as shown in goal-reaching tasks from the DMC Suite and Meta-World.

Disentanglement of Correlated Factors via Hausdorff Factorized Support

Karsten Roth,Mark Ibrahim,Zeynep Akata,Pascal Vincent,Diane Bouchacourt

A grand goal in deep learning research is to learn representations capable of generalizing across distribution shifts.

Disentanglement is one promising direction aimed at aligning a model's representation with the underlying factors generating the data (e.g. color or background). Existing disentanglement methods, however, rely on an often unrealistic assumption: that factors are statistically independent. In reality, factors (like object color and shape) are correlated. To address this limitation, we consider the use of a relaxed disentanglement criterion -- the Hausdorff Factorized Support (HFS) criterion -- that encourages only pairwise factorized support, rather than a factorial distribution, by minimizing a Hausdorff distance. This allows for arbitrary distributions of the factors over their support, including correlations between them. We show that the use of HFS consistently facilitates disentanglement and recovery of ground-truth factors across a variety of correlation settings and benchmarks, even under severe training correlations and correlation shifts, with in parts over +60% in relative improvement over existing disentanglement methods. In addition, we find that leveraging HFS for representation learning can even facilitate transfer to downstream tasks such as classification under distribution shifts. We hope our original approach and positive empirical results inspire further progress on the open problem of robust generalization. Code availab le at https://github.com/facebookresearch/disentangling-correlated-factors.

On the optimization and generalization of overparameterized implicit neural networks

Tianxiang Gao,Hongyang Gao

Implicit neural networks have become increasingly attractive in the machine learning community since they can achieve competitive performance but use much less computational resources. Recently, a line of theoretical works established the global convergences for first-order methods such as gradient descent if the implicit networks are over-parameterized. However, as they train all layers together, their analyses are equivalent to only studying the evolution of the output layer. It is unclear how the implicit layer contributes to the training. Thus, in this paper, we restrict ourselves to only training the implicit layer. We show that global convergence is guaranteed, even if only the implicit layer is trained. On the other hand, the theoretical understanding of when and how the training performance of an implicit neural network can be generalized to unseen data is still under-explored. Although this problem has been studied in standard feed-forward networks, the case of implicit neural networks is still intriguing since implicit networks theoretically have infinitely many layers. Therefore, this paper investigates the generalization error for implicit neural networks. Specifically, we study the generalization of an implicit network activated by the ReLU function over random initialization. We provide a generalization bound that is initialization sensitive. As a result, we show that gradient flow with proper random initialization can train a sufficient over-parameterized implicit network to achieve arbitrarily small generalization errors.

Differentially Private Conditional Text Generation For Synthetic Data Production

Pranav Putta,Ander Steele,Joseph W Ferrara

Companies have faced increasing pressure in recent years to anonymize user collected data when sharing internally or to third parties. Text data in particular contains copious amounts of personally identifiable information that has proven to be difficult to de-identify while remain useful for the party of interest. Previous works have suggested that synthetic text generation could provide a promising avenue to curate high performant and private datasets. In this paper, we introduce an approach to synthesize high utility text classification datasets by performing conditional generation through a large language model, distilGPT2, while providing measurable guarantees via differential privacy. We show that naive approaches suffer heavily from utility loss by entangling task-relevant factors in the transformer embedding space, making controlled generation more difficult. We analyze how incorporating a secondary learning objective can improve the performance of the generative model, improving utility of the generated data.

Multi-Task Structural Learning using Local Task Similarity induced Neuron Creation and Removal

Naresh Kumar Gurulingan,Elahe Arani,Bahram Zonooz

Multi-task learning has the potential to improve generalization by maximizing positive transfer between tasks while reducing task interference. Fully achieving this potential is hindered by manually designed architectures that remain static throughout training. In contrast, learning in the brain occurs through structural changes that are in tandem with changes in synaptic strength. Therefore, we propose Multi-Task Structural Learning (MTSL) which simultaneously learns the multi-task architecture and its parameters. MTSL begins with an identical single task network for each task and alternates between a task learning phase and a structural learning phase. In the task learning phase, each network specializes in the corresponding task. In each of the structural learning phases, starting from the earliest layer, locally similar task layers first transfer their knowledge to a newly created group layer after which they become redundant and are removed. Our experimental results show that MTSL achieves competitive generalization with various baselines and improves robustness to out-of-distribution data.

Generating Sequences by Learning to Self-Correct

Sean Welleck,Ximing Lu,Peter West,Faeze Brahman,Tianxiao Shen,Daniel Khashabi,Yejin Choi

Sequence generation applications require satisfying semantic constraints, such as ensuring that programs are correct, using certain keywords, or avoiding undesirable content. Language models, whether fine-tuned or prompted with few-shot demonstrations, frequently violate these constraints, and lack a mechanism to iteratively revise their outputs. Moreover, some powerful language models are of extreme scale or inaccessible, making it inefficient, if not infeasible, to update their parameters for task-specific adaptation. We present Self-Correction, an approach that decouples an imperfect base generator (an off-the-shelf language model or supervised sequence-to-sequence model) from a separate corrector that learns to iteratively correct imperfect generations. To train the corrector, we propose an online training procedure that can use either scalar or natural language feedback on intermediate imperfect generations. We show that Self-Correction improves upon the base generator in three diverse generation tasks - mathematical program synthesis, lexically-constrained generation, and toxicity control - even when the corrector is much smaller than the base generator.

Bringing robotics taxonomies to continuous domains via GPLVM on hyperbolic manifolds

Noémie Jaquier,Leonel Rozo,Miguel González-Duque,Viacheslav Borovitskiy,Tamim Asfour

Robotic taxonomies have appeared as high-level hierarchical abstractions that classify how humans move and interact with their environment. They have proven useful to analyse grasps, manipulation skills, and whole-body support poses. Despite the efforts devoted to design their hierarchy and underlying categories, their use in application fields remains scarce. This may be attributed to the lack of computational models that fill the gap between the discrete hierarchical structure of the taxonomy and the high-dimensional heterogeneous data associated to its categories. To overcome this problem, we propose to model taxonomy data via hyperbolic embeddings that capture the associated hierarchical structure. To do so, we formulate a Gaussian process hyperbolic latent variable model and enforce the taxonomy structure through graph-based priors on the latent space and distance-preserving back constraints. We test our model on the whole-body support pose taxonomy to learn hyperbolic embeddings that comply with the original graph structure. We show that our model properly encodes unseen poses from existing or new taxonomy categories, it can be used to generate trajectories between the embeddings, and it outperforms its Euclidean counterparts.

COC curve: operating neural networks at high accuracy and low manual effort

Sara Sangalli,Ertunc Erdil,Ender Konukoglu

In human-AI collaboration systems for critical applications based on neural networks, humans should set an operating point based on a model's confidence to determine when the decision should be delegated to experts.

The underlying assumption is that the network's confident predictions are also correct.

However, modern neural networks are notoriously overconfident in their predictions, thus they achieve lower accuracy even when operated at high confidence. Network calibration methods mitigate this problem by encouraging models to make predictions whose confidence is consistent with the accuracy, i.e., encourage confidence to reflect the number of mistakes the network is expected to make. However, they do not consider that data need to be manually analysed by experts in critical applications if the confidence of the network is below a certain level. This can be crucial for applications where available expert time is limited and expensive, e.g., medical ones.

In this paper, we propose (1) Confidence Operating Characteristics (COC) curve that assesses a predictive model in terms of accuracy and manual analysis it requires for varying operating points on confidence, and (2) a new loss function for classification that takes into account both aspects and derived from the COC curve.

We perform extensive experiments on multiple computer vision and medical image datasets for classification and compare the proposed approach with the existing network calibration methods. Our results demonstrate that our method improves classification accuracy while delegating less number of decisions to human experts, achieves better out-of-distribution samples detection and on par calibration performance compared to existing methods.

Repository-Level Prompt Generation for Large Language Models of Code

Disha Shrivastava,Hugo Larochelle,Daniel Tarlow

With the success of large language models (LLMs) of code and their use as code assistants (e.g.\ Codex used in GitHub Copilot, techniques for introducing domain-specific knowledge in the prompt design process become important. In this work, we propose a framework called Repo-Level Prompt Generator that learns to generate example-specific prompts using prompt proposals. The prompt proposals take context from the entire repository, thereby incorporating both the structure of the repository and the context from other relevant files (e.g.\ imports, parent class files). Our technique doesn't require any access to the weights of the LLM, making it applicable in cases where we only have black-box access to the LLM. We conduct experiments on the task of single-line code-autocompletion using code repositories taken from Google Code archives. We demonstrate that an oracle constructed from our prompt proposals gives a remarkably high relative improvement of 36\% over Codex, showing the quality of these proposals. Further, we show that when we train a model to select the best prompt proposal, we can achieve significant performance gains over Codex and other baselines.

FP_AINet: Fusion Prototype with Adaptive Induction Network for Few-Shot Learning

Mengping Dong,xue Liu,Chaojun Cen,YANG MI,Zhenbo Li

Conventional prototypical network treats all samples equally and does not consider the effects of noisy samples, which leads to a biased class representation. In this paper, we propose a novel Fusion Prototype with Adaptive Induction Network (FP_AINet) for few-shot learning that can learn representative prototypes from a few support samples. Specifically, to address the problem of noisy samples in the support set, an adaptive induction network is developed, which can learn different class representations for diverse queries and assign adaptive scores for support samples according to their relative significance. Moreover, the proposed model can generate a more accurate prototype than comparison methods by considering the query-related samples. With an increasing of samples, the prototypical network is more expressive since the Adaptive Induction Network ignores the relative local features. As a result, a Gaussian-based fusion algorithm is designed to learn more representative prototypes. Extensive experiments are conducted on three datasets: miniImageNet, tieredImageNet, and CIFAR_FS. The experimental results compared with the state-of-the-art few-shot learning methods demonstrate the superiority of FP_AINet.

Neural Network Differential Equation Solvers allow unsupervised error estimation and correction

Akshunna S. Dogra,Jeffrey B. Lai,Min Chul Lee,Martin Peev

Neural Network Differential Equation (NN DE) solvers have surged in popularity due to a combination of factors: computational advances making their optimization more tractable, their capacity to handle high dimensional problems, easy interpretability, etc. However, most NN DE solvers suffer from a fundamental limitation: their loss functions are not explicitly dependent on the errors associated with the solution estimates. As such, validation and error estimation usually requires knowledge of the true solution. Indeed, when the true solution is unknown, we are often reduced to simply hoping that a ``\textit{low enough}'' loss implies ``\textit{small enough}'' errors, since explicit relationships between the two are not available. In this work, we describe a general strategy for efficiently constructing error estimates and corrections for Neural Network Differential Equation solvers. Our methods do not require \textit{a priori} knowledge of the true solutions and obtain explicit relationships between loss functions and the errors, given certain assumptions on the DE. In turn, these explicit relationships directly allow us to estimate and correct for the errors.

Wide Attention is the Way Forward for Transformers

Jason Ross Brown,Yiren Zhao,Ilia Shumailov,Robert D. Mullins

The Transformer is an extremely powerful and prominent deep learning architecture. In this work, we challenge the commonly held belief in deep learning that going deeper is better, and show an alternative design approach that is building wider attention Transformers. We demonstrate that wide single layer Transformer models can compete with or outperform deeper ones in a variety of Natural Language Processing (NLP) tasks when both are trained from scratch. The impact of changing the model aspect ratio on Transformers is then studied systematically. This ratio balances the number of layers and the number of attention heads per layer while keeping the total number of attention heads and all other hyperparameters constant. On average, across 4 NLP tasks and 10 attention types, single layer wide models perform 0.3% better than their deep counterparts. We show an in-depth evaluation and demonstrate how wide models require a far smaller memory footprint and can run faster on commodity hardware, in addition, these wider models are also more interpretable. For example, a single layer Transformer on the IMDb byte level text classification has 3.1x faster inference latency on a CPU than its equally accurate deeper counterpart, and is half the size. Our results suggest that the critical direction for building better Transformers for NLP is their width, and that their depth is less relevant.

****

Variational Prompt Tuning Improves Generalization of Vision-Language Models

Mohammad Mahdi Derakhshani,Enrique Sanchez,Adrian Bulat,Victor Guilherme Turrisi da Costa,Cees G. M. Snoek,Georgios Tzimiropoulos,Brais Martinez

Prompt tuning provides an efficient mechanism to adapt large vision-language models to downstream tasks by treating part of the input language prompts as learnable parameters while freezing the rest of the model. Existing works for prompt tuning are however prone to damaging the generalization capabilities of the foundation models, because the learned prompts lack the capacity of covering certain concepts within the language model. To avoid such limitation, we propose a probabilistic modeling of the underlying distribution of prompts, allowing prompts within the support of an associated concept to be derived through stochastic sampling. This results in a more complete and richer transfer of the information captured by the language model, providing better generalization capabilities for downstream tasks. The resulting algorithm relies on a simple yet powerful variational framework that can be directly integrated with other developments. We show our approach is seamlessly integrated into both standard and conditional prompt learning frameworks, improving the performance on both cases considerably, especially with regards to preserving the generalization capability of the original model. Our method provides the current state-of-the-art for prompt learning, surpassing CoCoOp by 1.6% average Top-1 accuracy on the standard benchmark. Remarkably, it even surpasses the original CLIP model in terms of generalization to new classes. Implementation code will be released.

****

DCT-DiffStride: Differentiable Strides with Real-Valued Data

Clayton Harper,Mitchell Thornton,Eric Larson

Reducing the size of intermediate feature maps within various neural network architectures is critical for generalization performance, and memory and computational complexity. Until recently, most methods required downsampling rates (i.e., decimation) to be predefined and static during training, with optimal downsampling rates requiring a vast hyper-parameter search. Recent work has proposed a novel and differentiable method for learning strides named DiffStride which uses the discrete Fourier transform (DFT) to learn strides for decimation. However, in many cases the DFT does not capture signal properties as efficiently as the disc rete cosine transform (DCT). Therefore, we propose an alternative method for learning decimation strides, DCT-DiffStride, as well as new regularization methods to reduce model complexity. Our work employs the DCT and its inverse as a low-pass filter in the frequency domain to reduce feature map dimensionality. Leveraging the well-known energy compaction properties of the DCT for natural signals, we evaluate DCT-DiffStride with its competitors on image and audio datasets demonstrating a favorable tradeoff in model performance and model complexity compared to competing methods. Additionally, we show DCT-DiffStride and DiffStride can be applied to data outside the natural signal domain, increasing the general applications of such methods.

Interneurons accelerate learning dynamics in recurrent neural networks for statistical adaptation

David Lipshutz,Cengiz Pehlevan,Dmitri Chklovskii

Early sensory systems in the brain rapidly adapt to fluctuating input statistics, which requires recurrent communication between neurons. Mechanistically, such recurrent communication is often indirect and mediated by local interneurons. In this work, we explore the computational benefits of mediating recurrent communication via interneurons compared with direct recurrent connections. To this end, we consider two mathematically tractable recurrent neural networks that statistically whiten their inputs --- one with direct recurrent connections and the other with interneurons that mediate recurrent communication. By analyzing the corresponding continuous synaptic dynamics and numerically simulating the networks, we show that the network with interneurons is more robust to initialization than the network with direct recurrent connections in the sense that the convergence time for the synaptic dynamics in the network with interneurons (resp. direct recurrent connections) scales logarithmically (resp. linearly) with the spectrum of their initialization. Our results suggest that interneurons are computationally useful for rapid adaptation to changing input statistics. Interestingly, the network with interneurons is an overparameterized solution of the whitening objective for the network with direct recurrent connections, so our results can be viewed as a recurrent neural network analogue of the implicit acceleration phenomenon observed in overparameterized feedforward linear networks.

Understanding DDPM Latent Codes Through Optimal Transport

Valentin Khrulkov,Gleb Ryzhakov,Andrei Chertkov,Ivan Oseledets

Diffusion models have recently outperformed alternative approaches to model the distribution of natural images. Such diffusion models allow for deterministic sampling via the probability flow ODE, giving rise to a latent space and an encoder map. While having important practical applications, such as the estimation of the likelihood, the theoretical properties of this map are not yet fully understood. In the present work, we partially address this question for the popular case of the VP-SDE (DDPM) approach. We show that, perhaps surprisingly, the DDPM encoder map coincides with the optimal transport map for common distributions; we support this claim by extensive numerical experiments using advanced tensor train solver for multidimensional Fokker-Planck equation. We provide additional theoretical evidence for the case of multivariate normal distributions.

Soft Sampling for Efficient Training of Deep Neural Networks on Massive Data

Xiaodong Cui,Ashish Mittal,Songtao Lu,Wei Zhang,George Saon,Brian Kingsbury

We investigate soft sampling which is a simple yet effective approach for efficient training of large-scale deep neural network models when dealing with massive data. Soft sampling selects a subset uniformly at random with replacement from the full data set in each epoch. First, we derive a theoretical convergence guarantee for soft sampling on non-convex objective functions and give the convergence rate. Next, we analyze the data coverage and occupancy properties of soft sampling from the perspective of the coupon collector's problem. And finally, we evaluate soft sampling on various machine learning tasks using various network architectures and demonstrate its effectiveness. Compared to existing coreset-based data selection methods, soft sampling offers a better accuracy-efficiency trade

-off. Especially on real-world industrial scale data sets, soft sampling can achieve significant speedup and competitive performance with almost no additional computing cost.

Learning About Progress From Experts

Jake Bruce,Ankit Anand,Bogdan Mazoure,Rob Fergus

Many important tasks involve some notion of long-term progress in multiple phases: e.g. to clean a shelf it must be cleared of items, cleaning products applied, and then the items placed back on the shelf. In this work, we explore the use of expert demonstrations in long-horizon tasks to learn a monotonically increasing function that summarizes progress. This function can then be used to aid agent exploration in environments with sparse rewards. As a case study we consider the NetHack environment, which requires long-term progress at a variety of scales and is far from being solved by existing approaches. In this environment, we demonstrate that by learning a model of long-term progress from expert data containing only observations, we can achieve efficient exploration in challenging sparse tasks, well beyond what is possible with current state-of-the-art approaches. We have made the curated gameplay dataset used in this work available at https://github.com/deepmind/nao_top10.

Learning Fair Graph Representations via Automated Data Augmentations

Hongyi Ling,Zhimeng Jiang,Youzhi Luo,Shuiwang Ji,Na Zou

We consider fair graph representation learning via data augmentations. While this direction has been explored previously, existing methods invariably rely on certain assumptions on the properties of fair graph data in order to design fixed strategies on data augmentations. Nevertheless, the exact properties of fair graph data may vary significantly in different scenarios. Hence, heuristically designed augmentations may not always generate fair graph data in different application scenarios. In this work, we propose a method, known as Graphair, to learn fair representations based on automated graph data augmentations. Such fairness-aware augmentations are themselves learned from data. Our Graphair is designed to automatically discover fairness-aware augmentations from input graphs in order to circumvent sensitive information while preserving other useful information. Experimental results demonstrate that our Graphair consistently outperforms many baselines on multiple node classification datasets in terms of fairness-accuracy trade-off performance. In addition, results indicate that Graphair can automatically learn to generate fair graph data without prior knowledge on fairness-relevant graph properties.

A new photoreceptor-inspired CNN layer enables deep learning models of retina to generalize across lighting conditions

Saad Idrees,Greg D Field,Frederick Rieke,Joel Zylberberg

As we move our eyes, and as lighting changes in our environment, the light intensity reaching our retinas changes dramatically and on multiple timescales. Despite these changing conditions, our retinas effortlessly extract visual information that allows downstream brain areas to make sense of the visual world. Such processing capabilities are desirable in many settings, including computer vision systems that operate in dynamic lighting environments like in self-driving cars, and in algorithms that translate visual inputs into neural signals for use in vision-restoring prosthetics. To mimic retinal processing, we first require models that can predict retinal ganglion cell (RGC) responses reliably. While existing state-of-the-art deep learning models can accurately predict RGC responses to visual scenes under steady-state lighting conditions, these models fail under dynamic lighting conditions. This is because changes in lighting markedly alter RGC responses: adaptation mechanisms dynamically tune RGC receptive fields on multiple timescales. Because current deep learning models of the retina have no in-built notion of light level or these adaptive mechanisms, they are unable to accurately predict RGC responses under lighting conditions that they were not trained on. We present here a new deep learning model of the retina that can predict RGC responses to visual scenes at different light levels without requiring trainin g at each light level. Our model combines a fully trainable biophysical front end capturing the fast and slow adaptation mechanisms in the photoreceptors with convolutional neural networks (CNNs) capturing downstream retinal processing. We tested our model’s generalization performance across light levels using monkey and rat retinal data. Whereas conventional CNN models without the photoreceptor layer failed to predict RGC responses when the lighting conditions changed, our model with the photoreceptor layer as a front end fared much better in this challenge. Overall, our work demonstrates a new hybrid approach that equips deep learning models with biological vision mechanisms enabling them to adapt to dynamic environments.

3D Neural Embedding Likelihood for Robust Sim-to-Real Transfer in Inverse Graphics

Guangyao Zhou,Nishad Gothoskar,Lirui Wang,Joshua B. Tenenbaum,Dan Gutfreund,Miguel Lazaro-Gredilla,Dileep George,Vikash Mansinghka

A central challenge in 3D scene perception via inverse graphics is robustly modelling the gap between 3D graphics and real-world data. We propose a novel 3D Neural Embedding Likelihood (3DNEL) over RGB-D images to address this gap. 3DNEL uses neural embeddings to predict 2D-3D correspondences from RGB and combines this with depth in a principled manner. 3DNEL is trained entirely from synthetic images and generalizes to real-world data. To showcase this capability, we develop a multi-stage inverse graphics pipeline that uses 3DNEL for 6D object pose estimation from real RGB-D images. Our method outperforms the previous state-of-the-art in sim-to-real pose estimation on the YCB-Video dataset, and improves robustness, with significantly fewer large-error predictions. Unlike existing bottom-up, discriminative approaches that are specialized for pose estimation, 3DNEL adopts a probabilistic generative formulation that jointly models multi-object scenes. This generative formulation enables easy extension of 3DNEL to additional tasks like object and camera tracking from video, using principled inference in the same probabilistic model without task specific retraining.

Dynamic Scheduled Sampling with Imitation Loss for Neural Text Generation

Xiang Lin,Prathyusha Jwalapuram,Shafiq Joty

State-of-the-art neural text generation models are typically trained to maximize the likelihood of each token in the ground-truth sequence conditioned on the previous target tokens. However, during inference, the model needs to make a prediction conditioned on the tokens generated by itself. This train-test discrepancy is referred to as exposure bias. Scheduled sampling is a curriculum learning strategy that gradually exposes the model to its own predictions during training to mitigate this bias. Most of the proposed approaches design a scheduler based on training steps, which generally requires careful tuning depending on the training setup. In this work, we introduce Dynamic Scheduled Sampling with Imitation Loss (DySI), which maintains the schedule based solely on the training time accuracy, while enhancing the curriculum learning by introducing an imitation loss, which attempts to make the behavior of the decoder indistinguishable from the behavior of a teacher-forced decoder. DySI is universally applicable across training setups with minimal tuning. Extensive experiments and analysis show that DySI not only achieves notable improvements on standard machine translation benchmarks, but also significantly improves the robustness of other text generation models.

Emergence of Maps in the Memories of Blind Navigation Agents

Erik Wijmans,Manolis Savva,Irfan Essa,Stefan Lee,Ari S. Morcos,Dhruv Batra

Animal navigation research posits that organisms build and maintain internal spa- tial representations, or maps, of their environment. We ask if machines – specifically, artificial intelligence (AI) navigation agents – also build implicit (or ‘mental’) maps. A positive answer to this question would (a) explain the surprising phenomenon in recent literature of ostensibly map-free neural-networks achieving strong performance, and (b) strengthen the evidence of mapping as a fundamental mechanism for navigation by intelligent embodied agents, whether they be

biological or artificial. Unlike animal navigation, we can judiciously design the agent’s perceptual system and control the learning paradigm to nullify alternative navigation mechanisms. Specifically, we train ‘blind’ agents – with sensing limited to only egomotion and no other sensing of any kind – to perform PointGoal navigation (‘go to Δx, Δy’) via reinforcement learning. Our agents are composed of navigation-agnostic components (fully-connected and recurrent neural networks), and our experimental setup provides no inductive bias towards mapping. Despite these harsh conditions, we find that blind agents are (1) surprisingly effective navigators in new environments (~95% success); (2) they utilize memory over long horizons (remembering ~1,000 steps of past experience in an episode); (3) this memory enables them to exhibit intelligent behavior (following walls, detecting collisions, taking shortcuts); (4) there is emergence of maps and collision detection neurons in the representations of the environment built by a blind agent as it navigates; and (5) the emergent maps are selective and task dependent (e.g. the agent ‘forgets’ exploratory detours). Overall, this paper presents no new techniques for the AI audience, but a surprising finding, an insight, and an explanation.
****
Latent Neural ODEs with Sparse Bayesian Multiple Shooting
Valerii Iakovlev,Cagatay Yildiz,Markus Heinonen,Harri Lähdesmäki
Training dynamic models, such as neural ODEs, on long trajectories is a hard problem that requires using various tricks, such as trajectory splitting, to make model training work in practice. These methods are often heuristics with poor theoretical justifications, and require iterative manual tuning. We propose a principled multiple shooting technique for neural ODEs that splits the trajectories into manageable short segments, which are optimized in parallel, while ensuring probabilistic control on continuity over consecutive segments. We derive variational inference for our shooting-based latent neural ODE models and propose amortized encodings of irregularly sampled trajectories with a transformer-based recognition network with temporal attention and relative positional encoding. We demonstrate efficient and stable training, and state-of-the-art performance on multiple large-scale benchmark datasets.

$\mathcal{O}$-GNN: incorporating ring priors into molecular modeling
Jinhua Zhu,Kehan Wu,Bohan Wang,Yingce Xia,Shufang Xie,Qi Meng,Lijun Wu,Tao Qin,Wengang Zhou,Houqiang Li,Tie-Yan Liu
Cyclic compounds that contain at least one ring play an important role in drug design. Despite the recent success of molecular modeling with graph neural networks (GNNs), few models explicitly take rings in compounds into consideration, consequently limiting the expressiveness of the models. In this work, we design a new variant of GNN, ring-enhanced GNN ($\mathcal{O}$-GNN), that explicitly models rings in addition to atoms and bonds in compounds. In $\mathcal{O}$-GNN, each ring is represented by a latent vector, which contributes to and is iteratively updated by atom and bond representations. Theoretical analysis shows that $\mathcal{O}$-GNN is able to distinguish two isomorphic subgraphs lying on different rings using only one layer while conventional graph convolutional neural networks require multiple layers to distinguish, demonstrating that $\mathcal{O}$-GNN is more expressive. Through experiments, $\mathcal{O}$-GNN shows good performance on $\bf{11}$ public datasets. In particular, it achieves state-of-the-art validation result on the PCQM4Mv1 benchmark (outperforming the previous KDDCup champion solution) and the drug-drug interaction prediction task on DrugBank. Furthermore, $\mathcal{O}$-GNN outperforms strong baselines (without modeling rings) on the molecular property prediction and retrosynthesis prediction tasks.

MACTA: A Multi-agent Reinforcement Learning Approach for Cache Timing Attacks and Detection
Jiaxun Cui,Xiaomeng Yang,Mulong Luo,Geunbae Lee,Peter Stone,Hsien-Hsin S. Lee,Benjamin Lee,G. Edward Suh,Wenjie Xiong,Yuandong Tian
Security vulnerabilities in computer systems raise serious concerns as computers process an unprecedented amount of private and sensitive data today. Cache timi

ng attacks (CTA) pose an important practical threat as they can effectively breach many protection mechanisms in today’s systems. However, the current detection techniques for cache timing attacks heavily rely on heuristics and expert knowledge, which can lead to brittleness and the inability to adapt to new attacks. To mitigate the CTA threat, we propose MACTA, a multi-agent reinforcement learning (MARL) approach that leverages population-based training to train both attackers and detectors. Following best practices, we develop a realistic simulated MARL environment, MA-AUTOCAT, which enables training and evaluation of cache-timing attackers and detectors. Our empirical results suggest that MACTA is an effective solution without any manual input from security experts. MACTA detectors can generalize to a heuristic attack not exposed in training with a 97.8% detection rate and reduce the attack bandwidth of adaptive attackers by 20% on average. In the meantime, MACTA attackers are qualitatively more effective than other attacks studied, and the average evasion rate of MACTA attackers against an unseen state-of-the-art detector can reach up to 99%. Furthermore, we found that agents equipped with a Transformer encoder can learn effective policies in situations when agents with multi-layer perceptron encoders do not in this environment, suggesting the potential of Transformer structures in CTA problems.

****

Training Normalizing Flows from Dependent Data

Matthias Kirchler,Christoph Lippert,Marius Kloft

Normalizing flows are powerful non-parametric statistical models that function as a hybrid between density estimators and generative models. Current learning algorithms for normalizing flows assume that data points are sampled independently, an assumption that is frequently violated in practice, which may lead to erroneous density estimation and data generation. We propose a likelihood objective of normalizing flows incorporating dependencies between the data points, for which we derive a flexible and efficient learning algorithm suitable for different dependency structures. We show that respecting dependencies between observations can improve empirical results on both synthetic and real-world data.

Spectral Augmentation for Self-Supervised Learning on Graphs

Lu Lin,Jinghui Chen,Hongning Wang

Graph contrastive learning (GCL), as an emerging self-supervised learning technique on graphs, aims to learn representations via instance discrimination. Its performance heavily relies on graph augmentation to reflect invariant patterns that are robust to small perturbations; yet it still remains unclear about what graph invariance GCL should capture. Recent studies mainly perform topology augmentations in a uniformly random manner in the spatial domain, ignoring its influence on the intrinsic structural properties embedded in the spectral domain. In this work, we aim to find a principled way for topology augmentations by exploring the invariance of graphs from the spectral perspective. We develop spectral augmentation which guides topology augmentations by maximizing the spectral change. Extensive experiments on both graph and node classification tasks demonstrate the effectiveness of our method in self-supervised representation learning. The proposed method also brings promising generalization capability in transfer learning, and is equipped with intriguing robustness property under adversarial attacks. Our study sheds light on a general principle for graph topology augmentation.

****

An ensemble view on mixup

David Lopez-Paz,Ishmael Belghazi,Diane Bouchacourt,Elvis Dohmatob,Badr Youbi Idrissi,Levent Sagun,Andrew M Saxe

Deep ensembles are widely used to improve the generalization, calibration, uncertainty estimates and adversarial robustness of neural networks. In parallel, the data augmentation technique of mixup has grown popular for the very same reasons. Could these two techniques be related? This work suggests that both implement a similar inductive bias to “linearize” decision boundaries. We show how to obt

ain diverse predictions from a single mixup machine by interpolating a test instance with multiple reference points. These “mixup ensembles” are cheap: one needs to train and store one single model, as opposed to the K independent members forming a deep ensemble. Motivated by the limitations of ensembles to model uncertainty far away from the training data, we propose a variant of mixup that builds augmented examples using both random interpolations and extrapolations of examples. We evaluate the efficacy of our proposed methods across a variety of in-domain and out-domain metrics on the CIFAR-10 and CIFAR-10-NEG datasets.
****

Improving Adversarial Robustness by Contrastive Guided Diffusion Process
Yidong Ouyang,Liyan Xie,Guang Cheng

Synthetic data generation has become an emerging tool to help improve the adversarial robustness in classification tasks since robust learning requires a significantly larger amount of training samples compared with standard classification tasks. Among various deep generative models, the diffusion model has been shown to produce high-quality synthetic images and has achieved good performance in improving the adversarial robustness. However, diffusion-type methods are typically slow in data generation as compared with other generative models. Although different acceleration techniques have been proposed recently, it is also of great importance to study how to improve the sample efficiency of generated data for the downstream task. In this paper, we first analyze the optimality condition of synthetic distribution for achieving non-trivial robust accuracy. We show that enhancing the distinguishability among the generated data is critical for improving adversarial robustness. Thus, we propose the Contrastive-Guided Diffusion Process (Contrastive-DP), which adopts the contrastive loss to guide the diffusion model in data generation. We verify our theoretical results using simulations and demonstrate the good performance of Contrastive-DP on image datasets.

σReparam: Stable Transformer Training with Spectral Reparametrization
Shuangfei Zhai,Tatiana Likhomanenko,Etai Littwin,Jason Ramapuram,Dan Busbridge,Yizhe Zhang,Jiatao Gu,Joshua M. Susskind

Training stability is of great importance to Transformers. In this work, we investigate the training dynamics of Transformers by examining the evolution of the attention layers. In particular, we track the "attention entropy" for each attention head during the course of training, which is a proxy of the attention's sharpness. We observe a common, non monotonic evolution of attention entropy across different settings: the attention entropy first quickly decreases in the initial phase of training, followed by quickly increasing, and finally entering a long stable phase. While the exact shape can be affected by hyperparameters such as warmup, initialization, learning rate etc., we found that there is a close correlation between the minima of attention entropy and the model's training stability. To this end, we propose a simple and efficient solution dubbed σReparam, where we reparametrize all linear layers with Spectral Normalization and an additional learned scalar. We provide a lower bound on the attention entropy as a function of the spectral norms of the query and key projections, which suggests that small attention entropy can be obtained with large spectral norms. σReparam decouples the growth rate of a weight matrix's spectral norm from its dimensionality, which we verify empirically. We conduct experiments with σReparam on image classification, image self supervised learning, automatic speech recognition and language modeling tasks. We show that σReparam provides great stability and robustness with respect to the choice of hyperparameters.

PAC Reinforcement Learning for Predictive State Representations
Wenhao Zhan,Masatoshi Uehara,Wen Sun,Jason D. Lee

In this paper we study online Reinforcement Learning (RL) in partially observable dynamical systems. We focus on the Predictive State Representations (PSRs) model, which is an expressive model that captures other well-known models such as Partially Observable Markov Decision Processes (POMDP). PSR represents the states using a set of predictions of future observations and is defined entirely using observable quantities. We develop a novel model-based algorithm for PSRs that c an learn a near optimal policy in sample complexity scaling polynomially with respect to all the relevant parameters of the systems. Our algorithm naturally works with function approximation to extend to systems with potentially large state and observation spaces. We show that given a realizable model class, the sample complexity of learning the near optimal policy only scales polynomially with respect to the statistical complexity of the model class, without any explicit polynomial dependence on the size of the state and observation spaces. Notably, our work is the first work that shows polynomial sample complexities to compete with the globally optimal policy in PSRs. Finally, we demonstrate how our general theorem can be directly used to derive sample complexity bounds for special models including m-step weakly revealing and m-step decodable tabular POMDPs, POMDPs with low-rank latent transition, and POMDPs with linear emission and latent transition.

Federated Learning on Adaptively Weighted Nodes by Bilevel Optimization

Yankun Huang,Qihang Lin,Nick Street,Stephen Baek

We propose a federated learning method with weighted nodes in which the weights can be modified to optimize the model’s performance on a separate validation set. The problem is formulated as a bilevel optimization problem where the inner problem is a federated learning problem with weighted nodes and the outer problem focuses on optimizing the weights based on the validation performance of the model returned from the inner problem. A communication-efficient federated optimization algorithm is designed to solve this bilevel optimization problem. We analyze the generalization performance of the output model and identify the scenarios when our method is in theory superior to training a model locally and superior to federated learning with static and evenly distributed weights.

Removing Structured Noise with Diffusion Models

Tristan Stevens,Ruud Van Sloun,Jean-luc Robert,Faik C Meral,Jason Yu,Junseob Shin

Solving ill-posed inverse problems requires careful formulation of prior beliefs over the signals of interest and an accurate description of their manifestation into noisy measurements. Handcrafted signal priors based on e.g. sparsity are increasingly replaced by data-driven deep generative models, and several groups have recently shown that state-of-the-art score-based diffusion models yield particularly strong performance and flexibility. In this paper, we show that the powerful paradigm of posterior sampling with diffusion models can be extended to include rich, structured, noise models. To that end, we propose a joint conditional reverse diffusion process with learned scores for the noise and signal-generating distribution. We demonstrate strong performance gains across various inverse problems with structured noise, outperforming competitive baselines that use normalizing flows and adversarial networks. This opens up new opportunities and relevant practical applications of diffusion modeling for inverse problems in the context of non-Gaussian measurements.

Stein Variational Goal Generation for adaptive Exploration in Multi-Goal Reinforcement Learning

Nicolas Castanet,Olivier Sigaud,sylvain lamprier

Multi-goal Reinforcement Learning has recently attracted a large amount of research interest. By allowing experience to be shared between related training tasks, this setting favors generalization for new tasks at test time, whenever some smoothness exists in the considered representation space of goals. However, in settings with discontinuities in state or goal spaces (e.g. walls in a maze), a majority of goals are difficult to reach, due to the sparsity of rewards in the absence of expert knowledge. This implies hard exploration, for which some curriculum of goals must be discovered, to help agents learn by adapting training tasks to their current capabilities. We propose a novel approach: Stein Variational Goal Generation (SVGG), which builds on recent automatic curriculum learning techniques for goal-conditioned policies. SVGG seeks at preferably sampling new goals in the zone of proximal development of the agent, by leveraging a learned mode l of its abilities and a goal distribution modeled as particles in the exploration space. Our approach relies on Stein Variational Gradient Descent to dynamically attract the goal sampling distribution in areas of appropriate difficulty. We demonstrate the performances of the approach, in terms of success coverage in the goal space, compared to recent state-of-the-art RL methods for hard exploration problems.

Fourier PINNs: From Strong Boundary Conditions to Adaptive Fourier Bases

Madison Cooley,Da Long,Robert Kirby,Shandian Zhe

Interest in Physics-Informed Neural Networks (PINNs) is rising as a mesh-free alternative to traditional numerical solvers for partial differential equations (PDEs). While successful, PINNs often struggle to learn high-frequency and multi-scale target solutions—which, according to prior analysis, might arise from competition during optimization between the weakly enforced boundary loss and residual loss terms. By creatively modifying the neural network architecture, some simple boundary conditions (BCs) can be satisfied exactly without jointly optimizing an additional loss term, thus avoiding the aforementioned competition altogether. Motivated by this analysis, we first study a strong BC version of PINNs for Dirichlet BCs and observe a consistent improvement compared to the standard PINNs. We conducted a Fourier analysis and found that strong BC PINNs can better learn the amplitudes of high-frequency components of the target solutions. While BC PINNs provide a promising improvement, constructing these unique architectures is an intricate process made difficult (if not impossible) by certain BCs and domain geometries. Enlightened by our analysis, we propose Fourier PINNs—a simple, general, yet powerful method that augments PINNs with pre-specified, dense Fourier bases. Our proposed architecture likewise better learns high-frequency components but places no restrictions on the particular BCs. We developed an adaptive learning and basis selection algorithm based on alternating NN basis optimization, Fourier and NN basis coefficient estimations, and coefficient truncation. This schema can flexibly identify the significant frequencies while weakening the nominal to better capture the target solution's power spectrum. We show the advantage of our approach in learning high-frequency and multi-scale solutions in a set of systematic experiments.

Distributed Graph Neural Network Training with Periodic Stale Representation Synchronization

Zheng Chai,Guangji Bai,Liang Zhao,Yue Cheng

Despite the recent success of Graph Neural Networks (GNNs), it remains challenging to train a GNN on large graphs with over millions of nodes & billions of edges, which are prevalent in many graph-based applications such as social networks, recommender systems, and knowledge graphs. Traditional sampling-based methods accelerate GNN training by dropping edges and nodes, which impairs the graph integrity and model performance. Differently, distributed GNN algorithms accelerate GNN training by utilizing multiple computing devices and can be classified into two types: "partition-based" methods enjoy low communication cost but suffer from information loss due to dropped edges, while "propagation-based" methods avoid information loss but suffer from prohibitive communication overhead caused by neighbor explosion. To jointly address these problems, this paper proposes DIGEST (DIstributed Graph reprEsentation SynchronizaTion), a novel distributed GNN training framework that synergizes the complementary strength of both categories of existing methods. We propose to allow each device utilize the stale representations of its neighbors in other subgraphs during subgraph parallel training. This way, out method preserves global graph information from neighbors to avoid information loss and reduce the communication cost. Therefore, DIGEST is both computation-efficient and communication-efficient as it does not need to frequently (re-)compute and transfer the massive representation data across the devices, due to neighbor explosion. DIGEST provides synchronous and asynchronous training manners for homogeneous and heterogeneous training environment, respectively. We proved that the approximation error induced by the staleness of the representations can be upper-bounded. More importantly, our convergence analysis demonstrates that DIGEST enjoys the state-of-the-art convergence rate. Extensive experimental evaluation on large, real-world graph datasets shows that DIGEST achieves up to 21.82× speedup without compromising the performance compared to state-of-the-art distributed GNN training frameworks

SAGE: Semantic-Aware Global Explanations for Named Entity Recognition

Andrea Zugarini,Leonardo Rigutini

In the last decades, deep learning approaches achieved impressive results in many research fields,
such as Computer Vision and Natural Language Processing (NLP).
NLP in particular has greatly benefit from unsupervised methods that allow to learn distributed representation of language.
On the race for better performances Language Models have reached hundred of billions parameters nowadays.
Despite the remarkable results, deep models are still far from being fully exploited in real world applications.
Indeed, these approaches are black-boxes, i.e. they are not interpretable by design nor explainable, which is often crucial to make decisions in business.
Several task-agnostic methods have been proposed in literature to explain models' decisions.
Most techniques rely on the "local" assumption, i.e. explanations are made example-wise.
In this paper instead, we present a post-hoc method to produce highly interpretable global rules to explain NLP classifiers.
Rules are extracted with a data mining approach on a semantically enriched input representation, instead of using words/wordpieces solely.
Semantic information yields more abstract and general rules that are both more explanatory and less complex, while being also better at reflecting the model behaviour.
In the experiments we focus on Named Entity Recognition, an NLP task where explainability is under-investigated.
We explain the predictions of BERT NER classifiers trained on two popular benchmarks, CoNLL03 and Ontonotes, and compare our model against LIME.

Decentralized Optimistic Hyperpolicy Mirror Descent: Provably No-Regret Learning in Markov Games

Wenhao Zhan,Jason D. Lee,Zhuoran Yang

We study decentralized policy learning in Markov games where we control a single agent to play with nonstationary and possibly adversarial opponents. Our goal is to develop a no-regret online learning algorithm that (i) takes actions based on the local information observed by the agent and (ii) is able to find the best policy in hindsight. For such a problem, the nonstationary state transitions due to the varying opponent pose a significant challenge. In light of a recent hardness result (Liu et al., 2022), we focus on the setting where the opponent's previous policies are revealed to the agent for decision making. With such an information structure, we propose a new algorithm, Decentralized Optimistic hypeRpolicy mIrror deScent (DORIS), which achieves $\sqrt{K}$-regret in the context of general function approximation, where K is the number of episodes. Moreover, when all the agents adopt DORIS, we prove that their mixture policy constitutes an approximate coarse correlated equilibrium. In particular, DORIS maintains a hyperpolicy which is a distribution over the policy space. The hyperpolicy is updated via mirror descent, where the update direction is obtained by an optimistic variant of least-squares policy evaluation. Furthermore, to illustrate the power of our method, we apply DORIS to constrained and vector-valued MDPs, which can be formulated as zero-sum Markov games with a fictitious opponent.

Graph Contrastive Learning with Model Perturbation

Qiaoyu Tan,Sirui Ding,Ninghao Liu,Soo-Hyun Choi,Li Li,Rui Chen,Xia Hu

Graph contrastive learning (GCL) has achieved great success in pre-training graph neural networks (GNN) without ground-truth labels. The performance of GCL main ly rely on designing high quality contrastive views via data augmentation. However, finding desirable augmentations is difficult and requires cumbersome efforts due to the diverse modalities in graph data. In this work, we study model perturbation to perform efficient contrastive learning on graphs without using data augmentation. Instead of searching for the optimal combination among perturbing nodes, edges or attributes, we propose to conduct perturbation on the model architectures (i.e., GNNs). However, it is non-trivial to achieve effective perturbations on GNN models without performance dropping compared with its data augmentation counterparts. This is because data augmentation 1) makes complex perturbation in the graph space, so it is hard to mimic its effect in the model parameter space with a fixed noise distribution, and 2) has different disturbances even on the same nodes between two views owning to the randomness. Motivated by this, we propose a novel model perturbation framework -- \textsc{PerturbGCL} to pre-train GNN encoders. We focus on perturbing two key operations in a GNN, including message propagation and transformation. Specifically, we propose \emph{weightPrune} to create a dynamic perturbed model to contrast with the target one by pruning its transformation weights according to their magnitudes. Contrasting the two models will lead to adaptive mining of the perturbation distribution from the data. Furthermore, we present \emph{randMP} to disturb the steps of message propagation in two contrastive models. By randomly choosing the propagation steps during training, it helps to increase local variances of nodes between the contrastive views. Despite the simplicity, coupling the two strategies together enable us to perform effective contrastive learning on graphs with model perturbation. We conduct extensive experiments on 15 benchmarks. The results demonstrate the superiority of \textsc{PerturbGCL}: it can achieve competitive results against strong baselines across both node-level and graph-level tasks, while requiring shorter computation time. The code is available at \url{https://anonymous.4open.science/r/PerturbGCL-F17D}.

Robust Scheduling with GFlowNets

David W Zhang,Corrado Rainone,Markus Peschl,Roberto Bondesan

Finding the best way to schedule operations in a computation graph is a classical NP-hard problem which is central to compiler optimization. However, evaluating the goodness of a schedule on the target hardware can be very time-consuming. Traditional approaches as well as previous machine learning ones typically optimize proxy metrics, which are fast to evaluate but can lead to bad schedules when tested on the target hardware. In this work, we propose a new approach to scheduling by sampling proportionally to the proxy metric using a novel GFlowNet method. We introduce a technique to control the trade-off between diversity and goodness of the proposed schedules at inference time and demonstrate empirically that the pure optimization baselines can lead to subpar performance with respect to our approach when tested on a target model. Furthermore, we show that conditioning the GFlowNet on the computation graph enables generalization to unseen scheduling problems for both synthetic and real-world compiler datasets.

Pareto Manifold Learning: Tackling multiple tasks via ensembles of single-task models

Nikolaos Dimitriadis,Pascal Frossard,François Fleuret

In Multi-Task Learning, tasks may compete and limit the performance achieved on each other rather than guiding the optimization trajectory to a common solution, superior to its single-task counterparts. There is often not a single solution that is optimal for all tasks, leading practitioners to balance tradeoffs between tasks' performance, and to resort to optimality in the Pareto sense. Current Multi-Task Learning methodologies either completely neglect this aspect of functional diversity, and produce one solution in the Pareto Front predefined by their optimization schemes, or produce diverse but discrete solutions, each requiring a separate training run. In this paper, we conjecture that there exist Pareto Subspaces, i.e., weight subspaces where multiple optimal functional solutions lie. We propose Pareto Manifold Learning, an ensembling method in weight space that is able to discover such a parameterization and produces a continuous Pareto Fr ont in a single training run, allowing practitioners to modulate the performance on each task during inference on the fly. We validate the proposed method on a diverse set of multi-task learning benchmarks, ranging from image classification to tabular datasets and scene understanding, and show that Pareto Manifold Learning outperforms state-of-the-art algorithms.

Autoregressive Conditional Neural Processes

Wessel Bruinsma,Stratis Markou,James Requeima,Andrew Y. K. Foong,Tom Andersson,Anna Vaughan,Anthony Buonomo,Scott Hosking,Richard E Turner

Conditional neural processes (CNPs; Garnelo et al., 2018a) are attractive meta-learning models which produce well-calibrated predictions and are trainable via a simple maximum likelihood procedure. Although CNPs have many advantages, they are unable to model dependencies in their predictions. Various works propose solutions to this, but these come at the cost of either requiring approximate inference or being limited to Gaussian predictions. In this work, we instead propose to change how CNPs are deployed at test time, without any modifications to the model or training procedure. Instead of making predictions independently for every target point, we autoregressively define a joint predictive distribution using the chain rule of probability, taking inspiration from the neural autoregressive density estimator (NADE) literature. We show that this simple procedure allows factorised Gaussian CNPs to model highly dependent, non-Gaussian predictive distributions. Perhaps surprisingly, in an extensive range of tasks with synthetic and real data, we show that CNPs in autoregressive (AR) mode not only significantly outperform non-AR CNPs, but are also competitive with more sophisticated models that are significantly more computationally expensive and challenging to train. This performance is remarkable given that AR CNPs are not trained to model joint dependencies. Our work provides an example of how ideas from neural distribution estimation can benefit neural processes, and motivates research into the AR deployment of other neural process models.

$k$NN Prompting: Beyond-Context Learning with Calibration-Free Nearest Neighbor Inference

Benfeng Xu,Quan Wang,Zhendong Mao,Yajuan Lyu,Qiaoqiao She,Yongdong Zhang

In-Context Learning (ICL), which formulates target tasks as prompt completion conditioned on in-context demonstrations, has become the prevailing utilization of LLMs. In this paper, we first disclose an actual predicament for this typical usage that it can not scale up with training data due to context length restriction. Besides, existing works have shown that ICL also suffers from various biases and requires delicate calibration treatment. To address both challenges, we advocate a simple and effective solution, $k$NN Prompting, which first queries LLM with training data for distributed representations, then predicts test instances by simply referring to nearest neighbors. We conduct comprehensive experiments to demonstrate its two-fold superiority: 1) Calibration-Free: $k$NN Prompting does not directly align LLM output distribution with task-specific label space, instead leverages such distribution to align test and training instances. It significantly outperforms state-of-the-art calibration-based methods under comparable few-shot scenario. 2) Beyond-Context: $k$NN Prompting can further scale up effectively with as many training data as are available, continually bringing substantial improvements. The scaling trend holds across 10 orders of magnitude ranging from 2 shots to 1024 shots as well as different LLMs scales ranging from 0.8B to 30B. It successfully bridges data scaling into model scaling, and brings new potentials for the gradient-free paradigm of LLM deployment. Code is publicly available at https://github.com/BenfengXu/KNNPrompting

Closed-loop Transcription via Convolutional Sparse Coding

Xili Dai,Ke Chen,Shengbang Tong,Jingyuan Zhang,Xingjian Gao,Yuexiang Zhai,Mingyang Li,Xiaojun Yuan,Heung-Yeung Shum,Lionel Ni,Yi Ma

Autoencoding has been a popular and effective framework for learning generative models for images, with much empirical success. Autoencoders often use generic d eep networks as the encoder and decoder, which are difficult to interpret, and the learned representations lack clear structure. In this work, we replace the encoder and decoder with standard convolutional sparse coding and decoding layers, obtained from unrolling an optimization algorithm for solving a (convexified) sparse coding program. Furthermore, to avoid computational difficulties in minimizing distributional distance between the real and generated images, we utilize the recent closed-loop transcription (CTRL) framework that maximizes the rate reduction of the learned sparse representations. We show that such a simple framework demonstrates surprisingly competitive performance on large datasets, such as ImageNet-1K, compared to existing autoencoding and generative methods under fair conditions. Even with simpler networks and less computational resources, our method demonstrates splendid visual quality in regenerated images with striking sample-wise consistency. More surprisingly, the learned autoencoder generalizes to unseen datasets. Our method enjoys several side benefits, including more structured and interpretable representations, more stable convergence, scalability to large datasets -- indeed, our method is the first sparse coding generative method to scale up to ImageNet -- and trainability with smaller batch sizes.

Transformers Learn Shortcuts to Automata

Bingbin Liu,Jordan T. Ash,Surbhi Goel,Akshay Krishnamurthy,Cyril Zhang

Algorithmic reasoning requires capabilities which are most naturally understood through recurrent models of computation, like the Turing machine. However, Transformer models, while lacking recurrence, are able to perform such reasoning using far fewer layers than the number of reasoning steps. This raises the question: what solutions are these shallow and non-recurrent models finding? We investigate this question in the setting of learning automata, discrete dynamical systems naturally suited to recurrent modeling and expressing algorithmic tasks. Our theoretical results completely characterize shortcut solutions, whereby a shallow Transformer with only $o(T)$ layers can exactly replicate the computation of an automaton on an input sequence of length T. By representing automata using the algebraic structure of their underlying transformation semigroups, we obtain $O(\log T)$-depth simulators for all automata and $O(1)$-depth simulators for all automata whose associated groups are solvable. Empirically, we perform synthetic experiments by training Transformers to simulate a wide variety of automata, and show that shortcut solutions can be learned via standard training. We further investigate the brittleness of these solutions and propose potential mitigations.

Efficient neural representation in the cognitive neuroscience domain: Manifold Capacity in One-vs-rest Recognition Limit

Nga Yu Lo,SueYeon Chung

The structure in neural representations as manifolds has become a popular approach to study information encoding in neural populations. One particular interest is the connection between object recognition capability and the separability of neural representations for different objects, often called "object manifolds." In learning theory, separability has been studied under the notion of storage capacity, which refers to the number of patterns encoded in a feature dimension. Chung et al (2018) extended the notion of capacity from discrete points to manifolds, where manifold capacity refers to the maximum number of object manifolds that can be linearly separated with high probability given random assignment of labels. Despite the use of manifold capacity in analyzing artificial neural networks (ANNs), its application to neuroscience has been limited. Due to the limited number of "features", such as neurons, available in neural experiments, manifold capacity cannot be verified empirically, unlike in ANNs. Additionally, the usage of random label assignment, while common in learning theory, is of limited relevance to the definition of object recognition tasks in cognitive science. To overcome these limits, we present the Sparse Replica Manifold analysis to study object recognition. Sparse manifold capacity measures how many object manifolds can be separated under one versus the rest classification, a form of task widely used in both in cognitive neuroscience experiments and machine learning applicatio ns. We demonstrate the application of sparse manifold capacity allows analysis of a wider class of neural data - in particular, neural data that has a limited number of neurons with empirical measurements. Furthermore, sparse manifold capacity requires less computations to evaluate underlying geometries and enables a connection to a measure of dimension, the participation ratio. We analyze the relationship between capacity and dimension, and demonstrate that both manifold intrinsic dimension and the ambient space dimension play a role in capacity.

ULF: UNSUPERVISED LABELING FUNCTION CORRECTION USING CROSS-VALIDATION FOR WEAK SUPERVISION

Anastasiia Sedova,Benjamin Roth

A way to overcome expensive and time-consuming manual data labeling is weak supervision - automatic annotation of data samples via a predefined set of labeling functions (LFs), rule-based mechanisms that generate artificial labels for the classes associated with the LFs. In this work, we investigate noise reduction techniques for weak supervision based on the principle of k-fold cross-validation. We introduce a new algorithm ULF for denoising weakly annotated data which uses models trained on all but some LFs to detect and correct biases specific to the held-out LFs. Specifically, ULF refines the allocation of LFs to classes by re-estimating this assignment on highly reliable cross-validated samples. We realize two variants of this algorithm: feature-based ULF (relying on count-based feature vectors), and DeepULF (fine-tuning pre-trained language models). We compare ULF to methods originally developed for detecting erroneous samples in manually annotated data, as well as to our extensions of such methods to the weakly supervised setting. Our new weak supervision-specific methods (ULF and extensions) leverage the information about matching LFs, making detecting noisy samples more accurate. Evaluation on several datasets shows that ULF can successfully improve weakly supervised learning without utilizing any manually labeled data.

****

Islands of Confidence: Robust Neural Network Classification with Uncertainty Quantification

Sibylle Hess,Tianjin Huang,Wouter Duivesteijn

We propose a Gaussian confidence measure and its optimization, for use in neural network classifiers. The measure comes with theoretical results, simultaneously resolving two pressing problems in NN classification: uncertainty quantification, and robustness. Existing research in uncertainty quantification mostly revolves around the confidence reflected in the input feature space. Instead, we focus on the learned representation of the network and analyze the confidence in the penultimate layer space. We formally prove that, independent of optimization-procedural effects, a set of centroids always exists such that softmax classifiers are nearest-centroid classifiers. Softmax confidence, however, does not reflect that the classification is based on nearest centroids: artificially inflated confidence is also given to out-of-distributions samples that are not near any centroid, but slightly less distant from one centroid than from the others. Our new confidence measure is centroid-based, and hence no longer suffers from the artificial confidence inflation of out-of-distribution samples. We also show that our proposed centroidal confidence measure is providing a robustness certificate against attacks. As such, it manages to reflect what the model doesn't know (as demanded by uncertainty quantification), and to resolve the issue of robustness of neural networks.

****

Quantization-aware Policy Distillation (QPD)

Thomas Avé,Kevin Mets,Tom De Schepper,Steven Latre

Recent advancements have made Deep Reinforcement Learning (DRL) exceedingly more powerful, but the produced models remain very computationally complex and therefore difficult to deploy on edge devices.

Compression methods such as quantization and distillation can be used to increase the applicability of DRL models on these low-power edge devices by decreasing the necessary precision and number of operations respectively.

Training in low-precision is notoriously less stable however, which is amplified by the decrease in representational power when limiting the number of trainable parameters.

We propose Quantization-aware Policy Distillation (QPD), which overcomes this instability by providing a smoother transition from high to low-precision network parameters.

A new distillation loss specifically designed for the compression of actor-critic networks is also defined, resulting in a higher accuracy after compression.

Our experiments show that these combined methods can effectively compress a network down to 0.5% of its original size, without any loss in performance.

FIFA: Making Fairness More Generalizable in Classifiers Trained on Imbalanced Data

Zhun Deng,Jiayao Zhang,Linjun Zhang,Ting Ye,Yates Coley,Weijie J Su,James Zou

Algorithmic fairness plays an important role in machine learning and imposing fairness constraints during learning is a common approach. However, many datasets are imbalanced in certain label classes (e.g. "healthy") and sensitive subgroups (e.g. "older patients"). Empirically, this imbalance leads to a lack of generalizability not only of classification but also of fairness properties, especially in over-parameterized models. For example, fairness-aware training may ensure equalized odds (EO) on the training data, but EO is far from being satisfied on new users. In this paper, we propose a theoretically-principled, yet {\bf F}lexible approach that is {\bf I}mbalance-{\bf F}airness-{\bf A}ware ({\bf FIFA}). Specifically, FIFA encourages both classification and fairness generalization and can be flexibly combined with many existing fair learning methods with logits-based losses. While our main focus is on EO, FIFA can be directly applied to achieve equalized opportunity (EqOpt); and under certain conditions, it can also be applied to other fairness notions. We demonstrate the power of FIFA by combining it with a popular fair classification algorithm, and the resulting algorithm achieves significantly better fairness generalization on several real-world datasets.

GMML is All you Need

Sara Atito,Muhammad Awais,Josef Kittler

Vision transformers have generated significant interest in the computer vision (CV) community because of their flexibility in exploiting contextual information, whether it is sharply confined local, or long range global. However, they are known to be data hungry. This has motivated the research in self-supervised transformer pretraining, which does not need to decode the semantic information conveyed by labels to link it to the image properties, but rather focuses directly on extracting a concise representation of the image data that reflects the notion of similarity and is invariant to nuisance factors. The key vehicle for the self-learning process used by the majority of self-learning methods is the generation of multiple views of the training data and the creation of pretext tasks which use these views to define the notion of image similarity and data integrity. However, this approach lacks the natural propensity to extract contextual information. We propose group mask model learning (GMML), a self-supervised learning (SSL) mechanism for pretraining vision transformers with the ability to extract the contextual information present in all the concepts in an image. GMML achieves this by manipulating random groups of connected tokens, ensuingly covering a meaningful part of a semantic concept, and then recovering the hidden semantic information from the visible part of the concept. GMML implicitly introduces a novel data augmentation process. Unlike most of the existing SSL approaches, GMML does not require momentum encoder, nor rely on careful implementation details such as large batches and gradient stopping, which are all artefacts of most of the current self-supervised learning techniques. Since its conception at the beginning of 2021, GMML maintains itself as unbeaten SSL method with several desirable benefits and marked a significant milestone in computer vision by being one of the first self-supervised pretraining methods which outperform supervised pretraining consistently with a large margin. GMML is simple, elegant, and currently the best mechanism to extract information from a given dataset and instil this infor mation into transformer's weights. The code will be made publicly available for the community to train on bigger corpora.

Understanding The Robustness of Self-supervised Learning Through Topic Modeling

Zeping Luo,Shiyou Wu,Cindy Weng,Mo Zhou,Rong Ge

Self-supervised learning has significantly improved the performance of many NLP tasks. However, how can self-supervised learning discover useful features, and why is it better than traditional approaches such as probabilistic models are still largely unknown. In this paper, we focus on the context of topic modeling and highlight a key advantage of self-supervised learning - when applied to data generated by topic models, self-supervised learning can be oblivious to the specific model, and hence is less susceptible to model misspecification. In particular, we prove that commonly used self-supervised objectives based on reconstruction or contrastive samples can both recover useful posterior information for general topic models. Empirically, we show that the same objectives can perform on par with posterior inference using the correct model, while outperforming posterior inference using misspecified models.

****

Temporal Disentanglement of Representations for Improved Generalisation in Reinforcement Learning

Mhairi Dunion,Trevor McInroe,Kevin Sebastian Luck,Josiah P. Hanna,Stefano V Albrecht

Reinforcement Learning (RL) agents are often unable to generalise well to environment variations in the state space that were not observed during training. This issue is especially problematic for image-based RL, where a change in just one variable, such as the background colour, can change many pixels in the image. The changed pixels can lead to drastic changes in the agent's latent representation of the image, causing the learned policy to fail. To learn more robust representations, we introduce TEmporal Disentanglement (TED), a self-supervised auxiliary task that leads to disentangled image representations exploiting the sequential nature of RL observations. We find empirically that RL algorithms utilising TED as an auxiliary task adapt more quickly to changes in environment variables with continued training compared to state-of-the-art representation learning methods. Since TED enforces a disentangled structure of the representation, our experiments also show that policies trained with TED generalise better to unseen values of variables irrelevant to the task (e.g. background colour) as well as unseen values of variables that affect the optimal policy (e.g. goal positions).

VIPeR: Provably Efficient Algorithm for Offline RL with Neural Function Approximation

Thanh Nguyen-Tang,Raman Arora

We propose a novel algorithm for offline reinforcement learning called Value Iteration with Perturbed Rewards (VIPeR), which amalgamates the pessimism principle with random perturbations of the value function. Most current offline RL algorithms explicitly construct statistical confidence regions to obtain pessimism via lower confidence bounds (LCB), which cannot easily scale to complex problems where a neural network is used to estimate the value functions. Instead, VIPeR implicitly obtains pessimism by simply perturbing the offline data multiple times with carefully-designed i.i.d. Gaussian noises to learn an ensemble of estimated state-action {value functions} and acting greedily with respect to the minimum of the ensemble. The estimated state-action values are obtained by fitting a parametric model (e.g., neural networks) to the perturbed datasets using gradient descent. As a result, VIPeR only needs $\mathcal{O}(1)$ time complexity for action selection, while LCB-based algorithms require at least $\Omega(K^2)$, where K is the total number of trajectories in the offline data. We also propose a novel data-splitting technique that helps remove a factor involving the log of the covering number in our bound. We prove that VIPeR yields a provable uncertainty quantifier with overparameterized neural networks and enjoys a bound on sub-optimality of $\tilde{\mathcal{O}}({ \kappa H^{5/2} \tilde{d} }/{\sqrt{K}})$, where $\tilde{d}$ is the effective dimension, H is the horizon length and κ

measures the distributional shift. We corroborate the statistical and computational efficiency of VIPeR with an empirical evaluation on a wide set of synthetic and real-world datasets. To the best of our knowledge, VIPeR is the first algorithm for offline RL that is provably efficient for general Markov decision processes (MDPs) with neural network function approximation.

Deep Probabilistic Time Series Forecasting over Long Horizons

Gregory Benton,Nate Gruver,Wesley Maddox,Andrew Gordon Wilson

Recent advances in neural network architectures for time series have led to significant improvements on deterministic forecasting metrics like mean squared error. We show that for many common benchmark datasets with deterministic evaluation metrics, intrinsic stochasticity is so significant that simply predicting summary statistics of the inputs outperforms many state-of-the-art methods, despite these simple forecasters capturing essentially no information from the noisy signals in the dataset. We demonstrate that using a probabilistic framework and moving away from deterministic evaluation acts as a simple fix for this apparent misalignment between good performance and poor understanding. With simple and scalable approaches for uncertainty representation we can adapt state-of-the-art architectures for point prediction to be excellent probabilistic forecasters, outperforming complex probabilistic methods constructed from deep generative models (DGMs) on popular benchmarks. Finally, we demonstrate that our simple adaptations to point predictors yield reliable probabilistic forecasts on many problems of practical significance, namely large and highly stochastic datasets of climatological and economic data.

Revealing Dominant Eigendirections via Spectral Non-Robustness Analysis in the Deep Reinforcement Learning Policy Manifold

Ezgi Korkmaz

Deep neural policies have recently been installed in a diverse set of settings, from biotechnology to automated financial systems. However, the utilization of deep neural networks to approximate the state-action value function commences concerns on the decision boundary stability, in particular, with regard to the sensitivity of policy decision making to indiscernible, non-robust features due to highly non-convex and complex deep neural manifolds. These concerns constitute an obstruction to understanding the reasoning made by deep neural policies, and their foundational limitations. Thus, it is crucial to develop techniques that aim to understand the sensitivities in the learnt representations of neural network policies. To achieve this we introduce a method that identifies the dominant eigen-directions via spectral analysis of non-robust directions in the deep neural policy decision boundary across both time and space. Through experiments in the Arcade Learning Environment (ALE), we demonstrate the effectiveness of our spectral analysis algorithm for identifying correlated non-robust directions, and for measuring how sample shifts remold the set of sensitive directions in the neural policy landscape. Most importantly, we show that state-of-the-art adversarial training techniques yield learning of sparser high-sensitivity directions, with dramatically larger oscillations over time, when compared to standard training. We believe our results reveal the fundamental properties of the decision process made by the deep reinforcement learning policies, and can help in constructing safe, reliable and value-aligned deep neural policies.

MC-SSL: Towards Multi-Concept Self-Supervised Learning

Sara Atito,Muhammad Awais,Ammarah Farooq,Zhenhua Feng,Josef Kittler

Self-supervised pre-training is the method of choice for natural language processing models and is rapidly gaining popularity in many vision tasks. Recently, self-supervised pre-training has shown to outperform supervised pre-training for many downstream vision applications, marking a milestone in the area. This superiority is attributed to the negative impact of incomplete labelling of the training images, which convey multiple concepts, but are annotated using a single dominant class label. Although Self-Supervised Learning (SSL), in principle, is free of this limitation, the choice of a pretext task facilitating SSL can perpetuat e this shortcoming by driving the learning process towards a single concept output. This study aims to investigate the possibility of modelling all the concepts present in an image without using labels. In this respect the proposed Multi-Concept SSL (MC-SSL) framework is a step towards unsupervised learning which embraces all the diverse content in an image with the aim of explicitly modelling the information from all the concepts present in the image. MC-SSL involves two core design steps: group masked model learning (GMML) and learning of pseudo-concepts for data tokens using a momentum encoder (teacher-student) framework. An added benefit of MC-SSL is the ability to train data hungry transformers on small datasets with high accuracy without external data. Experimental results on multi-label and multi-class image classification downstream tasks demonstrate that MC-SSL not only surpasses existing SSL methods but also outperforms supervised transfer learning. The source code will be made publicly available for the community to train on bigger corpus.

Latent Hierarchical Imitation Learning for Stochastic Environments

Maximilian Igl,Punit Shah,Paul Mougin,Sirish Srinivasan,Tarun Gupta,Brandyn White,Kyriacos Shiarlis,Shimon Whiteson

Many applications of imitation learning require the agent to avoid mode collapse and mirrorthe full distribution of observed behaviors. Existing methods improving this distributional realism typically rely on hierarchical policies conditioned on sampled types that model agent-internal features like persona, goal, or strategy. However, these methods are often inappropriate for stochastic environments, where internal and external factors of influence on the observed agent trajectories have to be disentangled, and only internal factors should be encoded in the agent type to be robust to changing environment conditions. We formalize this challenge as distribution shifts in the marginal and conditional distributions of agent types under environmental stochasticity, in addition to the familiar covariate shift in state visitations. We propose Robust Type Conditioning (RTC), which eliminates these shifts with adversarial training under randomly sampled types. Experiments on two domains, including the large-scal eWaymo Open Motion Dataset, show improved distributional realism while maintaining or improving task performance compared to state of the art baselines.

Exploring the Limits of Differentially Private Deep Learning with Group-wise Clipping

Jiyan He,Xuechen Li,Da Yu,Huishuai Zhang,Janardhan Kulkarni,Yin Tat Lee,Arturs Backurs,Nenghai Yu,Jiang Bian

Differentially private deep learning has recently witnessed advances in computational efficiency and privacy-utility trade-off. We explore whether further improvements along the two axes are possible and provide affirmative answers leveraging two instantiations of \emph{group-wise clipping}. To reduce the compute time overhead of private learning, we show that \emph{per-layer clipping}, where the gradient of each neural network layer is clipped separately, allows clipping to be performed in conjunction with backpropagation in differentially private optimization. This results in private learning that is as memory-efficient and almost as fast per training update as non-private learning for many workflows of interest. While per-layer clipping with constant thresholds tends to underperform standard flat clipping, per-layer clipping with adaptive thresholds matches or outperforms flat clipping under given training epoch constraints, hence attaining similar or better task performance within less wall time. To explore the limits of scaling (pretrained) models in differentially private deep learning, we privately fine-tune the 175 billion-parameter GPT-3. We bypass scaling challenges associated with clipping gradients that are distributed across multiple devices with \emph{per-device clipping} that clips the gradient of each model piece separately on its host device. Privately fine-tuning GPT-3 with per-device clipping achieves a task performance at $\epsilon=1$ better than what is attainable by non-privately fine-tuning the largest GPT-2 on a summarization task.

Mesh-free Eulerian Physics-Informed Neural Networks

Fabricio Arend Torres,Marcello Massimo Negri,Monika Nagy-Huber,Maxim Samarin,Volker Roth

Physics-informed Neural Networks (PINNs) have recently emerged as a principled way to include prior physical knowledge in form of partial differential equations (PDEs) into neural networks. Although PINNs are generally viewed as mesh-free, current approaches still rely on collocation points within a bounded region, even in settings with spatially sparse signals. Furthermore, if the boundaries are not known, the selection of such a region is difficult and often results in a large proportion of collocation points being selected in areas of low relevance. To resolve this severe drawback of current methods, we present a mesh-free and adaptive approach termed particle-density PINN (pdPINN), which is inspired by the microscopic viewpoint of fluid dynamics. The method is based on the Eulerian formulation and, different from classical mesh-free method, does not require the introduction of Lagrangian updates. We propose to sample directly from the distribution over the particle positions, eliminating the need to introduce boundaries while adaptively focusing on the most relevant regions. This is achieved by interpreting a non-negative physical quantity (such as the density or temperature) as an unnormalized probability distribution from which we sample with dynamic Monte Carlo methods. The proposed method leads to higher sample efficiency and improved performance of PINNs. These advantages are demonstrated on various experiments based on the continuity equations, Fokker-Planck equations, and the heat equation.

Self-supervised learning with rotation-invariant kernels

Léon Zheng,Gilles Puy,Elisa Riccietti,Patrick Perez,Rémi Gribonval

We introduce a regularization loss based on kernel mean embeddings with rotation-invariant kernels on the hypersphere (also known as dot-product kernels) for self-supervised learning of image representations. Besides being fully competitive with the state of the art, our method significantly reduces time and memory complexity for self-supervised training, making it implementable for very large embedding dimensions on existing devices and more easily adjustable than previous methods to settings with limited resources. Our work follows the major paradigm where the model learns to be invariant to some predefined image transformations (cropping, blurring, color jittering, etc.), while avoiding a degenerate solution by regularizing the embedding distribution. Our particular contribution is to propose a loss family promoting the embedding distribution to be close to the uniform distribution on the hypersphere, with respect to the maximum mean discrepancy pseudometric. We demonstrate that this family encompasses several regularizers of former methods, including uniformity-based and information-maximization methods, which are variants of our flexible regularization loss with different kernels. Beyond its practical consequences for state of the art self-supervised learning with limited resources, the proposed generic regularization approach opens perspectives to leverage more widely the literature on kernel methods in order to improve self-supervised learning methods.

Strong inductive biases provably prevent harmless interpolation

Michael Aerni,Marco Milanta,Konstantin Donhauser,Fanny Yang

Classical wisdom suggests that estimators should avoid fitting noise to achieve good generalization. In contrast, modern overparameterized models can yield small test error despite interpolating noise — a phenomenon often called "benign overfitting" or "harmless interpolation". This paper argues that the degree to which interpolation is harmless hinges upon the strength of an estimator's inductive bias, i.e., how heavily the estimator favors solutions with a certain structure: while strong inductive biases prevent harmless interpolation, weak inductive biases can even require fitting noise to generalize well. Our main theoretical result establishes tight non-asymptotic bounds for high-dimensional kernel regression that reflect this phenomenon for convolutional kernels, where the filter size regulates the strength of the inductive bias. We further provide empirical evidence of the same behavior for deep neural networks with varying filter sizes and rotational invariance.

Active Learning based Structural Inference

Aoran Wang,Jun Pang

In this paper, we propose an active-learning based framework, Active Learning based Structural Inference (ALaSI), to infer the existence of directed connections from observed agents' states over a time period in a dynamical system. With the help of deep active learning, ALaSI is competent in learning the representation of connections with relatively small pool of prior knowledge. Moreover, based on information theory, we propose inter- and out-of-scope message learning pipelines, which are remarkably beneficial to the structural inference for large dynamical systems. We evaluate ALaSI on various large datasets including simulated systems and real-world networks, to demonstrate that ALaSI is able to precisely infer the existence of connections in these systems under either supervised learning or unsupervised learning, with better performance than baseline methods.

****

Batch Normalization Explained

Randall Balestriero,Richard Baraniuk

A critically important, ubiquitous, and yet poorly understood ingredient in modern deep networks (DNs) is batch normalization (BN), which centers and normalizes the feature maps. To date, only limited progress has been made understanding why BN boosts DN learning and inference performance; work has focused exclusively on showing that BN smooths a DN's loss landscape. In this paper, we study BN theoretically from the perspective of function approximation; we exploit the fact that most of today's state-of-the-art DNs are continuous piecewise affine (CPA) splines that fit a predictor to the training data via affine mappings defined over a partition of the input space (the so-called ``linear regions''). We demonstrate that BN is an unsupervised learning technique that -- independent of the DN's weights or gradient-based learning -- adapts the geometry of a DN's spline partition to match the data. BN provides a ``smart initialization'' that boosts the performance of DN learning, because it adapts even a DN initialized with random weights to align its spline partition with the data. We also show that the variation of BN statistics between mini-batches introduces a dropout-like random perturbation to the partition boundaries and hence the decision boundary for classification problems. This per mini-batch perturbation reduces overfitting and improves generalization by increasing the margin between the training samples and the decision boundary.

AN OPERATOR NORM BASED PASSIVE FILTER PRUNING METHOD FOR EFFICIENT CNNS

Arshdeep Singh,Yunpeng Li,Mark D Plumbley

Convolutional neural networks (CNNs) have shown state-of-the-art performance in various applications. However, CNNs are resource-hungry due to their requirement of high computational complexity and memory storage. Recent efforts toward achieving computational efficiency in CNNs involve filter pruning methods that eliminate some of the filters in CNNs based on the "importance" of the filters. Existing passive filter pruning methods typically use the entry-wise norm of the filters to quantify filter importance, without considering how well the filter contributes in producing the node output. Under situations where the large number of filters are to be pruned from the network, the entry-wise norm methods always select high entry-wise norm filters as important, and ignore the diversity learned by the other filters that may result in degradation in the performance. To address this, we present a passive filter pruning method where the filters are pruned based on their contribution in producing output by implicitly considering the operator norm of the filters. The computational cost and memory requirement is reduced significantly by eliminating filters and their corresponding feature maps from the network. Accuracy similar to the original network is recovered by fine-tuning the pruned network. The proposed pruning method gives similar or better performance and recovers accuracy faster during the fine-tuning process than the entry-wise norm-based pruning methods. The efficacy of the proposed pruning method is evaluated on audio scene classification (e.g. TAU Urban Acoustic Scenes 2020) and image classification (MNIST handwritten digit classification).

Neuromechanical Autoencoders: Learning to Couple Elastic and Neural Network Nonlinearity

Deniz Oktay,Mehran Mirramezani,Eder Medina,Ryan P Adams

Intelligent biological systems are characterized by their embodiment in a complex environment and the intimate interplay between their nervous systems and the nonlinear mechanical properties of their bodies. This coordination, in which the dynamics of the motor system co-evolved to reduce the computational burden on the brain, is referred to as "mechanical intelligence" or "morphological computation". In this work, we seek to develop machine learning analogs of this process, in which we jointly learn the morphology of complex nonlinear elastic solids along with a deep neural network to control it. By using a specialized differentiable simulator of elastic mechanics coupled to conventional deep learning architectures---which we refer to as neuromechanical autoencoders---we are able to learn to perform morphological computation via gradient descent. Key to our approach is the use of mechanical metamaterials---cellular solids, in particular---as the morphological substrate. Just as deep neural networks provide flexible and massively-parametric function approximators for perceptual and control tasks, cellular solid metamaterials are promising as a rich and learnable space for approximating a variety of actuation tasks. In this work we take advantage of these complementary computational concepts to co-design materials and neural network controls to achieve nonintuitive mechanical behavior. We demonstrate in simulation how it is possible to achieve translation, rotation, and shape matching, as well as a "digital MNIST" task. We additionally manufacture and evaluate one of the designs to verify its real-world behavior.

Temporal Dynamics Aware Adversarial Attacks On Discrete-Time Graph Models

Kartik Sharma,Rakshit Trivedi,Rohit Sridhar,Srijan Kumar

Real-world graphs such as social networks, communication networks, and rating networks are constantly evolving over time. Many architectures have been developed to learn effective node representations using both graph structure and its dynamics. While the robustness of static graph models is well-studied, the vulnerability of the dynamic graph models to adversarial attacks is underexplored. In this work, we design a novel adversarial attack on discrete-time dynamic graph models where we desire to perturb the input graph sequence in a manner that preserves the temporal dynamics of the graph. To this end, we motivate a novel Temporal Dynamics-Aware Perturbation (TDAP) constraint, which ensures that perturbations introduced at each time step are restricted to only a small fraction of the number of changes in the graph since the previous time step. We present a theoretically-grounded Projected Gradient Descent approach for dynamic graphs to find the effective perturbations under the TDAP constraint. Experiments on two tasks — dynamic link prediction and node classification, show that our approach is up to 4x more effective than the baseline methods for attacking these models. We also consider the practical online setting where graph snapshots become available in real-time and extend our attack approach to use Online Gradient Descent for performing attacks under the TDAP constraint. In this more challenging setting, we demonstrate that our method achieves upto 5x superior performance when compared to representative baselines.

Automatic Curriculum Generation for Reinforcement Learning in Zero-Sum Games

Jiayu Chen,Yunfei Li,Zelai Xu,Huazhong Yang,Jiaming Song,Yu Wang,Yi Wu

Curriculum learning (CL), whose core idea is to train from easy to hard, is a popular technique to accelerate reinforcement learning (RL) training. It has also been a trend to automate the curriculum generation process. Automatic CL works primarily focus on goal-conditioned RL problems, where an explicit indicator of training progress, e.g., reward or success rate, can be used to prioritize the training tasks. However, such a requirement is no longer valid in zero-sum games: there are no goals for the agents, and the accumulative reward of the learning policy can constantly fluctuate throughout training. In this work, we present the first theoretical framework of automatic curriculum learning in the setting of zero-sum games and derive a surprisingly simple indicator of training progress, i.e., the Q-value variance, which can be directly approximated by computing the variance of value network ensembles. With such a progression metric, we further adopt a particle-based task sampler to generate initial environment configurations for training, which is particularly lightweight, computation-efficient, and naturally multi-modal. Combining these techniques with multi-agent PPO training, we obtain our final algorithm, Zero-sum Automatic Curriculum Learning (ZACL). We first evaluate ZACL in a 2D particle-world environment, where ZACL produces much stronger policies than popular RL methods for zero-sum games using the same amount of samples. Then we show in the challenging hide-and-seek environment that ZACL can lead to all four emergent phases using a single desktop computer, which is reported for the first time in the literature. The project website is at https://sites.google.com/view/zacl.

Internet-augmented language models through few-shot prompting for open-domain question answering

Angeliki Lazaridou,Elena Gribovskaya,Wojciech Jan Stokowiec,Nikolai Grigorev

In this work, we aim to capitalize on the unique few-shot capabilities of large-scale language models (LSLMs) to overcome some of their challenges with respect to grounding to factual and up-to-date information. Motivated by semi-parametric lan4 guage models (LMs), which ground their decisions in external retrieved evidence, we use few-shot prompting to learn to condition LMs on information returned from the web using Google Search, a broad and constantly updated knowledge source. Our approach does not involve fine-tuning or learning additional parameters, thus making it applicable to any LM, offering therefore a strong baseline. Indeed, we find that LMs conditioned on the web surpass performance of closed-book models of similar, or even larger, model sizes in open-domain question answering. Finally, we find that increasing the inference-time compute of models, achieved via using multiple retrieved evidences to generate multiple answers followed by a reranking stage that uses scores generated by the same LMs, leads to better performance and alleviates lower performance of smaller few-shot LMs. All in all, our findings suggest that it might be beneficial to slow down the race towards the biggest model and instead shift attention towards finding more effective ways to use models, including but not limited to, better prompting or increasing inference-time compute.

VIP: Towards Universal Visual Reward and Representation via Value-Implicit Pre-Training

Yecheng Jason Ma,Shagun Sodhani,Dinesh Jayaraman,Osbert Bastani,Vikash Kumar,Amy Zhang

Reward and representation learning are two long-standing challenges for learning an expanding set of robot manipulation skills from sensory observations. Given the inherent cost and scarcity of in-domain, task-specific robot data, learning from large, diverse, offline human videos has emerged as a promising path towards acquiring a generally useful visual representation for control; however, how these human videos can be used for general-purpose reward learning remains an open question. We introduce $\textbf{V}$alue-$\textbf{I}$mplicit $\textbf{P}$re-training (VIP), a self-supervised pre-trained visual representation capable of generating dense and smooth reward functions for unseen robotic tasks. VIP casts representation learning from human videos as an offline goal-conditioned reinforcement learning problem and derives a self-supervised dual goal-conditioned value-function objective that does not depend on actions, enabling pre-training on unlabeled human videos. Theoretically, VIP can be understood as a novel implicit time contrastive objective that generates a temporally smooth embedding, enabling the value function to be implicitly defined via the embedding distance, which can then be used to construct the reward for any goal-image specified downstream task. Trained on large-scale Ego4D human videos and without any fine-tuning on in-domain, task-specific data, VIP can provide dense visual reward for an extensive set of simulated and $\textbf{real-robot}$ tasks, enabling diverse reward-based

visual control methods and significantly outperforming all prior pre-trained representations. Notably, VIP can enable simple, few-shot offline RL on a suite of real-world robot tasks with as few as 20 trajectories.

Language Modeling Using Tensor Trains

Zhan Su,Yuqin Zhou,Benyou Wang,Qiuchi Li,Jakob Grue Simonsen

Tensor networks have previously been shown to have potential in language modelling in theory, but lack of practical evidence support. We propose a novel Tensor Train Language Model (TTLM) based on Tensor-Train decomposition. We prove that TTLM generalizes Second-order Recurrent Neural Networks (RNNs), Recurrent Arithmetic Circuits and Multiplicative Integration RNNs in the sense that the architecture of all of these are, essentially, special cases of that of TTLM. To show the usefulness of TTLM, we perform a principled experimental evaluation on language modeling tasks, showing that our proposed variants, TTLM-large and TTLM-Tiny, can be more effective than Vanilla RNN while TTLM-Tiny has the half of the model size.

Bridging the Gap to Real-World Object-Centric Learning

Maximilian Seitzer,Max Horn,Andrii Zadaianchuk,Dominik Zietlow,Tianjun Xiao,Carl-Johann Simon-Gabriel,Tong He,Zheng Zhang,Bernhard Schölkopf,Thomas Brox,Francesco Locatello

Humans naturally decompose their environment into entities at the appropriate level of abstraction to act in the world. Allowing machine learning algorithms to derive this decomposition in an unsupervised way has become an important line of research. However, current methods are restricted to simulated data or require additional information in the form of motion or depth in order to successfully discover objects. In this work, we overcome this limitation by showing that reconstructing features from models trained in a self-supervised manner is a sufficient training signal for object-centric representations to arise in a fully unsupervised way. Our approach, DINOSAUR, significantly out-performs existing object-centric learning models on simulated data and is the first unsupervised object-centric model that scales to real world-datasets such as COCO and PASCAL VOC. DINOSAUR is conceptually simple and shows competitive performance compared to more involved pipelines from the computer vision literature.
****

Towards a Unified Theoretical Understanding of Non-contrastive Learning via Rank Differential Mechanism

Zhijian Zhuo,Yifei Wang,Jinwen Ma,Yisen Wang

Recently, a variety of methods under the name of non-contrastive learning (like BYOL, SimSiam, SwAV, DINO) show that when equipped with some asymmetric architectural designs, aligning positive pairs alone is sufficient to attain good performance in self-supervised visual learning. Despite some understandings of some specific modules (like the predictor in BYOL), there is yet no unified theoretical understanding of how these seemingly different asymmetric designs can all avoid feature collapse, particularly considering methods that also work without the predictor (like DINO). In this work, we propose a unified theoretical understanding for existing variants of non-contrastive learning. Our theory named Rank Differential Mechanism (RDM) shows that all these asymmetric designs create a consistent rank difference in their dual-branch output features. This rank difference will provably lead to an improvement of effective dimensionality and alleviate either complete or dimensional feature collapse. Different from previous theories, our RDM theory is applicable to different asymmetric designs (with and without the predictor), and thus can serve as a unified understanding of existing non-contrastive learning methods. Besides, our RDM theory also provides practical guidelines for designing many new non-contrastive variants. We show that these variants indeed achieve comparable performance to existing methods on benchmark datasets, and some of them even outperform the baselines. Our code is available at \url{https://github.com/PKU-ML/Rank-Differential-Mechanism}.

Stay Moral and Explore: Learn to Behave Morally in Text-based Games

Zijing Shi,Meng Fang,Yunqiu Xu,Ling Chen,Yali Du

Reinforcement learning (RL) in text-based games has developed rapidly and achieved promising results. However, little effort has been expended to design agents that pursue objectives while behaving morally, which is a critical issue in the field of autonomous agents. In this paper, we propose a general framework named Moral Awareness Adaptive Learning (MorAL) that enhances the morality capacity of an agent using a plugin moral-aware learning model. The framework allows the agent to execute task learning and morality learning adaptively. The agent selects trajectories from past experiences during task learning. Meanwhile, the trajectories are used to conduct self-imitation learning with a moral-enhanced objective. In order to achieve the trade-off between morality and task progress, the agent uses the combination of task policy and moral policy for action selection. We evaluate on the Jiminy Cricket benchmark, a set of text-based games with various scenes and dense morality annotations. Our experiments demonstrate that, compared with strong contemporary value alignment approaches, the proposed framework improves task performance while reducing immoral behaviours in various games.

Efficient Discovery of Dynamical Laws in Symbolic Form

Sören Becker,Michal Klein,Alexander Neitz,Giambattista Parascandolo,Niki Kilbertus

We propose a transformer-based sequence-to-sequence model that recovers scalar ordinary differential equations (ODEs) in symbolic form from time-series data of a single observed solution trajectory of the ODE. Our method is efficiently scalable: after one-time pretraining on a large set of ODEs, we can infer the governing laws of a new observed solution in a few forward passes of the model. First, we generate and make available a large dataset of more than 3M ODEs together with more than 63M numerical solutions for different initial conditions that may serve as a useful benchmark for future work on machine learning for dynamical systems. Then we show that our model performs better or on par with existing methods in various test cases in terms of accurate symbolic recovery of the ODE, especially for more complex expressions. Reliably recovering the symbolic form of dynamical laws is important as it allows for further dissemination of the inferred dynamics as well as meaningful modifications for predictions under interventions.

Brain2GAN; Reconstructing perceived faces from the primate brain via StyleGAN3

Thirza Dado,Paolo Papale,Antonio Lozano,Lynn Le,Feng Wang,Marcel van Gerven,Pieter R. Roelfsema,Ya■mur Güçlütürk,Umut Güçlü

Neural coding characterizes the relationship between stimuli and their corresponding neural responses. The usage of synthesized yet photorealistic reality by generative adversarial networks (GANs) allows for superior control over these data: the underlying feature representations that account for the semantics in synthesized data are known a priori and their relationship is perfect rather than approximated post-hoc by feature extraction models. We exploit this property in neural decoding of multi-unit activity responses that we recorded from the primate brain upon presentation with synthesized face images in a passive fixation experiment. The face reconstructions we acquired from brain activity were astonishingly similar to the originally perceived face stimuli. This provides strong evidence that the neural face manifold and the disentangled w-latent space conditioned on StyleGAN3 (rather than the z-latent space of arbitrary GANs or other feature representations we encountered so far) share how they represent the high-level semantics of the high-dimensional space of faces.

Optimistic Exploration with Learned Features Provably Solves Markov Decision Processes with Neural Dynamics

Sirui Zheng,Lingxiao Wang,Shuang Qiu,Zuyue Fu,Zhuoran Yang,Csaba Szepesvari,Zhaoran Wang

Incorporated with the recent advances in deep learning, deep reinforcement learning (DRL) has achieved tremendous success in empirical study. However, analyzing DRL is still challenging due to the complexity of the neural network class. In

this paper, we address such a challenge by analyzing the Markov decision process (MDP) with neural dynamics, which covers several existing models as special cases, including the kernelized nonlinear regulator (KNR) model and the linear MDP. We propose a novel algorithm that designs exploration incentives via learnable representations of the dynamics model by embedding the neural dynamics into a kernel space induced by the system noise. We further establish an upper bound on the sample complexity of the algorithm, which demonstrates the sample efficiency of the algorithm. We highlight that, unlike previous analyses of RL algorithms with function approximation, our bound on the sample complexity does not depend on the Eluder dimension of the neural network class, which is known to be exponentially large (Dong et al., 2021).

Would decentralization hurt generalization?
Tongtian Zhu,Fengxiang He,Kaixuan Chen,Mingli Song,Dacheng Tao
Decentralized stochastic gradient descent (D-SGD) allows collaborative learning on massive devices without controlling of a central server. Existing theory suggests that the decentralization degrades the generalizability, which conflicts with experimental results in the large-batch settings that D-SGD generalize better than centralized SGD (C-SGD). This work presents new theory that reconciles the conflict between the two perspectives. We prove that D-SGD introduces an implicit regularization that simultaneously penalizes (1) the sharpness of the learned minima and (2) the consensus distance between the consensus model and local models. We then prove that the implicit regularization is amplified in the large-batch settings when the linear scaling rule is applied. We further analyze the escaping efficiency of D-SGD, which suggests that D-SGD favors super-quadratic flat minima. Experiments are in full agreement with our theory. The code will be released publicly. To our best knowledge, this is the first work on the implicit regularization and escaping efficiency of D-SGD.

Variational Pseudo Labels for Meta Test-time Adaptation
Sameer Ambekar,Zehao Xiao,Jiayi Shen,Xiantong Zhen,Cees G. M. Snoek
Test-time model adaptation has shown great effectiveness in generalizing over domain shifts. A most successful tactic for test-time adaptation conducts further optimization on the target data using the predictions by the source-trained model. However, due to domain shifts, the source-trained model predictions themselves can be largely inaccurate, which results in a model misspecified to the target data and therefore damages their adaptation ability. In this paper, we address test-time adaptation from a probabilistic perspective. We formulate model adaption as a probabilistic inference problem, which incorporates the uncertainty into source model predictions by modeling pseudo labels as distributions. Based on the probabilistic formalism, we propose variational pseudo labels that explore the information of neighboring target samples to improve pseudo labels and achieve a model better specified to target data. By a meta-learning paradigm, we train our model by simulating domain shifts and the test-time adaptation procedure. In doing so, our model learns the ability to generate more accurate pseudo-label distributions and to adapt to new domains. Experiments on three widely used datasets demonstrate the effectiveness of our proposal.

No-Regret Learning in Strongly Monotone Games Converges to a Nash Equilibrium
Zifan Wang,Yi Shen,Michael Zavlanos,Karl Henrik Johansson
This paper studies a class of online games involving multiple agents with continuous actions that aim to minimize their local loss functions. An open question in the study of online games is whether no-regret learning for such agents leads to a Nash equilibrium. We address this question by providing a sufficient condition for strongly monotone games that guarantees Nash equilibrium convergence in a time average sense. Furthermore, we show that the class of games for which no-regret learning leads to a Nash equilibrium can be expanded if some further information on the learning algorithm is known. Specifically, we provide relaxed sufficient conditions for first-order and zeroth-order gradient descent algorithms as well as for best response algorithms in which agents choose actions that best

respond to other players' actions during the last episode. We analyze the convergence rate for these algorithms and present numerical experiments on three economic market problems to illustrate their performance.

****

Generalized Belief Transport

Junqi Wang,PEI WANG,Patrick Shafto

Human learners have ability to adopt appropriate learning approaches depending on constraints such as prior on the hypothesis and urgency of decision. However, existing learning models are typically considered individually rather than in relation to one and other. To build agents that have the ability to move between different modes of learning over time, it is important to understand how learning models are related as points in a broader space of possibilities. We introduce a mathematical framework, Generalized Belief Transport (GBT), that unifies and generalizes prior models, including Bayesian inference, cooperative communication and classification, as parameterizations of three learning constraints within Unbalanced Optimal Transport (UOT). We visualize the space of learning models encoded by GBT as a cube which includes classic learning models as special points. We derive critical properties of this parameterized space including proving continuity and differentiability which is the basis for model interpolation, and study limiting behavior of the parameters, which allows attaching learning models on the boundaries. Moreover, we investigate the long-run behavior of GBT, explore convergence properties of models in GBT mathematical and computationally, and formulate conjectures about general behavior. We conclude with open questions and implications for more unified models of learning.

Adversarial Cheap Talk

Chris Lu,Timon Willi,Alistair Letcher,Jakob Nicolaus Foerster

Adversarial attacks in reinforcement learning (RL) often assume highly-privileged access to the victim’s parameters, environment, or data. Instead, this paper proposes a novel adversarial setting called a Cheap Talk MDP in which an Adversary can merely append deterministic messages to the Victim’s observation, resulting in a minimal range of influence. The Adversary cannot occlude ground truth, influence underlying environment dynamics or reward signals, introduce non-stationarity, add stochasticity, see the Victim’s actions, or access their parameters. Additionally, we present a simple meta-learning algorithm called Adversarial Cheap Talk (ACT) to train Adversaries in this setting. We demonstrate that an Adversary trained with ACT can still significantly influence the Victim’s training and testing performance, despite the highly constrained setting. Affecting train-time performance reveals a new attack vector and provides insight into the success and failure modes of existing RL algorithms. More specifically, we show that an ACT Adversary is capable of harming performance by interfering with the learner’s function approximation, or instead helping the Victim’s performance by outputting useful features. Finally, we show that an ACT Adversary can manipulate messages during train-time to directly and arbitrarily control the Victim at test-time.

Learning to Induce Causal Structure

Nan Rosemary Ke,Silvia Chiappa,Jane X Wang,Jorg Bornschein,Anirudh Goyal,Melanie Rey,Theophane Weber,Matthew Botvinick,Michael Curtis Mozer,Danilo Jimenez Rezende

The fundamental challenge in causal induction is to infer the underlying graph structure given observational and/or interventional data. Most existing causal induction algorithms operate by generating candidate graphs and evaluating them using either score-based methods (including continuous optimization) or independence tests. In our work, we instead treat the inference process as a black box and design a neural network architecture that learns the mapping from both observational and interventional data to graph structures via supervised training on synthetic graphs. The learned model generalizes to new synthetic graphs, is robust to train-test distribution shifts, and achieves state-of-the-art performance on naturalistic graphs for low sample complexity.

****

Personalized federated composite learning with forward-backward envelopes

Jiang Hu,Jinhyun Ahn,Na Li,Quanzheng Li

Federated composite optimization (FCO) is an optimization problem in federated learning whose loss function contains a non-smooth regularizer. It arises naturally in the applications of federated learning (FL) that involve requirements such as sparsity, low rankness, and monotonicity. In this study, we propose a personalization method, called pFedFBE, for FCO by using forward-backward envelope (FBE) as clients’ loss functions. With FBE, we not only decouple the personalized model from the global model, but also allow personalized models to be smooth and easily optimized. In spite of the nonsmoothness of FCO, pFedFBE shows the same convergence complexity results as FedAvg for FL with unconstrained smooth objectives. Numerical experiments are shown to demonstrate the effectiveness of our proposed method.

****

Tackling Imbalanced Class in Federated Learning via Class Distribution Estimation

You-Ru Lu,Xiaoqian Wang,Dengfeng Sun

Federated Learning (FL) has become an upsurging machine learning method due to its applicability in large-scale distributed system and its privacy-preserving property. However, in real-world applications, the presence of class imbalance issue, especially the mismatch between local and global class distribution, greatly degrades the performance of FL. Moreover, due to the privacy constrain, the class distribution information of clients can not be accessed directly. To tackle class imbalance issue under FL setting, a novel algorithm, FedRE, is proposed in this paper. We propose a new class distribution estimation method for the FedRE algorithm, which requires no extra client data information and thus has no privacy concern. Both experimental results and theoretical analysis are provided to support the validity of our distribution estimation method. The proposed algorithm is verified with several experiment, including different datasets with the presence of class imbalance and local-global distribution mismatch. The experimental results show that FedRE is effective and it outperforms other related methods in terms of both overall and minority class classification accuracy.

Diffusion Policies as an Expressive Policy Class for Offline Reinforcement Learning

Zhendong Wang,Jonathan J Hunt,Mingyuan Zhou

Offline reinforcement learning (RL), which aims to learn an optimal policy using a previously collected static dataset, is an important paradigm of RL. Standard RL methods often perform poorly in this regime due to the function approximation errors on out-of-distribution actions. While a variety of regularization methods have been proposed to mitigate this issue, they are often constrained by policy classes with limited expressiveness that can lead to highly suboptimal solutions. In this paper, we propose representing the policy as a diffusion model, a recent class of highly-expressive deep generative models. We introduce Diffusion Q-learning (Diffusion-QL) that utilizes a conditional diffusion model to represent the policy. In our approach, we learn an action-value function and we add a term maximizing action-values into the training loss of the conditional diffusion model, which results in a loss that seeks optimal actions that are near the behavior policy. We show the expressiveness of the diffusion model-based policy, and the coupling of the behavior cloning and policy improvement under the diffusion model both contribute to the outstanding performance of Diffusion-QL. We illustrate the superiority of our method compared to prior works in a simple 2D bandit example with a multimodal behavior policy. We then show that our method can achieve state-of-the-art performance on the majority of the D4RL benchmark tasks.

Subquadratic Algorithms for Kernel Matrices via Kernel Density Estimation

Ainesh Bakshi,Piotr Indyk,Praneeth Kacham,Sandeep Silwal,Samson Zhou

Kernel matrices, as well as weighted graphs represented by them, are ubiquitous objects in machine learning, statistics and other related fields. The main drawback of using kernel methods (learning and inference using kernel matrices) is efficiency -- given n input points, most kernel-based algorithms need to materialize the full $n \times n$ kernel matrix before performing any subsequent computation, thus incurring $\Omega(n^2)$ runtime. Breaking this quadratic barrier for various problems has therefore, been a subject of extensive research efforts.

We break the quadratic barrier and obtain \emph{subquadratic} time algorithms for several fundamental linear-algebraic and graph processing primitives, including approximating the top eigenvalue and eigenvector, spectral sparsification, solving linear systems, local clustering, low-rank approximation, arboricity estimation and counting weighted triangles. We build on the recently developed Kernel Density Estimation framework, which (after preprocessing in time subquadratic in n) can return estimates of row/column sums of the kernel matrix. In particular, we develop efficient reductions from \emph{weighted vertex} and \emph{weighted edge sampling} on kernel graphs, \emph{simulating random walks} on kernel graphs, and \emph{importance sampling} on matrices to Kernel Density Estimation and show that we can generate samples from these distributions in \emph{sublinear} (in the support of the distribution) time. Our reductions are the central ingredient in each of our applications and we believe they may be of independent interest. We empirically demonstrate the efficacy of our algorithms on low-rank approximation (LRA) and spectral sparsification, where we observe a $\textbf{9x}$ decrease in the number of kernel evaluations over baselines for LRA and a $\textbf{41x}$ reduction in the graph size for spectral sparsification.

CASA: Bridging the Gap between Policy Improvement and Policy Evaluation with Conflict Averse Policy Iteration

Changnan Xiao,Haosen Shi,Jiajun Fan,Shihong Deng,Haiyan Yin

We study the problem of model-free reinforcement learning, which is often solved following the principle of Generalized Policy Iteration (GPI). While GPI is typically an interplay between policy evaluation and policy improvement, most conventional model-free methods with function approximation assume the independence of GPI steps, despite of the inherent connections between them. In this paper, we present a method that attempts to eliminate the inconsistency between policy evaluation step and policy improvement step, leading to a conflict averse GPI solution with gradient-based functional approximation. Our method is capital to balancing exploitation and exploration between policy-based and value-based methods and is applicable to existed policy-based and value-based methods. We conduct extensive experiments to study theoretical properties of our method and demonstrate the effectiveness of our method on Atari 200M benchmark.

Achieving Near-Optimal Individual Regret & Low Communications in Multi-Agent Bandits

Xuchuang Wang,Lin Yang,Yu-Zhen Janice Chen,Xutong Liu,Mohammad Hajiesmaili,Don Towsley,John C.S. Lui

Cooperative multi-agent multi-armed bandits (CM2AB) study how distributed agents cooperatively play the same multi-armed bandit game. Most existing CM2AB works focused on maximizing the group performance of all agents---the accumulation of all agents' individual performance (i.e., individual reward). However, in many applications, the performance of the system is more sensitive to the ``bad'' agent---the agent with the worst individual performance. For example, in a drone swarm, a ``bad'' agent may crash into other drones and severely degrade the system performance. In that case, the key of the learning algorithm design is to coordinate computational and communicational resources among agents so to optimize the individual learning performance of the ``bad'' agent. In CM2AB, maximizing the group performance is equivalent to minimizing the group regret of all agents, and minimizing the individual performance can be measured by minimizing the maximum (worst) individual regret among agents. Minimizing the maximum individual regret was largely ignored in prior literature, and currently, there is little work on how to minimize this objective with a low communication overhead. In this pap

er, we propose a near-optimal algorithm on both individual and group regrets, in addition, we also propose a novel communication module in the algorithm, which only needs \(O(\log (\log T))\) communication times where \(T\) is the number of decision rounds. We also conduct simulations to illustrate the advantage of our algorithm by comparing it to other known baselines.

Online Boundary-Free Continual Learning by Scheduled Data Prior
Hyunseo Koh,Minhyuk Seo,Jihwan Bang,Hwanjun Song,Deokki Hong,Seulki Park,Jung-Woo Ha,Jonghyun Choi
Typical continual learning setup assumes that the dataset is split into multiple discrete tasks. We argue that it is less realistic as the streamed data would have no notion of task boundary in real-world data. Here, we take a step forward to investigate more realistic online continual learning – learning continuously changing data distribution without explicit task boundary, which we call boundary-free setup. As there is no clear boundary of tasks, it is not obvious when and what information in the past to be preserved as a better remedy for the stability-plasticity dilemma. To this end, we propose a scheduled transfer of previously learned knowledge. We further propose a data-driven balancing between the knowledge in the past and the present in learning objective. Moreover, since it is not straight-forward to use the previously proposed forgetting measure without task boundaries, we further propose a novel forgetting measure based on information theory that can capture forgetting. We empirically evaluate our method on a Gaussian data stream, its periodic extension, which assumes periodic data distribution frequently observed in real-life data, as well as the conventional disjoint task-split. Our method outperforms prior arts by large margins in various setups, using four popular benchmark datasets – CIFAR-10, CIFAR-100, TinyImageNet and ImageNet.

HypeR: Multitask Hyper-Prompted Training Enables Large-Scale Retrieval Generalization
ZeFeng Cai,Chongyang Tao,Tao Shen,Can Xu,Xiubo Geng,Xin Alex Lin,Liang He,Daxin Jiang
Recently, large-scale text retrieval has made impressive progress, facilitating both information retrieval and downstream knowledge-intensive tasks (e.g., open-domain QA and dialogue). With a moderate amount of data, a neural text retriever can outperform traditional methods such as BM25 by a large step. However, while being applied to out-of-domain data, the performance of a neural retriever degrades considerably. Therefore, how to enable a retriever to perform more robustly across different domains or tasks and even show strong zero-shot transfer ability is critical for building scalable IR systems. To this end, we propose HypeR, a hyper-prompted training mechanism to enable uniform retrieval across tasks of different domains. Specifically, our approach jointly trains the query encoder with a shared prompt-based parameter pool and a prompt synthesizer that dynamically composes hyper-prompt for encoding each query from different tasks or domains. Besides, to avoid the mode collapse of prompt attention distribution for different queries, we design a contrastive prompt regularization that promotes the mode of prompt attention to be aligned and uniform. Through multi-task hyper-prompted training, our retriever can master the ability to dynamically represent different types of queries and transfer knowledge across different domains and tasks. Extensive experiments show our model attains better retrieval performance across different tasks and better zero-shot transfer ability compared with various previous methods.

Learning Rationalizable Equilibria in Multiplayer Games
Yuanhao Wang,Dingwen Kong,Yu Bai,Chi Jin
A natural goal in multi-agent learning is to learn \emph{rationalizable} behavior, where players learn to avoid any Iteratively Dominated Action (IDA). However, standard no-regret based equilibria-finding algorithms could take exponential samples to find such rationalizable strategies. In this paper, we first propose a simple yet sample-efficient algorithm for finding a rationalizable action profi

le in multi-player general-sum games under bandit feedback, which substantially improves over the results of Wu et al. We further develop algorithms with the first efficient guarantees for learning rationalizable Coarse Correlated Equilibria (CCE) and Correlated Equilibria (CE). Our algorithms incorporate several novel techniques to guarantee the elimination of IDA and no (swap-)regret simultaneously, including a correlated exploration scheme and adaptive learning rates, which may be of independent interest. We complement our results with a sample complexity lower bound showing the sharpness of our guarantees.

A Higher Precision Algorithm for Computing the 1-Wasserstein Distance

Pankaj K Agarwal,Sharath Raghvendra,Pouyan Shirzadian,Rachita Sowle

We consider the problem of computing the 1-Wasserstein distance $\mathcal{W}(\mu,\nu)$ between two d-dimensional discrete distributions μ and ν whose support lie within the unit hypercube. There are several algorithms that estimate $\mathcal{W}(\mu,\nu)$ within an additive error of ε. However, when $\mathcal{W}(\mu,\nu)$ is small, the additive error ε dominates, leading to noisy results. Consider any additive approximation algorithm with execution time $T(n,\varepsilon)$. We propose an algorithm that runs in $O(T(n,\varepsilon/d) \log n)$ time and boosts the accuracy of estimating $\mathcal{W}(\mu,\nu)$ from ε to an expected additive error of $\min\{\varepsilon, (d\log_{\sqrt{d}/\varepsilon} n)\mathcal{W}(\mu,\nu)\}$. For the special case where every point in the support of μ and ν has a mass of $1/n$ (also called the Euclidean Bipartite Matching problem), we describe an algorithm to boost the accuracy of any additive approximation algorithm from ε to an expected additive error of $\min\{\varepsilon, (d\log\log n)\mathcal{W}(\mu,\nu)\}$ in $O(T(n, \varepsilon/d)\log\log n)$ time.

Energy-Based Test Sample Adaptation for Domain Generalization

Zehao Xiao,Xiantong Zhen,Shengcai Liao,Cees G. M. Snoek

In this paper, we propose energy-based sample adaptation at test time for domain generalization. Where previous works adapt their models to target domains, we adapt the unseen target samples to source-trained models. To this end, we design a discriminative energy-based model, which is trained on source domains to jointly model the conditional distribution for classification and data distribution for sample adaptation. The model is optimized to simultaneously learn a classifier and an energy function. To adapt target samples to source distributions, we iteratively update the samples by energy minimization with stochastic gradient Langevin dynamics. Moreover, to preserve the categorical information in the sample during adaptation, we introduce a categorical latent variable into the energy-based model. The latent variable is learned from the original sample before adaptation by variational inference and fixed as a condition to guide the sample update. Experiments on six benchmarks for classification of images and microblog threads demonstrate the effectiveness of our proposal.

Representation Power of Graph Convolutions : Neural Tangent Kernel Analysis

Mahalakshmi Sabanayagam,Pascal Esser,Debarghya Ghoshdastidar

The fundamental principle of Graph Neural Networks (GNNs) is to exploit the structural information of the data by aggregating the neighboring nodes using a `graph convolution’. Therefore, understanding its influence on the network performance is crucial. Convolutions based on graph Laplacian have emerged as the dominant choice with the symmetric normalization of the adjacency matrix A, defined as $D^{-1/2}AD^{−1/2}$, being the most widely adopted one, where D is the degree matrix. However, some empirical studies show that row normalization $D^{−1}A$ outperforms it in node classification. Despite the widespread use of GNNs, there is no rigorous theoretical study on the representation power of these convolution operators, that could explain this behavior. In this work, we analyze the influence of the graph convolutions theoretically using Graph Neural Tangent Kernel in a semi-supervised node classification setting. Under a Degree Corrected Stochastic Block Model, we prove that: (i) row normalization preserves the underlying class structure better than other graph convolutions; (ii) performance degrade s with network depth due to over-smoothing, but the loss in class information is the slowest in row normalization; (iii) skip connections retain the class information even at infinite depth, thereby eliminating over-smoothing. We finally validate our theoretical findings on real datasets.

Bidirectional Language Models Are Also Few-shot Learners

Ajay Patel,Bryan Li,Mohammad Sadegh Rasooli,Noah Constant,Colin Raffel,Chris Callison-Burch

Large language models such as GPT-3 (Brown et al., 2020) can perform arbitrary tasks without undergoing fine-tuning after being prompted with only a few labeled examples. An arbitrary task can be reformulated as a natural language prompt, and a language model can be asked to generate the completion, indirectly performing the task in a paradigm known as prompt-based learning. To date, emergent prompt-based learning capabilities have mainly been demonstrated for unidirectional language models. However, bidirectional language models pre-trained on denoising objectives such as masked language modeling produce stronger learned representations for transfer learning. This motivates the possibility of prompting bidirectional models, but their pre-training objectives have made them largely incompatible with the existing prompting paradigm. We present SAP (Sequential Autoregressive Prompting), a technique that enables the prompting of bidirectional models. Utilizing the machine translation task as a case study, we prompt the bidirectional mT5 model (Xue et al., 2021) with SAP and demonstrate its few-shot and zero-shot translations outperform the few-shot translations of unidirectional models like GPT-3 and XGLM (Lin et al., 2021), despite mT5's approximately 50% fewer parameters. We further show SAP is effective on question answering and summarization. For the first time, our results demonstrate prompt-based learning is an emergent property of a broader class of language models, rather than only unidirectional models.

Revisiting adapters with adversarial training

Sylvestre-Alvise Rebuffi,Francesco Croce,Sven Gowal

While adversarial training is generally used as a defense mechanism, recent works show that it can also act as a regularizer. By co-training a neural network on clean and adversarial inputs, it is possible to improve classification accuracy on the clean, non-adversarial inputs. We demonstrate that, contrary to previous findings, it is not necessary to separate batch statistics when co-training on clean and adversarial inputs, and that it is sufficient to use adapters with few domain-specific parameters for each type of input. We establish that using the classification token of a Vision Transformer (ViT) as an adapter is enough to match the classification performance of dual normalization layers, while using significantly less additional parameters. First, we improve upon the top-1 accuracy of a non-adversarially trained ViT-B16 model by +1.12% on ImageNet (reaching 83.76% top-1 accuracy). Second, and more importantly, we show that training with adapters enables model soups through linear combinations of the clean and adversarial tokens. These model soups, which we call adversarial model soups, allow us to trade-off between clean and robust accuracy without sacrificing efficiency. Finally, we show that we can easily adapt the resulting models in the face of distribution shifts. Our ViT-B16 obtains top-1 accuracies on ImageNet variants that are on average +4.00% better than those obtained with Masked Autoencoders.

Human-AI Coordination via Human-Regularized Search and Learning

Hengyuan Hu,David J Wu,Adam Lerer,Jakob Nicolaus Foerster,Noam Brown

We consider the problem of making AI agents that collaborate well with humans in partially observable fully cooperative environments given datasets of human behavior. Inspired by piKL, a human-data-regularized search method that improves upon a behavioral cloning policy without diverging far away from it, we develop a three-step algorithm that achieve strong performance in coordinating with real humans in the Hanabi benchmark. We first use a regularized search algorithm and behavioral cloning to produce a better human model that captures diverse skill levels. Then, we integrate the policy regularization idea into reinforcement learn ing to train a human-like best response to the human model. Finally, we apply regularized search on top of the best response policy at test time to handle out-of-distribution challenges when playing with humans. We evaluate our method in two large scale experiments with humans. First, we show that our method outperforms experts when playing with a group of diverse human players in ad-hoc teams. Second, we show that our method beats a vanilla best response to behavioral cloning baseline by having experts play repeatedly with the two agents.

Solving Math Word Problems with Process-based and Outcome-based Feedback

Jonathan Uesato,Nate Kushman,Ramana Kumar,H. Francis Song,Noah Yamamoto Siegel,Lisa Wang,Antonia Creswell,Geoffrey Irving,Irina Higgins

Recent work has shown that prompting language models to generate reasoning steps improves performance on many reasoning tasks. When moving beyond prompting, this raises the question of how we should supervise the finetuning of such models: outcome-based approaches which supervise the final result, or process-based approaches which supervise the reasoning process itself? Differences between these approaches might naturally be expected not just in final-answer errors but also in reasoning errors, which can be difficult to detect and are problematic in many real-world domains such as education. We run the first comprehensive comparison between process- and outcome-based approaches trained on a natural language task, GSM8K. We find that pure outcome-based supervision produces similar final-answer error rates with less label supervision. However, for correct reasoning steps we find it necessary to use process-based supervision or supervision from learned reward models that emulate process-based feedback. In total, we improve the previous best results from 16.8% $\rightarrow$ 12.7% final-answer error and 14.0% $\rightarrow$ 3.4% reasoning error among final-answer-correct solutions.

EPISODE: Episodic Gradient Clipping with Periodic Resampled Corrections for Federated Learning with Heterogeneous Data

Michael Crawshaw,Yajie Bao,Mingrui Liu

Gradient clipping is an important technique for deep neural networks with exploding gradients, such as recurrent neural networks. Recent studies have shown that the loss functions of these networks do not satisfy the conventional smoothness condition, but instead satisfy a relaxed smoothness condition, i.e., the Lipschitz constant of the gradient scales linearly in terms of the gradient norm. Due to this observation, several gradient clipping algorithms have been developed for nonconvex and relaxed-smooth functions. However, the existing algorithms only apply to the single-machine or multiple-machine setting with homogeneous data across machines. It remains unclear how to design provably efficient gradient clipping algorithms in the general Federated Learning (FL) setting with heterogeneous data and limited communication rounds. In this paper, we design EPISODE, the very first algorithm to solve FL problems with heterogeneous data in the nonconvex and relaxed smoothness setting. The key ingredients of the algorithm are two new techniques called \textit{episodic gradient clipping} and \textit{periodic resampled corrections}. At the beginning of each round, EPISODE resamples stochastic gradients from each client and obtains the global averaged gradient, which is used to (1) determine whether to apply gradient clipping for the entire round and (2) construct local gradient corrections for each client. Notably, our algorithm and analysis provide a unified framework for both homogeneous and heterogeneous data under any noise level of the stochastic gradient, and it achieves state-of-the-art complexity results. In particular, we prove that EPISODE can achieve linear speedup in the number of machines, and it requires significantly fewer communication rounds. Experiments on several heterogeneous datasets, including text classification and image classification, show the superior performance of EPISODE over several strong baselines in FL. The code is available at https://github.com/MingruiLiu-ML-Lab/episode.

Memory-Efficient Reinforcement Learning with Priority based on Surprise and On-policyness

Ryosuke Unno,Yoshimasa Tsuruoka

In off-policy reinforcement learning, an agent collects transition data (a.k.a. experience tuples) from the environment and stores them in a replay buffer for the incoming parameter updates. Storing those tuples consumes a large amount of memory when the environment observations are given as images. Large memory consumption is especially problematic when reinforcement learning methods are applied in scenarios where the computational resources are limited. In this paper, we introduce a method to prune relatively unimportant experience tuples by a simple metric that estimates the importance of experiences and saves the overall memory consumption by the buffer. To measure the importance of experiences, we use $\textit{surprise}$ and $\textit{on-policyness}$. Surprise is quantified by the information gain the model can obtain from the experiences and on-policyness ensures that they are relevant to the current policy. In our experiments, we empirically show that our method can significantly reduce the memory consumption by the replay buffer without decreasing the performance in vision-based environments.

****

Uncovering Directions of Instability via Quadratic Approximation of Deep Neural Loss in Reinforcement Learning

Ezgi Korkmaz,Jonah Brown-Cohen

Learning in MDPs with highly complex state representations is currently possible due to multiple advancements in reinforcement learning algorithm design. However, this incline in complexity, and furthermore the increase in the dimensions of the observation came at the cost of non-robustness that can be taken advantage of (i.e. moving along worst-case directions in the observation space). To solve this policy instability problem we propose a novel method to ascertain the presence of these non-robust directions via quadratic approximation of the deep neural policy loss. Our method provides a theoretical basis for the fundamental cut-off between stable observations and non-robust observations. Furthermore, our technique is computationally efficient, and does not depend on the methods used to produce the worst-case directions. We conduct extensive experiments in the Arcade Learning Environment with several different non-robust alteration techniques. Most significantly, we demonstrate the effectiveness of our approach even in the setting where alterations are explicitly optimized to circumvent our proposed method.

A Theory of Dynamic Benchmarks

Ali Shirali,Rediet Abebe,Moritz Hardt

Dynamic benchmarks interweave model fitting and data collection in an attempt to mitigate the limitations of static benchmarks. In contrast to an extensive theoretical and empirical study of the static setting, the dynamic counterpart lags behind due to limited empirical studies and no apparent theoretical foundation to date. Responding to this deficit, we initiate a theoretical study of dynamic benchmarking. We examine two realizations, one capturing current practice and the other modeling more complex settings. In the first model, where data collection and model fitting alternate sequentially, we prove that model performance improves initially but can stall after only three rounds. Label noise arising from, for instance, annotator disagreement leads to even stronger negative results. Our second model generalizes the first to the case where data collection and model fitting have a hierarchical dependency structure. We show that this design guarantees strictly more progress than the first, albeit at a significant increase in complexity. We support our theoretical analysis by simulating dynamic benchmarks on two popular datasets. These results illuminate the benefits and practical limitations of dynamic benchmarking, providing both a theoretical foundation and a causal explanation for observed bottlenecks in empirical work.

On the Trade-Off between Actionable Explanations and the Right to be Forgotten

Martin Pawelczyk,Tobias Leemann,Asia Biega,Gjergji Kasneci

As machine learning (ML) models are increasingly being deployed in high-stakes applications, policymakers have suggested tighter data protection regulations (e.g., GDPR, CCPA). One key principle is the “right to be forgotten” which gives users the right to have their data deleted. Another key principle is the right to an actionable explanation, also known as algorithmic recourse, allowing users to reverse unfavorable decisions. To date, it is unknown whether these two principles can be operationalized simultaneously. Therefore, we introduce and study the problem of recourse invalidation in the context of data deletion requests. More specifically, we theoretically and empirically analyze the behavior of popular state-of-the-art algorithms and demonstrate that the recourses generated by these algorithms are likely to be invalidated if a small number of data deletion requests (e.g., 1 or 2) warrant updates of the predictive model. For the setting of differentiable models, we suggest a framework to identify a minimal subset of critical training points which, when removed, maximize the fraction of invalidated recourses.Using our framework, we empirically show that the removal of as little as 2 data instances from the training set can invalidate up to 95 percent of all recourses output by popular state-of-the-art algorithms. Thus, our work raises fundamental questions about the compatibility of ``the right to an actionable explanation'' in the context of the ``right to be forgotten'', while also providing constructive insights on the determining factors of recourse robustness.

****

Learning to Cooperate and Communicate Over Imperfect Channels

Jannis Weil,Gizem Ekinci,Heinz Koeppl,Tobias Meuser

Information exchange in multi-agent systems improves the cooperation among agents, especially in partially observable settings. This can be seen as part of the problem in which the agents learn how to communicate and to solve a shared task simultaneously. In the real world, communication is often carried out over imperfect channels and this requires the agents to deal with uncertainty due to potential information loss. In this paper, we consider a cooperative multi-agent system where the agents act and exchange information in a decentralized manner using a limited and unreliable channel. To cope with such channel constraints, we propose a novel communication approach based on independent Q-learning. Our method allows agents to dynamically adapt how much information to share by sending messages of different size, depending on their local observations and the channel properties. In addition to this message size selection, agents learn to encode and decode messages to improve their policies. We show that our approach outperforms approaches without adaptive capabilities and discuss its limitations in different environments.

****

Uncertainty-aware off policy learning

Xiaoying Zhang,Junpu Chen,Hongning Wang,Hong Xie,Hang Li

Off-policy learning, referring to the procedure of policy optimization with access only to logged feedback data, has shown importance in various real-world applications, such as search engines, recommender systems, etc. While the ground-truth logging policy, which generates the logged data, is usually unknown, previous work directly takes its estimated value in off-policy learning, resulting in a biased estimator. This estimator has both high bias and variance on samples with small and inaccurate estimated logging probabilities.

In this work, we explicitly model the uncertainty in the estimated logging policy and propose a novel \underline{U}ncertainty-aware \underline{I}nverse \underline{P}ropensity \underline{S}core estimator (UIPS) for improved off-policy learning. Experiment results on synthetic and three real-world recommendation datasets demonstrate the advantageous sample efficiency of the proposed UIPS estimator.

****

Renamer: A Transformer Architecture In-variant to Variable Renaming

Zachary Ankner,Alex Renda,Michael Carbin

Modeling tasks often take inputs from languages including programming languages and natural language. Many such tasks involve learning functions which are invariant to certain types of input transformations. In this work we consider a specific class of invariance: semantics-preserving variable renaming. We first show that transformer networks trained on such tasks do not always mirror the invariance of the underlying function. In this work we propose Renamer, a transformer architecture which is invariant to semantics-preserving variable renaming. Renamer improves over a vanilla transformer by between a 24.79% to 52.80% reduction in error on a case study on learning a surrogate of a large-scale CPU simualtor. Furthermore, the invariant network does not experience the same sensitivity to variable renaming, and its error remains constant when evaluated on a variable renamed version of the test set. Finally, the invariant network is more efficient to train, and matches the best error of the vanilla network with a between 25.15% to 60.00% reduction in training epochs.

Learning What and Where: Disentangling Location and Identity Tracking Without Supervision

Manuel Traub,Sebastian Otte,Tobias Menge,Matthias Karlbauer,Jannik Thuemmel,Martin V. Butz

Our brain can almost effortlessly decompose visual data streams into background and salient objects. Moreover, it can anticipate object motion and interactions, which are crucial abilities for conceptual planning and reasoning. Recent object reasoning datasets, such as CATER, have revealed fundamental shortcomings of current vision-based AI systems, particularly when targeting explicit object representations, object permanence, and object reasoning. Here we introduce a self-supervised LOCation and Identity tracking system (Loci), which excels on the CATER tracking challenge. Inspired by the dorsal and ventral pathways in the brain, Loci tackles the binding problem by processing separate, slot-wise encodings of 'what' and 'where'. Loci's predictive coding-like processing encourages active error minimization, such that individual slots tend to encode individual objects. Interactions between objects and object dynamics are processed in the disentangled latent space. Truncated backpropagation through time combined with forward eligibility accumulation significantly speeds up learning and improves memory efficiency. Besides exhibiting superior performance in current benchmarks, Loci effectively extracts objects from video streams and separates them into location and Gestalt components. We believe that this separation offers a representation that will facilitate effective planning and reasoning on conceptual levels.

****

BALTO: fast tensor program optimization with diversity-based active learning

Jun Bi,Xiaqing Li,Qi Guo,Rui Zhang,Yuanbo Wen,Xing Hu,Zidong Du,Xinkai Song,Yifan Hao,Yunji Chen

Tensor program optimization (TPO) based on pre-trained models can effectively reduce the computing time of deep neural networks. However, training of such models is prohibitively expensive, which highly depends on a large-scale dataset and thus requires tremendous time-consuming performance measurements (more than 1 million) on target platforms. In this paper, we propose BALTO, a fast TPO approach with biased-diversity-based active learning, aiming at reducing much lower training costs under similar optimization accuracy.The key insight is that random sampling of existing approaches suffers from a heavy redundancy of low-performance programs, which incurs tremendous duplicated time-consuming measurements. Inspired by this, BALTO removes such redundancy by introducing active learning (AL) to TPO for a much lower training cost. However, applying AL with a brute-force way in BALTO can lead to an overestimation problem. To address this, we further propose a biased-diversity-based diversity scheme specially designed for BALTO. We compare BALTO against TenSet on 6 typical hardware platforms over 2 learning models. Experimental results show that, on average, BALTO only requires 5% of the total performance measurements of TenSet to achieve the same or higher model accuracy. Moreover, the optimized tensor programs even outperform that of TenSet by 1.06% due to higher model accuracy.

****

RoCourseNet: Distributionally Robust Training of a Prediction Aware Recourse Model

Hangzhi Guo,Feiran Jia,Jinghui Chen,Anna Squicciarini,Amulya Yadav

Counterfactual (CF) explanations for machine learning (ML) models are preferred by end-users, as they explain the predictions of ML models by providing a recourse (or contrastive) case to individuals who are adversely impacted by predicted outcomes. Existing CF explanation methods generate recourses under the assumptio n that the underlying target ML model remains stationary over time. However, due to commonly occurring distributional shifts in training data, ML models constantly get updated in practice, which might render previously generated recourses invalid and diminish end-users trust in our algorithmic framework. To address this problem, we propose RoCourseNet, a training framework that jointly optimizes for predictions and recourses that are robust to future data shifts. We have three main contributions: (i) We propose a novel \emph{virtual data shift (VDS)} algorithm to find worst-case shifted ML models by explicitly considering the worst-case data shift in the training dataset. (ii) We leverage adversarial training to solve a novel tri-level optimization problem inside RoCourseNet, which simultaneously generates predictions and corresponding robust recourses. (iii) Finally, we evaluate RoCourseNet's performance on three real-world datasets and show that RoCourseNet outperforms state-of-the-art baselines by $\sim$10\% in generating robust CF explanations.

Inducing Meaningful Units from Character Sequences with Dynamic Capacity Slot Attention

Melika Behjati,James Henderson

Characters do not convey meaning, but sequences of characters do. We propose an unsupervised distributional method to learn the abstract meaning-bearing units in a sequence of characters. Rather than segmenting the sequence, our Dynamic Capacity Slot Attention model discovers continuous representations of the \textit{objects} in the sequence, extending an architecture for object discovery in images. We train our model on different languages and evaluate the quality of the obtained representations with forward and reverse probing classifiers. These experiments show that our model succeeds in discovering units which are similar to those proposed previously in form, content and level of abstraction, and which show promise for capturing meaningful information at a higher level of abstraction.

****

In-context Reinforcement Learning with Algorithm Distillation

Michael Laskin,Luyu Wang,Junhyuk Oh,Emilio Parisotto,Stephen Spencer,Richie Steigerwald,DJ Strouse,Steven Stenberg Hansen,Angelos Filos,Ethan Brooks,maxime gazeau,Himanshu Sahni,Satinder Singh,Volodymyr Mnih

We propose Algorithm Distillation (AD), a method for distilling reinforcement learning (RL) algorithms into neural networks by modeling their training histories with a causal sequence model. Algorithm Distillation treats learning to reinforcement learn as an across-episode sequential prediction problem. A dataset of learning histories is generated by a source RL algorithm, and then a causal transformer is trained by autoregressively predicting actions given their preceding learning histories as context. Unlike sequential policy prediction architectures that distill post-learning or expert sequences, AD is able to improve its policy entirely in-context without updating its network parameters. We demonstrate that AD can reinforcement learn in-context in a variety of environments with sparse rewards, combinatorial task structure, and pixel-based observations, and find that AD learns a more data-efficient RL algorithm than the one that generated the source data.

Computing all Optimal Partial Transports

Abhijeet Phatak,Sharath Raghvendra,CHITTARANJAN TRIPATHY,Kaiyi Zhang

We consider the classical version of the optimal partial transport problem. Let

μ (with a mass of U) and ν (with a mass of S) be two discrete mass distributions with $S \le U$ and let n be the total number of points in the supports of μ and ν. For a parameter $\alpha \in [0,S]$, consider the minimum-cost transport plan σ_α that transports a mass of α from ν to μ. An \emph{OT-profile} captures the behavior of the cost of σ_α as α varies from 0 to S. There is only limited work on OT-profile and its mathematical properties (see~\cite{figalli2010optimal}). In this paper, we present a novel framework to analyze the properties of the OT-profile and also present an algorithm to compute it. When μ and ν are discrete mass distributions, we show that the OT-profile is a piecewise-linear non-decreasing convex function. Let K be the combinatorial complexity of this function, i.e., the number of line segments required to represent the OT-profile. Our exact algorithm computes the OT-profile in $\tilde{O}(n^2K)$ time. Given $\delta > 0$, we also show that the algorithm by ~\cite{lahn2019graph} can be used to δ-approximate the OT-profile in $O(n^2/\delta + n/\delta^2)$ time. This approximation is a piecewise-linear function of a combinatorial complexity of $O(1/\delta)$.

An OT-profile is arguably more valuable than the OT-cost itself and can be used within applications. Under a reasonable assumption of outliers, we also show that the first derivative of the OT-profile sees a noticeable rise before any of the mass from outliers is transported. By using this property, we get an improved prediction accuracy for an outlier detection experiment. We also use this property to predict labels and estimate the class priors within PU-Learning experiments. Both these experiments are conducted on real datasets.

Towards Federated Learning of Deep Graph Neural Networks

Zhihua Tian,Yuan Ding,Rui Zhang,Jian Liu,Kui Ren

Graph neural networks (GNNs) learn node representations by recursively aggregating neighborhood information on graph data. However, in the federated setting, data samples (nodes) located in different clients may be connected to each other, leading to huge information loss to the training method.

Existing federated graph learning frameworks solve such a problem by generating missing neighbors or sending information across clients directly. None are suitable for training deep GNNs, which require a more expansive receptive field and higher communication costs.

In this work, we introduce a novel framework named Fed^2GNN for federated graph learning of deep GNNs via reconstructing neighborhood information of nodes. Specifically, we design a graph structure named rooted tree. The node embedding obtained by encoding on the rooted tree is the same as that obtained by encoding on the induced subgraph surrounding the node, which allows us to reconstruct the neighborhood information by building the rooted tree of the node. An encoder-decoder framework is then proposed, wherein we first encode missing neighbor information and then decode it to build the rooted tree.

Extensive experiments on real-world network datasets show the effectiveness of our framework for training deep GNNs while also achieving better performance for training shadow GNN models

CounterNet: End-to-End Training of Prediction Aware Counterfactual Explanations

Hangzhi Guo,Thanh Hong Nguyen,Amulya Yadav

Counterfactual (or CF) explanations are a type of local explanations for Machine Learning (ML) model predictions, which offer a contrastive case as an explanation by finding the smallest changes (in feature space) to the input data point, which will lead to a different prediction by the ML model. Existing CF explanation techniques suffer from two major limitations: (i) all of them are post-hoc methods designed for use with proprietary ML models --- as a result, their procedure for generating CF explanations is uninformed by the training of the ML model, which leads to misalignment between model predictions and explanations; and (ii) most of them rely on solving separate time-intensive optimization problems to find CF explanations for each input data point (which negatively impacts their runtime). This work makes a novel departure from the prevalent post-hoc paradigm (

of generating CF explanations) by presenting CounterNet, an end-to-end learning framework which integrates predictive model training and the generation of counterfactual (CF) explanations into a single pipeline. We adopt a block-wise coordinate descent procedure which helps in effectively training CounterNet's network. Our extensive experiments on multiple real-world datasets show that CounterNet generates high-quality predictions, and consistently achieves 100% CF validity and very low proximity scores (thereby achieving a well-balanced cost-invalidity trade-off) for any new input instance, and runs 3X faster than existing state-of-the-art baselines.

SmilesFormer: Language Model for Molecular Design

Joshua Owoyemi,Nazim Medzhidov

The objective of drug discovery is to find novel compounds with desirable chemical properties. Generative models have been utilized to sample molecules at the intersection of multiple property constraints. In this paper we pose molecular design as a language modeling problem where the model implicitly learns the vocabulary and composition of valid molecules, hence it is able to generate new molecules of interest. We present SmilesFormer, a Transformer-based model which is able to encode molecules, molecule fragments, and fragment compositions as latent variables, which are in turn decoded to stochastically generate novel molecules. This is achieved by fragmenting the molecules into smaller combinatorial groups, then learning the mapping between the input fragments and valid SMILES sequences.

The model is able to optimize molecular properties through a stochastic latent space traversal technique. This technique systematically searches the encoded latent space to find latent vectors that are able to produce molecules to meet the multi-property objective. The model was validated through various de novo molecular design tasks, achieving state-of-the-art performances when compared to previous methods. Furthermore, we used the proposed method to demonstrate a drug rediscovery pipeline for Donepezil, a known Acetylcholinesterase Inhibitor.

AE-FLOW: Autoencoders with Normalizing Flows for Medical Images Anomaly Detection

Yuzhong Zhao,Qiaoqiao Ding,Xiaoqun Zhang

Anomaly detection from medical images is an important task for clinical screening and diagnosis. In general, a large dataset of normal images are available while only few abnormal images can be collected in clinical practice. By mimicking the diagnosis process of radiologists, we attempt to tackle this problem by learning a tractable distribution of normal images and identify anomalies by differentiating the original image and the reconstructed normal image. More specifically, we propose a normalizing flow-based autoencoder for an efficient and tractable representation of normal medical images. The anomaly score consists of the likelihood originated from the normalizing flow and the reconstruction error of the autoencoder, which allows to identify the abnormality and provide an interpretability at both image and pixel levels. Experimental evaluation on two medical images datasets showed that the proposed model outperformed the other approaches by a large margin, which validated the effectiveness and robustness of the proposed method.

****

Learning a Domain-Agnostic Policy through Adversarial Representation Matching for Cross-Domain Policy Transfer

Hayato Watahiki,Ryo Iwase,Ryosuke Unno,Yoshimasa Tsuruoka

The low transferability of learned policies is one of the most critical problems limiting the applicability of learning-based solutions to decision-making tasks. In this paper, we present a way to align latent representations of states and actions between different domains by optimizing an adversarial objective. We train two models, a policy and a domain discriminator, with unpaired trajectories of proxy tasks through behavioral cloning as well as adversarial training. After the latent representations are aligned between domains, a domain-agnostic part o

f the policy trained with any method in the source domain can be immediately transferred to the target domain in a zero-shot manner. We empirically show that our simple approach achieves comparable performance to the latest methods in zero-shot cross-domain transfer. We also observe that our method performs better than other approaches in transfer between domains with different complexities, whereas other methods fail catastrophically.
****

A Self-Attention Ansatz for Ab-initio Quantum Chemistry
Ingrid von Glehn,James S Spencer,David Pfau

We present a novel neural network architecture using self-attention, the Wavefunction Transformer (PsiFormer), which can be used as an approximation (or "Ansatz") for solving the many-electron Schrödinger equation, the fundamental equation for quantum chemistry and material science. This equation can be solved *from first principles*, requiring no external training data. In recent years, deep neural networks like the FermiNet and PauliNet have been used to significantly improve the accuracy of these first-principle calculations, but they lack an attention-like mechanism for gating interactions between electrons. Here we show that the PsiFormer can be used as a drop-in replacement for these other neural networks, often dramatically improving the accuracy of the calculations. On larger molecules especially, the ground state energy can be improved by dozens of kcal/mol, a qualitative leap over previous methods. This demonstrates that self-attention networks can learn complex quantum mechanical correlations between electrons, and are a promising route to reaching unprecedented accuracy in chemical calculations on larger systems.

Probabilistically Robust Recourse: Navigating the Trade-offs between Costs and Robustness in Algorithmic Recourse
Martin Pawelczyk,Teresa Datta,Johan Van den Heuvel,Gjergji Kasneci,Himabindu Lakkaraju

As machine learning models are increasingly being employed to make consequential decisions in real-world settings, it becomes critical to ensure that individuals who are adversely impacted (e.g., loan denied) by the predictions of these models are provided with a means for recourse. While several approaches have been proposed to construct recourses for affected individuals, the recourses output by these methods either achieve low costs (i.e., ease-of-implementation) or robustness to small perturbations (i.e., noisy implementations of recourses), but not both due to the inherent trade-offs between the recourse costs and robustness. Furthermore, prior approaches do not provide end users with any agency over navigating the aforementioned trade-offs. In this work, we address the above challenges by proposing the first algorithmic framework which enables users to effectively manage the recourse cost vs. robustness trade-offs. More specifically, our framework Probabilistically ROBust rEcourse (PROBE) lets users choose the probability with which a recourse could get invalidated (recourse invalidation rate) if small changes are made to the recourse i.e., the recourse is implemented somewhat noisily. To this end, we propose a novel objective function which simultaneously minimizes the gap between the achieved (resulting) and desired recourse invalidation rates, minimizes recourse costs, and also ensures that the resulting recourse achieves a positive model prediction. We develop novel theoretical results to characterize the recourse invalidation rates corresponding to any given instance w.r.t. different classes of underlying models (e.g., linear models, tree based models etc.), and leverage these results to efficiently optimize the proposed objective. Experimental evaluation with multiple real world datasets demonstrates the efficacy of the proposed framework.

How robust is unsupervised representation learning to distribution shift?
Yuge Shi,Imant Daunhawer,Julia E Vogt,Philip Torr,Amartya Sanyal

The robustness of machine learning algorithms to distributions shift is primarily discussed in the context of supervised learning (SL). As such, there is a lack of insight on the robustness of the representations learned from unsupervised methods, such as self-supervised learning (SSL) and auto-encoder based algorithms

(AE), to distribution shift. We posit that the input-driven objectives of unsupervised algorithms lead to representations that are more robust to distribution shift than the target-driven objective of SL. We verify this by extensively evaluating the performance of SSL and AE on both synthetic and realistic distribution shift datasets. Following observations that the linear layer used for classification itself can be susceptible to spurious correlations, we evaluate the representations using a linear head trained on a small amount of out-of-distribution (OOD) data, to isolate the robustness of the learned representations from that of the linear head. We also develop “controllable” versions of existing realistic domain generalisation datasets with adjustable degrees of distribution shifts. This allows us to study the robustness of different learning algorithms under versatile yet realistic distribution shift conditions. Our experiments show that representations learned from unsupervised learning algorithms generalise better than SL under a wide variety of extreme as well as realistic distribution shifts.

Autoregressive Generative Modeling with Noise Conditional Maximum Likelihood Estimation

Henry Li,Yuval Kluger

We introduce a simple modification to the standard maximum likelihood estimation (MLE) framework. Rather than maximizing a single unconditional likelihood of the data under the model, we maximize a family of \textit{noise conditional} likelihoods consisting of the data perturbed by a continuum of noise levels. We find that models trained this way are more robust to noise, obtain higher test likelihoods, and generate higher quality images. They can also be sampled from via a novel score-based sampling scheme which combats the classical \textit{covariate shift} problem that occurs during sample generation in autoregressive models. Applying this augmentation to autoregressive image models, we obtain 3.32 bits per dimension on the ImageNet 64x64 dataset, and substantially improve the quality of generated samples in terms of the Frechet Inception distance (FID) --- from 37.50 to 12.09 on the CIFAR-10 dataset.

Multi-Behavior Dynamic Contrastive Learning for Recommendation

Wei Wei,Chao Huang,Lianghao Xia,Yanwei Yu,Chuxu Zhang

Dynamic behavior modeling has become an essential task in personalized recommender systems for learning the time-evolving user preference in online platforms. However, most next-item recommendation methods follow the single type behavior learning manner, which notably limits their user representation performance in reality, since the user-item relationships are often multi-typed in real-life applications (e.g., click, tag-as-favorite, review and purchase). To offer better recommendations, this work proposes Evolving Graph Contrastive Memory Network (EGCM) to model dynamic interaction heterogeneity for multi-behavior sequential recommendation. Specifically, we first develop a multi-behavior graph encoder to capture the short-term preference heterogeneity, and preserve the dedicated relation semantics for different types of user-item interactions. In addition, we design a dynamic cross-relational memory network, empowering EGCM to distill the long-term multi-behavior preference of users and the underlying evolving cross-type behavior dependencies over time. To enhance the user representation with multi-behavior commonality and diversity, we design a multi-behavior contrastive learning paradigm with heterogeneous short- and long-term interest modeling. Experiments on several real-world datasets show the superiority of our recommender system over various state-of-the-art baselines.

Analyzing diffusion as serial reproduction

Raja Marjieh,Ilia Sucholutsky,Thomas A Langlois,Nori Jacoby,Thomas L. Griffiths

Diffusion models are a class of generative models that learn to synthesize samples by inverting a diffusion process that gradually maps data into noise. While these models have enjoyed great success recently, a full theoretical understanding of their observed properties is still lacking, in particular, their weak sensi tivity to the choice of noise family and the role of adequate scheduling of noise levels for good synthesis. By identifying a correspondence between diffusion models and a well-known paradigm in cognitive science known as serial reproduction, whereby human agents iteratively observe and reproduce stimuli from memory, we show how the aforementioned properties of diffusion models can be explained as a natural consequence of this correspondence. We then complement our theoretical analysis with simulations that exhibit these key features. Our work highlights how classic paradigms in cognitive science can shed light on state-of-the-art machine learning problems.

****

Pseudo-label Training and Model Inertia in Neural Machine Translation

Benjamin Hsu,Anna Currey,Xing Niu,Maria Nadejde,Georgiana Dinu

Like many other machine learning applications, neural machine translation (NMT) benefits from over-parameterized deep neural models. However, these models have been observed to be brittle: NMT model predictions are sensitive to small input changes and can show significant variation across re-training or incremental model updates. This work studies a frequently used method in NMT, pseudo-label training (PLT), which is common to the related techniques of forward-translation (or self-training) and sequence-level knowledge distillation. While the effect of PLT on quality is well-documented, we highlight a lesser-known effect: PLT can enhance a model's stability to model updates and input perturbations, a set of properties we call \textit{model inertia}. We study inertia effects under different training settings and we identify distribution simplification as a mechanism behind the observed results.

Adaptive Smoothing Gradient Learning for Spiking Neural Networks

Ziming Wang,Runhao Jiang,Shuang Lian,Rui Yan,Huajin Tang

Spiking neural networks (SNNs) with biologically inspired spatio-temporal dynamics show higher energy efficiency on neuromorphic architectures. Error backpropagation in SNNs is prohibited by the all-or-none nature of spikes. The existing solution circumvents this problem by a relaxation on the gradient calculation using a continuous function with a constant relaxation degree, so-called surrogate gradient learning. Nevertheless, such solution introduces additional smoothness error on spiking firing which leads to the gradients being estimated inaccurately. Thus, how to adjust the relaxation degree adaptively and eliminate smoothness error progressively is crucial. Here, we propose a methodology such that training a prototype neural network will evolve into training an SNN gradually by fusing the learnable relaxation degree into the network with random spike noise. In this way, the network learns adaptively the accurate gradients of loss landscape in SNNs. The theoretical analysis further shows optimization on such a noisy network could be evolved into optimization on the embedded SNN with shared weights progressively. Moreover, we conduct extensive experiments on static images, dynamic event streams, speech, and instrumental sounds. The results show the proposed method achieves state-of-the-art performance across all the datasets with remarkable robustness on different relaxation degrees.

Going Beyond Approximation: Encoding Constraints for Explainable Multi-hop Inference via Differentiable Combinatorial Solvers

Mokanarangan Thayaparan,Marco Valentino,Andre Freitas

Integer Linear Programming (ILP) provides a viable mechanism to encode explicit and controllable assumptions about explainable multi-hop inference with natural language. However, an ILP formulation is non-differentiable and cannot be integrated into broader deep learning architectures. Recently, Thayaparan et al. (2021a) proposed a novel methodology to integrate ILP with Transformers to achieve end-to-end differentiability for complex multi-hop inference. While this hybrid framework has been demonstrated to deliver better answer and explanation selection than transformer-based and existing ILP solvers, the neuro-symbolic integration still relies on a convex relaxation of the ILP formulation, which can produce sub-optimal solutions. To improve these limitations, we propose Diff-Comb Explainer, a novel neuro-symbolic architecture based on Differentiable BlackBox Combina torial solvers (DBCS) (Pogan■i■ et al., 2019). Unlike existing differentiable solvers, the presented model does not require the transformation and relaxation of the explicit semantic constraints, allowing for direct and more efficient integration of ILP formulations. Diff-Comb Explainer demonstrates improved accuracy and explainability over non-differentiable solvers, Transformers and existing differentiable constraint-based multi-hop inference frameworks.

Robust and accelerated single-spike spiking neural network training with applicability to challenging temporal tasks

Luke Taylor,Andrew J King,Nicol Spencer Harper

Spiking neural networks (SNNs), particularly the single-spike variant in which neurons spike at most once, are considerably more energy efficient than standard artificial neural networks (ANNs). However, single-spike SSNs are difficult to train due to their dynamic and non-differentiable nature, where current solutions are either slow or suffer from training instabilities. These networks have also been critiqued for their limited computational applicability such as being unsuitable for time-series datasets. We propose a new model for training single-spike SNNs which mitigates the aforementioned training issues and obtains competitive results across various image and neuromorphic datasets, with up to a $13.98\times$ training speedup and up to an 81% reduction in spikes compared to the multi-spike SNN. Notably, our model performs on par with multi-spike SNNs in challenging tasks involving neuromorphic time-series datasets, demonstrating a broader computational role for single-spike SNNs than previously believed.

A NEW PARADIGM FOR CROSS-MODALITY PERSON RE-IDENTIFICATION

Yumeng Wang,Feng Yang,Tongkai Xu,Yanze Zhu

Visible and infrared Person Re-identification(ReID) is still very challenging on account of few cross-modality dataset and large inter-modality variation. Most existing cross-modality ReID methods have trouble eliminating cross-modality discrepancy resulting from the heterogeneous images. In this paper, we present an effective framework and build a large benchmark, named NPU-ReID. To this end, we propose a dual-path fusion network and taking transformer as the smallest feature extraction unit. To expand cross-modality sample diversity, we propose a modality augmentation strategy to generate semi-modality pedestrian images by exchanging certain patch and the main innovation is that the cross-modality gap can be indirectly minimized by reducing the variance of semi-modality and infrared or visible modality. Moreover, in order to make the traditional triplet loss more suitable for cross-modal matching tasks, multi-masking triplet loss is a targeted design for optimizing the relative distance between anchor and positive/negative samples pairs from cross-modality, especially constraining the distance between simple and hard positive samples. Experimental results demonstrate that our proposed method achieves superior performance than other methods on SYSU-MM01, RegDB and our proposed NPU-ReID dataset, especially on the RegDB dataset with significant improvement of 6.81$\%$ in rank1 and 9.65$\%$ in mAP.

Causal Mean Field Multi-Agent Reinforcement Learning

Hao Ma,Zhiqiang Pu,Yi Pan,Boyin Liu,Min Chen,Shijie Wang

Scalability remains a challenge in multi-agent reinforcement learning and is currently under active research. However, existing works lack the ability to identify the essential interaction under the non-stationary environment. We propose causal mean field Q-learning (CMFQ) to address this problem. It has the advantage of MFQ, which can compress the space size dramatically. Besides, it is ever more robust toward the non-stationary caused by increasing agents. We enable agents to identify which ally or opponent is more crucial by asking "what if" with the help of the structural causal model (SCM), then pay more attention to more crucial ones. We test CMFQ in mixed cooperative-competitive and cooperative games, which verify our method's scalability performance.

****

Hidden Markov Mixture of Gaussian Process Functional Regression: Utilizing Multi-Scale Structure for Time-Series Forecasting

Tao Li,Jinwen Ma

The mixture of Gaussian process functional regressions (GPFRs) assumes that there are a batch of time-series or sample curves which are generated by independent random processes with different temporal structures. However, in the real situations, these structures are actually transferred in a random manner from a long time scale. Therefore, the assumption of independent curves is not true in practice. In order to get rid of this limitation, we propose the hidden Markov based GPFR mixture model (HM-GPFR) by describing these curves with both fine and coarse level temporal structures. Specifically, the temporal structure is described by the Gaussian process model at the fine level and hidden Markov process at the coarse level. The whole model can be regarded as a random process with state switching dynamics. To further enhance the robustness of the model, we also give a priori to the model parameters and develop Bayesian hidden Markov based GPFR mixture model (BHM-GPFR). Experimental results demonstrate that the proposed methods have both high prediction accuracy and good interpretability.

****

HyperDeepONet: learning operator with complex target function space using the limited resources via hypernetwork

Jae Yong Lee,SungWoong CHO,Hyung Ju Hwang

Fast and accurate predictions for complex physical dynamics are a big challenge across various applications. Real-time prediction on resource-constrained hardware is even more crucial in the real-world problems. The deep operator network (DeepONet) has recently been proposed as a framework for learning nonlinear mappings between function spaces. However, the DeepONet requires many parameters and has a high computational cost when learning operators, particularly those with complex (discontinuous or non-smooth) target functions. In this study, we propose HyperDeepONet, which uses the expressive power of the hypernetwork to enable learning of a complex operator with smaller set of parameters. The DeepONet and its variant models can be thought of as a method of injecting the input function information into the target function. From this perspective, these models can be viewed as a special case of HyperDeepONet. We analyze the complexity of DeepONet and conclude that HyperDeepONet needs relatively lower complexity to obtain the desired accuracy for operator learning. HyperDeepONet was successfully applied to various operator learning problems using low computational resources compared to other benchmarks.

Edge Guided GANs with Contrastive Learning for Semantic Image Synthesis

Hao Tang,XIAOJUAN QI,Guolei Sun,Dan Xu,Nicu Sebe,Radu Timofte,Luc Van Gool

We propose a novel \underline{e}dge guided \underline{g}enerative \underline{a}dversarial \underline{n}etwork with \underline{c}ontrastive learning (ECGAN) for the challenging semantic image synthesis task. Although considerable improvement has been achieved, the quality of synthesized images is far from satisfactory due to three largely unresolved challenges. 1) The semantic labels do not provide detailed structural information, making it difficult to synthesize local details and structures. 2) The widely adopted CNN operations such as convolution, down-sampling, and normalization usually cause spatial resolution loss and thus cannot fully preserve the original semantic information, leading to semantically inconsistent results (e.g., missing small objects). 3) Existing semantic image synthesis methods focus on modeling ``local'' semantic information from a single input semantic layout. However, they ignore ``global'' semantic information of multiple input semantic layouts, i.e., semantic cross-relations between pixels across different input layouts. To tackle 1), we propose to use edge as an intermediate representation which is further adopted to guide image generation via a proposed attention guided edge transfer module. Edge information is produced by a convolutional generator and introduces detailed structure information. To tackle 2), we design an effective module to selectively highlight class-dependent feature maps according to the original semantic layout to preserve the semantic information. To tackle 3), inspired by current methods in contrastive learning, we propose a novel contrastive learning method, which aims to enforce pixel embeddings belonging to the same semantic class to generate more similar image content than those from different classes. Doing so can capture more semantic relations by explicitly exploring the structures of labeled pixels from multiple input semantic layouts. Experiments on three challenging datasets show that our ECGAN achieves significantly better results than state-of-the-art methods.

Towards Reliable Link Prediction with Robust Graph Information Bottleneck

Zhanke Zhou,Jiangchao Yao,Jiaxu Liu,Xiawei Guo,LI He,Shuo Yuan,quanming yao,Liang Wang,Bo Han

Link prediction on graphs has achieved great success with the rise of deep graph learning. However, the potential robustness under the edge noise is less investigated. We reveal that the inherent edge noise that naturally perturbs both input topology and target label leads to severe performance degradation and representation collapse. Here, we propose an information-theory guided principle, Robust Graph Information Bottleneck (RGIB), to extract reliable supervision signals and avoid representation collapse. Different from the general information bottleneck, RGIB decouples and balances the mutual dependence among graph topology, edge label, and representation, building a new learning objective for robust representation. We also provide two implementations, RGIB-SSL and RGIB-REP, that benefit from different methodologies, i.e., self-supervised learning and data reparametrization, for indirect and direct data denoising, respectively. Extensive experiments on six benchmarks with various scenarios verify the effectiveness of the proposed RGIB.

****

Enforcing Delayed-Impact Fairness Guarantees

Aline Weber,Blossom Metevier,Yuriy Brun,Philip S. Thomas,Bruno Castro da Silva

Recent research has shown that seemingly fair machine learning models, when used to inform decisions that have an impact on people's lives or well-being (e.g., applications involving education, employment, and lending), can inadvertently increase social inequality in the long term. Existing fairness-aware algorithms consider static fairness constraints, such as equal opportunity or demographic parity, but enforcing constraints of this type may result in models that have a negative long-term impact on disadvantaged individuals and communities. We introduce ELF (Enforcing Long-term Fairness), the first classification algorithm that provides high-confidence fairness guarantees in terms of long-term, or delayed, impact. Importantly, ELF solves the open problem of providing such guarantees based only on historical data that includes observations of delayed impact. Prior methods, by contrast, require prior knowledge (or an estimate) of analytical models describing the relationship between a classifier's predictions and their corresponding delayed impact. We prove that ELF satisfies delayed-impact fairness constraints with high confidence and that it is guaranteed to identify a fair solution, if one exists, given sufficient data. We show empirically, using real-life data, that ELF can successfully mitigate long-term unfairness with high confidence.

****

Affinity-Aware Graph Networks

Ameya Velingker,Ali Kemal Sinop,Ira Ktena,Petar Veli■kovi■,Sreenivas Gollapudi

Graph Neural Networks (GNNs) have emerged as a powerful technique for learning on relational data. Owing to the relatively limited number of message passing steps they perform—and hence a smaller receptive field—there has been significant interest in improving their expressivity by incorporating structural aspects of the underlying graph. In this paper, we explore the use of affinity measures as features in graph neural networks, in particular measures arising from random walks, including effective resistance, hitting and commute times. We propose message passing networks based on these features and evaluate their performance on a variety of node and graph property prediction tasks.

****

Towards the Detection of Diffusion Model Deepfakes

Jonas Ricker,Simon Damm,Thorsten Holz,Asja Fischer

Diffusion models (DMs) have recently emerged as a promising method in image synt hesis. They have surpassed generative adversarial networks (GANs) in both diversity and quality, and have achieved impressive results in text-to-image modeling. However, to date, only little attention has been paid to the detection of DM-generated images, which is critical to prevent adverse impacts on our society. While prior works have shown that GAN-generated images can be reliably detected using automated methods, it is unclear whether the same methods are effective against DMs. In this work, we address this challenge and take a first look at detecting DM-generated images. We approach the problem from two different angles: First, we evaluate the performance of state-of-the-art detectors on a variety of DMs. Second, we analyze DM-generated images in the frequency domain and study different factors that influence the spectral properties of these images. Most importantly, we demonstrate that GANs and DMs produce images with different characteristics, which requires adaptation of existing classifiers to ensure reliable detection. We believe this work provides the foundation and starting point for further research to detect DM deepfakes effectively.

Global-Scale Species Mapping From Crowdsourced Data

Elijah Cole,Grant Van Horn,Alexander Shepard,Patrick Leary,Scott Loarie,Pietro Perona,Oisin Mac Aodha

Estimating the geographical range of a species from in situ observational data is a challenging and important geospatial prediction problem. Given a set of locations indicating where a species has been observed, the goal is to learn a model that can predict how likely it is for the species to be present at any other location. While this is a well-studied problem, traditional approaches are unable to take advantage of more recently available large-scale datasets that cover many locations and species. We propose a new approach that jointly estimates the geographical ranges of tens of thousands of different species simultaneously. We develop a series of benchmark evaluation tasks that measure different aspects of the species range and spatial representation learning problems. We show that our approach scales both in terms of amount of training data and species, where adding more data enables the models to learn better spatial representations that generalize to other species. Despite being only trained on weakly supervised crowdsourced data, our models can approach the predictions of current expert-developed gold standard models.

CANIFE: Crafting Canaries for Empirical Privacy Measurement in Federated Learning

Samuel Maddock,Alexandre Sablayrolles,Pierre Stock

Federated Learning (FL) is a setting for training machine learning models in distributed environments where the clients do not share their raw data but instead send model updates to a server. However, model updates can be subject to attacks and leak private information. Differential Privacy (DP) is a leading mitigation strategy which involves adding noise to clipped model updates, trading off performance for strong theoretical privacy guarantees. Previous work has shown that the threat model of DP is conservative and that the obtained guarantees may be vacuous or may overestimate information leakage in practice. In this paper, we aim to achieve a tighter measurement of the model exposure by considering a realistic threat model. We propose a novel method, CANIFE, that uses canaries - carefully crafted samples by a strong adversary to evaluate the empirical privacy of a training round. We apply this attack to vision models trained on CIFAR-10 and CelebA and to language models trained on Sent140 and Shakespeare. In particular, in realistic FL scenarios, we demonstrate that the empirical per-round epsilon obtained with CANIFE is 4 -- 5$\times$ lower than the theoretical bound.

Multivariate Time Series Forecasting By Graph Attention Networks With Theoretical Guarantees

Zhi Zhang,Weijian Li,Han Liu

Multivariate time series forecasting (MTSF) aims to predict future values of multiple variables based on past values of multivariate time series, and has been applied in fields including traffic flow prediction, stock price forecasting, and anomaly detection. Capturing the inter-dependencies among variables poses one significant challenge to MTSF. Several methods that model the correlations between variables with an aim to improve the test prediction accuracy have been considered in recent works, however, none of them have theoretical guarantees. In this paper, we developed a new norm-bounded graph attention network (GAT) for MTSF by upper-bounding the Frobenius norm of weights in each layer of the GAT model to achieve optimal performance.

Under optimal parameters, we theoretically show that our model can achieve a generalization error bound which is expressed as products of Frobenius norm of weight in each layer and the numbers of neighbors and attention heads, while the latter is represented as polynomial terms with the degree as the number of layers.

Empirically, we investigate the impact of different components of GAT models on the performance of MTSF.

Our experiment also verifies our theoretical findings. Empirically, we also observe that the generalization performance of our method is dependent on the number of attention heads, the number of neighbors, the scales (norms) of the weight matrices, the scale of the input features, and the number of layers.

Our method provides novel perspectives for improving the generation performance for MTSF, and our theoretical guarantees give substantial implications for designing attention-based methods for MTSF.

Maximal Correlation-Based Post-Nonlinear Learning for Bivariate Causal Discovery

Tianjian Zhang,Feng Yin,Zhi-Quan Luo

Bivariate causal discovery aims to determine the causal relationship between two random variables from passive observational data (as intervention is not affordable in many scientific fields), which is considered fundamental and challenging. Designing algorithms based on the post-nonlinear (PNL) model has aroused much attention for its generality. However, the state-of-the-art (SOTA) PNL-based algorithms involve highly non-convex objectives for neural network training, which are time-consuming and unable to produce meaningful solutions with finite samples. In this paper, we propose a novel method that incorporates maximal correlation into the PNL model learning (short as MC-PNL) such that the underlying nonlinearities can be accurately recovered. Owing to the benign structure of our objective function when modeling the nonlinearities with linear combinations of random Fourier features, the target optimization problem can be solved rather efficiently and rapidly via the block coordinate descent. We also compare the MC-PNL with SOTA methods on the downstream synthetic and real causal discovery tasks to show its superiority in time and accuracy. Our code is available at https://anonymous.4open.science/r/MC-PNL-E446/.

A View From Somewhere: Human-Centric Face Representations

Jerone Theodore Alexander Andrews,Przemyslaw Joniak,Alice Xiang

Few datasets contain self-identified demographic information, inferring demographic information risks introducing additional biases, and collecting and storing data on sensitive attributes can carry legal risks. Besides, categorical demographic labels do not necessarily capture all the relevant dimensions of human diversity. We propose to implicitly learn a set of continuous face-varying dimensions, without ever asking an annotator to explicitly categorize a person. We uncover the dimensions by learning on A View From Somewhere (AVFS) dataset of 638,180 human judgments of face similarity. We demonstrate the utility of our learned embedding space for predicting face similarity judgments, collecting continuous face attribute values, attribute classification, and comparative dataset diversity auditing. Moreover, using a novel conditional framework, we show that an annotator's demographics influences the \emph{importance} they place on different attributes when judging similarity, underscoring the \emph{need} for diverse annotator groups to avoid biases. Data and code are available at \url{https://github.com/SonyAI/a_view_from_somewhere}.

Identifiability Results for Multimodal Contrastive Learning

Imant Daunhawer,Alice Bizeul,Emanuele Palumbo,Alexander Marx,Julia E Vogt

Contrastive learning is a cornerstone underlying recent progress in multi-view and multimodal learning, e.g., in representation learning with image/caption pairs. While its effectiveness is not yet fully understood, a line of recent work reveals that contrastive learning can invert the data generating process and recover ground truth latent factors shared between views. In this work, we present new identifiability results for multimodal contrastive learning, showing that it is possible to recover shared factors in a more general setup than the multi-view setting studied previously. Specifically, we distinguish between the multi-view setting with one generative mechanism (e.g., multiple cameras of the same type) and the multimodal setting that is characterized by distinct mechanisms (e.g., cameras and microphones). Our work generalizes previous identifiability results by redefining the generative process in terms of distinct mechanisms with modality-specific latent variables. We prove that contrastive learning can block-identify latent factors shared between modalities, even when there are nontrivial dependencies between factors. We empirically verify our identifiability results with numerical simulations and corroborate our findings on a complex multimodal dataset of image/text pairs. Zooming out, our work provides a theoretical basis for multimodal representation learning and explains in which settings multimodal contrastive learning can be effective in practice.

Federated Learning as Variational Inference: A Scalable Expectation Propagation Approach

Han Guo,Philip Greengard,Hongyi Wang,Andrew Gelman,Yoon Kim,Eric Xing

The canonical formulation of federated learning treats it as a distributed optimization problem where the model parameters are optimized against a global loss function that decomposes across client loss functions. A recent alternative formulation instead treats federated learning as a distributed inference problem, where the goal is to infer a global posterior from partitioned client data (Al-Shedivat et al., 2021). This paper extends the inference view and describes a variational inference formulation of federated learning where the goal is to find a global variational posterior that well-approximates the true posterior. This naturally motivates an expectation propagation approach to federated learning (FedEP), where approximations to the global posterior are iteratively refined through probabilistic message-passing between the central server and the clients. We conduct an extensive empirical study across various algorithmic considerations and describe practical strategies for scaling up expectation propagation to the modern federated setting. We apply FedEP on standard federated learning benchmarks and find that it outperforms strong baselines in terms of both convergence speed and accuracy.

Latent Graph Inference using Product Manifolds

Haitz Sáez de Ocáriz Borde,Anees Kazi,Federico Barbero,Pietro Lio

Graph Neural Networks usually rely on the assumption that the graph topology is available to the network as well as optimal for the downstream task. Latent graph inference allows models to dynamically learn the intrinsic graph structure of problems where the connectivity patterns of data may not be directly accessible. In this work, we generalize the discrete Differentiable Graph Module (dDGM) for latent graph learning. The original dDGM architecture used the Euclidean plane to encode latent features based on which the latent graphs were generated. By incorporating Riemannian geometry into the model and generating more complex embedding spaces, we can improve the performance of the latent graph inference system. In particular, we propose a computationally tractable approach to produce product manifolds of constant curvature model spaces that can encode latent features of varying structure. The latent representations mapped onto the inferred product manifold are used to compute richer similarity measures that are leveraged by the latent graph learning model to obtain optimized latent graphs. Moreover, the curvature of the product manifold is learned during training alongside the rest of the network parameters and based on the downstream task, rather than it being a static embedding space. Our novel approach is tested on a wide range of dat asets, and outperforms the original dDGM model.

UNICORN: A Unified Backdoor Trigger Inversion Framework

Zhenting Wang,Kai Mei,Juan Zhai,Shiqing Ma

The backdoor attack, where the adversary uses inputs stamped with triggers (e.g., a patch) to activate pre-planted malicious behaviors, is a severe threat to Deep Neural Network (DNN) models. Trigger inversion is an effective way of identifying backdoor models and understanding embedded adversarial behaviors. A challenge of trigger inversion is that there are many ways of constructing the trigger. Existing methods cannot generalize to various types of triggers by making certain assumptions or attack-specific constraints. The fundamental reason is that existing work does not formally define the trigger and the inversion problem. This work formally defines and analyzes the trigger and the inversion problem. Then, it proposes a unified framework to invert backdoor triggers based on the formalization of triggers and the identified inner behaviors of backdoor models from our analysis. Our prototype UNICORN is general and effective in inverting backdoor triggers in DNNs. The code can be found at https://github.com/RU-System-Software-and-Security/UNICORN.

DBA: Efficient Transformer with Dynamic Bilinear Low-Rank Attention

Bosheng Qin,Juncheng Li,Siliang Tang,Yueting Zhuang

Many studies have been conducted to improve the efficiency of the Transformer from quadric to linear over long sequence conditions. Among them, the low-rank-based methods aim to learn the projection matrices to compress the sequence length, thus achieving efficiency gain. However, the projection matrices are fixed once they have been learned, which compress the sequence length with dedicated coefficients for the tokens in the same position regardless of different sequences. Adopting such input-invariant low-rank projections ignores the fact that the most informative part of a sequence varies from sequence to sequence, thus failing to preserve the most useful information that lies in varied positions of different sequences. In addition, previous efficient Transformers only focus on the influence of sequence length while neglecting the effect of hidden state dimension to achieve further efficiency gain. To address the aforementioned problems, we present an efficient yet effective attention mechanism, namely the Dynamic Bilinear Low-Rank Attention (DBA), which compresses the sequence length by input-sensitive dynamic projection matrices and achieves linear time and space complexity by jointly optimizing the sequence length and hidden state dimension while maintaining state-of-the-art performance. Specifically, we first theoretically demonstrate that the sequence length can be compressed non-destructively from a novel perspective of the information theory, with the compression matrices dynamically determined by the input sequence. Furthermore, we show that the hidden state dimension can be approximated by extending the Johnson–Lindenstrauss lemma and achieves high-order small amount error, optimizing the attention in bilinear form. In addition, theoretical analysis shows that the DBA is proficient in capturing high-order relations in cross-attention problems. Experiments over tasks with diverse sequence length conditions show that the DBA achieves state-of-the-art performance compared with various strong baselines while maintaining less memory consumption with higher speed, demonstrating the effectiveness and efficiency of the DBA.

On the Robustness of Dataset Inference

Sebastian Szyller,Rui Zhang,Jian Liu,N Asokan

Machine learning (ML) models are costly to train as they can require a significant amount of data, computational resources and technical expertise. Thus, they constitute valuable intellectual property that needs protection from adversaries wanting to steal them. $\textit{Ownership verification}$ techniques allow the victims of model stealing attacks to demonstrate that a suspect model was in fact stolen from theirs.

Although a number of ownership verification techniques based on watermarking or fingerprinting have been proposed, most of them fall short either in terms of se curity guarantees (well-equipped adversaries can evade verification) or computational cost. A fingerprinting technique introduced at ICLR '21, $\textit{Dataset Inference}$ (DI), has been shown to offer better robustness and efficiency than prior methods.

The authors of DI provided a correctness proof for linear (suspect) models. However, in the same setting, we prove that DI suffers from high false positives (FPs) -- it can incorrectly identify an independent model trained with non-overlapping data from the same distribution as stolen. We further prove that DI also triggers FPs in realistic, non-linear suspect models. We then confirm empirically that DI leads to FPs, with high confidence.

Second, we show that DI also suffers from false negatives (FNs) -- an adversary can fool DI by regularising a stolen model's decision boundaries using adversarial training, thereby leading to an FN. To this end, we demonstrate that DI fails to identify a model adversarially trained from a stolen dataset -- the setting where DI is the hardest to evade.

Finally, we discuss the implications of our findings, the viability of fingerprinting-based ownership verification in general, and suggest directions for future work.

Client-agnostic Learning and Zero-shot Adaptation for Federated Domain Generalization

Seunghan Yang,Seokeon Choi,Hyunsin Park,Sungha Choi,Simyung Chang,Sungrack Yun

Federated domain generalization (federated DG) aims to learn a client-agnostic global model from various distributed source domains and generalize the model to new clients in completely unseen domains. The main challenges of federated DG are the difficulty of building the global model with local client models from different domains while keeping data private and low generalizability to test clients, where data distribution deviates from those of training clients. To solve these challenges, we present two strategies: (1) client-agnostic learning with mixed instance-global statistics and (2) zero-shot adaptation with estimated statistics. In client-agnostic learning, we first augment local features by using data distribution of other clients via global statistics in the global model's batch normalization layers. This approach allows the generation of diverse domains by mixing local and global feature statistics while keeping data private. Local models then learn client-invariant representations by applying our client-agnostic objectives with the augmented data. Next, we propose a zero-shot adapter to help the learned global model to directly bridge a large domain gap between seen and unseen clients. At inference time, the adapter mixes instance statistics of a test input with global statistics that are vulnerable to distribution shift. With the aid of the adapter, the global model improves generalizability further by reflecting test distribution. We comprehensively evaluate our methods on several benchmarks in federated DG.

Towards Robust Model Watermark via Reducing Parametric Vulnerability

Guanhao Gan,Yiming Li,Dongxian Wu,Shu-Tao Xia

Deep neural networks are valuable assets considering their commercial benefits and huge demands for costly annotation and computation resources. To protect the copyright of these deep models, backdoor-based ownership verification becomes popular recently, in which the model owner can watermark the model by embedding a specific behavior before releasing it. The defender (usually the model owner) can identify whether a suspicious third-party model is ``stolen'' from it based on the presence of the behavior. Unfortunately, these watermarks are proven to be vulnerable to removal attacks even like fine-tuning. To further explore this vulnerability, we investigate the parametric space and find there exist many watermark-removed models in the vicinity of the watermarked one, which may be easily used by removal attacks. Inspired by this finding, we propose a minimax formulation to find these watermark-removed models and recover their watermark behavior. Extensive experiments demonstrate that our method improves the robustness of the model watermarking against parametric changes and numerous watermark-removal attacks.

This Looks Like It Rather Than That: ProtoKNN For Similarity-Based Classifiers

Yuki Ukai,Tsubasa Hirakawa,Takayoshi Yamashita,Hironobu Fujiyoshi

Among research on the interpretability of deep learning models, the 'this looks like that' framework with ProtoPNet has attracted significant attention. By combining the strong power of deep learning models with the interpretability of case-based inference, ProtoPNet can achieve high accuracy while keeping its reasoning process interpretable. Many methods based on ProtoPNet have emerged to take advantage of this benefit, but despite their practical usefulness, they run into difficulty when utilizing similarity-based classifiers, e.g., in domains where unknown class samples exist. This is because ProtoPNet and its variants adopt the training process specific to linear classifiers, which allows the prototypes to represent useful image features for class recognition. Due to this difficulty, the effectiveness of similarity-based classifiers (e.g., k-nearest neighbor (KNN)) on the 'this looks like that' framework have not been sufficiently examined. To alleviate this problem, we propose ProtoKNN, an extension of ProtoPNet that adopts KNN classifiers. Extensive experiments on multiple open datasets demonstrate that the proposed method can achieve competitive results with a state-of-the-art method.

SEQuence-rPPG: A Fast BVP Signal Extraction Method From Frame Sequences

Kegang Wang,Yantao Wei,Mingwen Tong,Jie Gao,ZhongJin Zhao,YuJian Ma,Yi Tian

Non-contact heart rate estimation has essential implications for the development of affective computing and telemedicine. However, existing deep learning-based methods often endeavor to achieve real-time measurements, so a simple, fast, pre-processing-free approach is needed. Our work consists of two main parts. Firstly, we proposed SEQ-rPPG, which first transforms the RGB frame sequence into the original BVP signal sequence by learning-based linear mapping and then outputs the final BVP signal using 1DCNN-based spectral transform, and time-domain filtering. Secondly, to address the shortcomings of the existing dataset in training the model, a new large-scale dataset was collected for training and testing. Our approach achieved competitive results on the collected large dataset(the best) and public dataset UBFC-rPPG(0.81 MAE with 30s time window, test only). It requires no complex pre-processing, has the fastest speed, can run in real-time on mobile ARM CPUs, and can achieve real-time beat-to-beat performance on desktop CPUs. Benefiting from the high-quality training set, other deep learning-based models reduced errors by at least 53$\%$. We compared the methods with and without the spectral transformation, and the results show that the processing in the time domain is effective.

Understanding weight-magnitude hyperparameters in training binary networks

Joris Quist,Yunqiang Li,Jan van Gemert

Binary Neural Networks (BNNs) are compact and efficient by using binary weights instead of real-valued weights. Current BNNs use latent real-valued weights during training, where several training hyper-parameters are inherited from real-valued networks. The interpretation of several of these hyperparameters is based on the magnitude of the real-valued weights. For BNNs, however, the magnitude of binary weights is not meaningful, and thus it is unclear what these hyperparameters actually do. One example is weight-decay, which aims to keep the magnitude of real-valued weights small. Other examples are latent weight initialization, the learning rate, and learning rate decay, which influence the magnitude of the real-valued weights. The magnitude is interpretable for real-valued weights, but loses its meaning for binary weights. In this paper we offer a new interpretation of these magnitude-based hyperparameters based on higher-order gradient filtering during network optimization. Our analysis makes it possible to understand how magnitude-based hyperparameters influence the training of binary networks which allows for new optimization filters specifically designed for binary neural networks that are independent of their real-valued interpretation. Moreover, our improved understanding reduces the number of hyperparameters, which in turn eases the hyperparameter tuning effort which may lead to better hyperparameter values for improved accuracy. Code is available at https://github.com/jorisquist/Understanding-WM-HP-in-BNNs

Sample-efficient multi-objective molecular optimization with GFlowNets

Yiheng Zhu,Jialu Wu,Chaowen Hu,Jiahuan Yan,Chang-Yu Hsieh,Tingjun Hou,Jian Wu

Many crucial scientific problems involve designing novel molecules with desired properties, which can be formulated as an expensive black-box optimization problem over the discrete chemical space. Computational methods have achieved initial success but still struggle with simultaneously optimizing multiple competing properties in a sample-efficient manner. In this work, we propose a multi-objective Bayesian optimization (MOBO) algorithm leveraging the hypernetwork-based GFlowNets (HN-GFN) as an acquisition function optimizer, with the purpose of sampling a diverse batch of candidate molecular graphs from an approximate Pareto front. Using a single preference-conditioned hypernetwork, HN-GFN learns to explore various trade-offs between objectives. Inspired by reinforcement learning, we further propose a hindsight-like off-policy strategy to share high-performing molecules among different preferences in order to speed up learning for HN-GFN. Through synthetic experiments, we illustrate that HN-GFN has adequate capacity to generalize over preferences. Extensive experiments show that our framework outperforms the best baselines by a large margin in terms of hypervolume in various real-world MOBO settings.

Learning Robust Kernel Ensembles with Kernel Average Pooling

Pouya Bashivan,Adam Ibrahim,Amirozhan Dehghani,Yifei Ren

Model ensembles have long been used in machine learning to reduce the variance in individual model predictions, making them more robust to input perturbations. Pseudo-ensemble methods like dropout have also been commonly used in deep learning models to improve generalization. However, the application of these techniques to improve neural networks' robustness against input perturbations remains underexplored. We introduce \emph{Kernel Average Pool (KAP)}, a new neural network building block that applies the mean filter along the kernel dimension of the layer activation tensor. We show that ensembles of kernels with similar functionality naturally emerge in convolutional neural networks equipped with KAP and trained with backpropagation. Moreover, we show that when combined with activation noise, KAP models are remarkably robust against various forms of adversarial attacks. Empirical evaluations on CIFAR10, CIFAR100, TinyImagenet, and Imagenet datasets show substantial improvements in robustness against strong adversarial attacks such as AutoAttack that are on par with adversarially trained networks but are importantly obtained without training on any adversarial examples.

Causal Attention to Exploit Transient Emergence of Causal Effect

Xiaolei Ru,Xin-Ya Zhang,Jack Murdoch Moore,Gang Yan

We propose a causal reasoning mechanism called $\textit{causal attention}$ that can improve performance of machine learning models on a class of causal inference tasks by revealing the generation process behind the observed data. We consider the problem of reconstructing causal networks (e.g., biological neural networks) connecting large numbers of variables (e.g., nerve cells), of which evolution is governed by nonlinear dynamics consisting of weak coupling-drive (i.e., causal effect) and strong self-drive (dominants the evolution). The core difficulty is sparseness of causal effect that emerges (the coupling force is significant) only momentarily and otherwise remains dormant in the neural activity sequence. $\textit{Causal attention}$ is designed to guide the model to make inference focusing on the critical regions of time series data where causality may manifest. Specifically, attention coefficients are assigned autonomously by a neural network trained to maximise the Attention-extended Transfer Entropy, which is a novel generalization of the iconic transfer entropy metric. Our results show that, without any prior knowledge of dynamics, $\textit{causal attention}$ explicitly identifies areas where the strength of coupling-drive is distinctly greater than zero. This innovation substantially improves reconstruction performance for both synthetic and real causal networks using data generated by neuronal models widel y used in neuroscience.

Imitating Human Behaviour with Diffusion Models

Tim Pearce,Tabish Rashid,Anssi Kanervisto,Dave Bignell,Mingfei Sun,Raluca Georgescu,Sergio Valcarcel Macua,Shan Zheng Tan,Ida Momennejad,Katja Hofmann,Sam Devlin

Diffusion models have emerged as powerful generative models in the text-to-image domain. This paper studies their application as observation-to-action models for imitating human behaviour in sequential environments. Human behaviour is stochastic and multimodal, with structured correlations between action dimensions. Meanwhile, standard modelling choices in behaviour cloning are limited in their expressiveness and may introduce bias into the cloned policy. We begin by pointing out the limitations of these choices. We then propose that diffusion models are an excellent fit for imitating human behaviour, since they learn an expressive distribution over the joint action space. We introduce several innovations to make diffusion models suitable for sequential environments; designing suitable architectures, investigating the role of guidance, and developing reliable sampling strategies. Experimentally, diffusion models closely match human demonstrations in a simulated robotic control task and a modern 3D gaming environment.

MetaPhysiCa: Causality-aware Robustness to OOD Initial Conditions in Physics-informed Machine Learning

S Chandra Mouli,Bruno Ribeiro

A fundamental challenge in physics-informed machine learning (PIML) is the design of robust PIML methods for out-of-distribution (OOD) forecasting tasks, where the tasks require learning-to-learn from observations of the same (ODE) dynamical system with different unknown parameters, and demand accurate forecasts even under initial conditions outside the training support. In this work we propose a solution for such tasks, which we define as a meta-learning procedure for causal structural discovery (including invariant risk minimization). Using three different OOD tasks, we empirically observe that the proposed approach significantly outperforms existing state-of-the-art PIML and deep learning methods.

Representation Balancing with Decomposed Patterns for Treatment Effect Estimation

Yiyan HUANG,WANG Siyi,Cheuk Hang LEUNG,Qi WU,Dongdong WANG,Zhixiang Huang

Estimating treatment effects from observational data is subject to a problem of covariate shift caused by selection bias. Recent studies have attempted to mitigate this problem by group distance minimization, that is, balancing the distribution of representations between the treated and controlled groups. The rationale behind this is that learning balanced representations while preserving the predictive power of factual outcomes is expected to generalize to counterfactual inference. Inspired by this, we propose a new approach to better capture the patterns that contribute to representation balancing and outcome prediction. Specifically, we derive a theoretical bound that naturally ties the notion of propensity confusion to representation balancing, and further transform the balancing Patterns into Decompositions of Individual propensity confusion and Group distance minimization (PDIG). Moreover, we propose to decompose proxy features into Patterns of Pre-balancing and Balancing Representations (PPBR), as it is insufficient if only balanced representations are considered in outcome prediction. Extensive experiments on simulation and benchmark data confirm not only PDIG leads to mutual reinforcement between individual propensity confusion and group distance minimization, but also PPBR brings improvement to outcome prediction, especially counterfactual inference. We believe these findings are heuristics for further investigation of what affects the generalizability of representation balancing models in counterfactual estimation.

Selection-Inference: Exploiting Large Language Models for Interpretable Logical Reasoning

Antonia Creswell,Murray Shanahan,Irina Higgins

Large language models (LLMs) have been shown to be capable of impressive few-shot generalisation to new tasks. However, they still tend to perform poorly on multi-step logical reasoning problems. Here we carry out a comprehensive evaluation of LLMs on 46 tasks that probe different aspects of logical reasoning. We show that language models tend to perform fairly well at single step inference or entailment tasks, but struggle to chain together multiple reasoning steps to solve more complex problems. In light of this, we propose a Selection-Inference (SI) framework that exploits pre-trained LLMs as general processing modules, and alternates between selection and inference to generate a series of interpretable, casual reasoning steps leading to the final answer. We show that a 7B parameter LLM used within the SI framework in a 5-shot generalisation setting, with no fine-tuning, yields a performance improvement of over 100% compared to an equivalent vanilla baseline on a suite of 10 logical reasoning tasks. The same model in the same setting even outperforms a significantly larger 280B parameter baseline on the same suite of tasks. Moreover, answers produced by the SI framework are accompanied by a causal natural-language-based reasoning trace, which has important implications for the safety and trustworthiness of the system.
****

Guided Safe Shooting: model based reinforcement learning with safety constraints
Giuseppe Paolo,Jonas Gonzalez-Billandon,Albert Thomas,Balázs Kégl

In the last decade, reinforcement learning successfully solved complex control tasks and decision-making problems, like the Go board game. Yet, there are few success stories when it comes to deploying those algorithms to real-world scenarios.

One of the reasons is the lack of guarantees when dealing with and avoiding unsafe states, a fundamental requirement in critical control engineering systems. In this paper, we introduce Guided Safe Shooting (GuSS), a model-based RL approach that can learn to control systems with minimal violations of the safety constraints. The model is learned on the data collected during the operation of the system in an iterated batch fashion, and is then used to plan for the best action to perform at each time step. We propose three different safe planners, one based on a simple random shooting strategy and two based on MAP-Elites, a more advanced divergent-search algorithm. Experiments show that these planners help the learning agent avoid unsafe situations while maximally exploring the state space, a necessary aspect when learning an accurate model of the system. Furthermore, compared to model-free approaches, learning a model allows GuSS reducing the number of interactions with the real-system while still reaching high rewards, a fundamental requirement when handling engineering systems.

Contrastive Meta-Learning for Partially Observable Few-Shot Learning
Adam Jelley,Amos Storkey,Antreas Antoniou,Sam Devlin

Many contrastive and meta-learning approaches learn representations by identifying common features in multiple views. However, the formalism for these approaches generally assumes features to be shared across views to be captured coherently. We consider the problem of learning a unified representation from partial observations, where useful features may be present in only some of the views. We approach this through a probabilistic formalism enabling views to map to representations with different levels of uncertainty in different components; these views can then be integrated with one another through marginalisation over that uncertainty. Our approach, Partial Observation Experts Modelling (POEM), then enables us to meta-learn consistent representations from partial observations. We evaluate our approach on an adaptation of a comprehensive few-shot learning benchmark, Meta-Dataset, and demonstrate the benefits of POEM over other meta-learning methods at representation learning from partial observations. We further demonstrate the utility of POEM by meta-learning to represent an environment from partial views observed by an agent exploring the environment.

Enhancing the Inductive Biases of Graph Neural ODE for Modeling Physical Systems
Suresh Bishnoi,Ravinder Bhattoo,Jayadeva Jayadeva,Sayan Ranu,N M Anoop Krishnan

Neural networks with physics-based inductive biases such as Lagrangian neural networks (LNNs), and Hamiltonian neural networks (HNNs) learn the dynamics of physical systems by encoding strong inductive biases. Alternatively, Neural ODEs with appropriate inductive biases have also been shown to give similar performances. However, these models, when applied to particle-based systems, are transductive in nature and hence, do not generalize to large system sizes. In this paper, we present a graph-based neural ODE, GNODE, to learn the time evolution of dynamical systems. Further, we carefully analyze the role of different inductive biases on the performance of GNODE. We show that similar to LNN and HNN, encoding the constraints explicitly can significantly improve the training efficiency and performance of GNODE significantly. Our experiments also assess the value of additional inductive biases, such as Newton’s third law, on the final performance of the model. We demonstrate that inducing these biases can enhance the performance of the model by orders of magnitude in terms of both energy violation and rollout error. Interestingly, we observe that the GNODE trained with the most effective inductive biases, namely MCGNODE, outperforms the graph versions of LNN and HNN, namely, Lagrangian graph networks (LGN) and Hamiltonian graph networks (HGN) in terms of energy violation error by ~4 orders of magnitude for a pendulum system, and ~2 orders of magnitude for spring systems. These results suggest that NODE-based systems can give competitive performances with energy-conserving neural networks by employing appropriate inductive biases.

Efficient Planning in a Compact Latent Action Space
zhengyao jiang,Tianjun Zhang,Michael Janner,Yueying Li,Tim Rocktäschel,Edward Grefenstette,Yuandong Tian

Planning-based reinforcement learning has shown strong performance in tasks in discrete and low-dimensional continuous action spaces. However, planning usually brings significant computational overhead for decision making, so scaling such methods to high-dimensional action spaces remains challenging. To advance efficient planning for high-dimensional continuous control, we propose Trajectory Autoencoding Planner (TAP), which learns low-dimensional latent action codes with a state-conditional VQ-VAE. The decoder of the VQ-VAE thus serves as a novel dynamics model that takes latent actions and current state as input and reconstructs long-horizon trajectories. During inference time, given a starting state, TAP searches over discrete latent actions to find trajectories that have both high probability under the training distribution and high predicted cumulative reward. Empirical evaluation in the offline RL setting demonstrates low decision latency which is indifferent to the growing raw action dimensionality. For Adroit robotic hand manipulation tasks with high-dimensional continuous action space, TAP surpasses existing model-based methods by a large margin and also beats strong model-free actor-critic baselines.

Improved Stein Variational Gradient Descent with Importance Weights
Lukang Sun,Peter Richtárik

Stein Variational Gradient Descent~(\algname{SVGD}) is a popular sampling algorithm used in various machine learning tasks. It is well known that \algname{SVGD} arises from a discretization of the kernelized gradient flow of the Kullback-Leibler divergence $\KL\left(\cdot\mid\pi\right)$, where π is the target distribution. In this work, we propose to enhance \algname{SVGD} via the introduction of {\em importance weights}, which leads to a new method for which we coin the name \algname{β-SVGD}. In the continuous time and infinite particles regime, the time for this flow to converge to the equilibrium distribution π, quantified by the Stein Fisher information, depends on ρ_0 and π very we akly. This is very different from the kernelized gradient flow of Kullback-Leibler divergence, whose time complexity depends on $\KL\left(\rho_0\mid\pi\right)$. Under certain assumptions, we provide a descent lemma for the population limit \algname{β-SVGD}, which covers the descent lemma for the population limit \algname{SVGD} when $\beta\to 0$. We also illustrate the advantages of \algname{β-SVGD} over \algname{SVGD} by simple experiments.

Correlative Information Maximization Based Biologically Plausible Neural Networks for Correlated Source Separation

Bariscan Bozkurt,Ate■ ■sfendiyaro■lu,Cengiz Pehlevan,Alper Tunga Erdogan

The brain effortlessly extracts latent causes of stimuli, but how it does this at the network level remains unknown. Most prior attempts at this problem proposed neural networks that implement independent component analysis, which works under the limitation that latent elements are mutually independent. Here, we relax this limitation and propose a biologically plausible neural network that extracts correlated latent sources by exploiting information about their domains. To derive this network, we choose maximum correlative information transfer from inputs to outputs as the separation objective under the constraint that the outputs are restricted to their presumed sets. The online formulation of this optimization problem naturally leads to neural networks with local learning rules. Our framework incorporates infinitely many source domain choices and flexibly models complex latent structures. Choices of simplex or polytopic source domains result in networks with piecewise-linear activation functions. We provide numerical examples to demonstrate the superior correlated source separation capability for both synthetic and natural sources.

Simplicity bias leads to amplified performance disparities

Samuel Bell,Levent Sagun

The simple idea that not all things are equally difficult has surprising implications when applied in a fairness context.

In this work we explore how "difficulty" is model-specific, such that different models find different parts of a dataset challenging.

When difficulty correlates with group information, we term this difficulty disparity.

Drawing a connection with recent work exploring the inductive bias towards simplicity of SGD-trained models, we show that when such a disparity exists, it is further amplified by commonly-used models.

We quantify this amplification factor across a range of settings aiming towards a fuller understanding of the role of model bias. We also present a challenge to the simplifying assumption that ``fixing'' a dataset is sufficient to ensure unbiased performance.

****

Annealed Fisher Implicit Sampler

Weijian Luo,Boya Zhang,Zhihua Zhang

Sampling from an un-normalized target distribution is an important problem in many scientific fields. An implicit sampler uses a parametric transform $x=G_\theta(z)$ to push forward an easy-to-sample latent code z to obtain a sample x. Such samplers are favored for fast inference speed and flexible architecture. Thus it is appealing to train an implicit sampler for sampling from the un-normalized target. In this paper, we propose a novel approach to training an implicit sampler by minimizing the Fisher Divergence between sampler and target distribution. We find that the trained sampler works well for relatively simple targets but may fail for more complicated multi-modal targets. To improve the training for multi-modal targets, we propose another adaptive training approach that trains the sampler to gradually learn a sequence of annealed distributions. We construct the annealed distribution path to bridge a simple distribution and the complicated target. With the annealed approach, the sampler is capable of handling challenging multi-modal targets. In addition, we also introduce a few MCMC correction steps after the sampler to better spread the samples. We call our proposed sampler \emph{the Annealed Fisher Implicit Sampler} (AFIS). We test AFIS on several sampling benchmarks. The experiments show that our AFIS outperforms baseline methods in many aspects. We also show in theory that the added MC correction steps get faster mixing by using the learned sampler as MCMC's initialization.

Do You Remember? Overcoming Catastrophic Forgetting for Fake Audio Detection

XiaoHui Zhang,Jiangyan Yi,Chenglong Wang,Chu Yuan Zhang,Jianhua Tao

Current fake audio detection algorithms achieve promising performances on most datasets. However, their performance may be significantly degraded when dealing with audio of a different dataset. The orthogonal weight modification to overcome catastrophic forgetting does not consider the similarity of some audio, including fake audio obtained by the same algorithm and genuine audio, on different datasets. To overcome this limitation, we propose a continual learning algorithm for fake audio detection to overcome catastrophic forgetting, called Regularized Adaptive Weight Modification (RAWM). Specifically, when fine-tuning a detection network, our approach adaptively computes the direction of weight modification according to the ratio of genuine utterances and fake utterances. The adaptive modification direction ensures the network can detect fake audio on the new dataset while preserving its knowledge of previous model, thus mitigating catastrophic forgetting. In addition, orthogonal weight modification of fake audios in the new dataset will skew the distribution of inferences on audio in the previous dataset with similar acoustic characteristics, so we introduce a regularization constraint to force the network to remember this distribution. We evaluate our approach across multiple datasets and obtain a significant performance improvement on cross-dataset experiments.

Towards Conditionally Dependent Masked Language Models

Lucas Torroba Hennigen,Yoon Kim

Masked language modeling has proven to be an effective paradigm for learning representations of language. However, when multiple tokens are masked out, the masked language model's (MLM) distribution over the masked positions assumes that the masked tokens are conditionally independent given the unmasked tokens---an assumption that does not hold in practice. Existing work addresses this limitation by interpreting the sum of unary scores (i.e., the logits or the log probabilities of single tokens when conditioned on all others) as the log potential a Markov random field (MRF). While this new model no longer makes any independence assumptions, it remains unclear whether this approach (i) results in a good probabilistic model of language and further (ii) derives a model that is faithful (i.e., has matching unary distributions) to the original model. This paper studies MRFs derived this way in a controlled setting where only two tokens are masked out at a time, which makes it possible to compute exact distributional properties. We find that such pairwise MRFs are often worse probabilistic models of language from a perplexity standpoint, and moreover have unary distributions that do not match the unary distributions of the original MLM. We then study a statistically-motivated iterative optimization algorithm for deriving joint pairwise distributions that are more compatible with the original unary distributions. While this iterative approach outperforms the MRF approach, the algorithm itself is too expensive to be practical. We thus amortize this optimization process through a parameterized feed-forward layer that learns to modify the original MLM's pairwise distributions to be both non-independent and faithful, and find that this approach outperforms the MLM for scoring pairwise tokens.

Leveraging Importance Weights in Subset Selection

Gui Citovsky,Giulia DeSalvo,Sanjiv Kumar,Srikumar Ramalingam,Afshin Rostamizadeh,Yunjuan Wang

We present a subset selection algorithm designed to work with arbitrary model families in a practical batch setting. In such a setting, an algorithm can sample examples one at a time but, in order to limit overhead costs, is only able to update its state (i.e. further train model weights) once a large enough batch of examples is selected. Our algorithm, IWeS, selects examples by importance sampli ng where the sampling probability assigned to each example is based on the entropy of models trained on previously selected batches. IWeS admits significant performance improvement compared to other subset selection algorithms for seven publicly available datasets. Additionally, it is competitive in an active learning setting, where the label information is not available at selection time. We also provide an initial theoretical analysis to support our importance weighting approach, proving generalization and sampling rate bounds.

Interactive Sequential Generative Models

Dennis Fassmeyer,Pascal Fassmeyer,Ulf Brefeld

Understanding spatiotemporal relationships among several agents is of considerable relevance for many domains. Team sports represent a particularly interesting real-world proving ground since modeling interacting athletes requires capturing highly dynamic and complex agent-agent dependencies in addition to temporal components. However, existing generative methods in this field either entangle all latent factors into a single variable and are thus constrained in practical applicability, or they focus on uncovering interaction structures, which restricts their generative ability. To address this gap, we propose a framework for multiagent trajectories that augments sequential generative models with latent social structures. First, we derive a novel objective via approximate inference using a disentangled latent space that accurately describes the data generating process in such systems. Based on the proposed training criterion, we then present a model architecture that unifies insights from neural interaction inference and graph-structured variational recurrent neural networks for generating collective movements while allocating latent information. We validate our model on data from professional soccer and basketball. Our framework not only improves upon existing state-of-the-art approaches in forecasting trajectories, but also infers semantically meaningful representations that can be used in downstream tasks.

Gradient flow in the gaussian covariate model: exact solution of learning curves and multiple descent structures

Antoine Bodin,Nicolas Macris

A recent line of work has shown remarkable behaviors of the generalization error curves in simple learning models. Even the least-squares regression has shown atypical features such as the model-wise double descent, and further works have observed triple or multiple descents. Another important characteristic are the epoch-wise descent structures which emerge during training. The observations of model-wise and epoch-wise descents have been analytically derived in limited theoretical settings (such as the random feature model) and are otherwise experimental. In this work, we provide a full and unified analysis of the whole time-evolution of the generalization curve, in the asymptotic large-dimensional regime and under gradient-flow, within a wider theoretical setting stemming from a gaussian covariate model. In particular, we cover most cases already disparately observed in the literature, and also provide examples of the existence of multiple descent structures as a function of a model parameter or time. Furthermore, we show that our theoretical predictions adequately match the learning curves obtained by gradient descent over realistic datasets.

Technically we compute averages of rational expressions involving random matrices using recent developments in random matrix theory based on "linear pencils". Another contribution, which is also of independent interest in random matrix theory, is a new derivation of related fixed point equations (and an extension there-off) using Dyson brownian motions.

Copy is All You Need

Tian Lan,Deng Cai,Yan Wang,Heyan Huang,Xian-Ling Mao

The dominant text generation models compose the output by sequentially selecting words from a fixed vocabulary. In this paper, we formulate text generation as progressively copying text segments (e.g., words or phrases) from an existing text collection. We compute the contextualized representations of meaningful text segments and index them using efficient vector search toolkits. The task of text generation is then decomposed into a series of copy-and-paste operations: at each time step, we seek suitable text spans from the text collection rather than selecting from a standalone vocabulary. Experiments on the standard language modeling benchmark (WikiText-103) show that our approach achieves better generation quality according to both automatic and human evaluations. Besides, its inference efficiency is comparable to token-level autoregressive models thanks to the reduction of decoding steps. We also show that our approach allows for effective domain adaptation by simply switching to domain-specific text collection without extra training. Finally, we observe that our approach attains additional performance gains by simply scaling up to larger text collections, again without further training.\footnote{Our source codes are publicly available at \url{https://github.com/gmftbyGMFTBY/Copyisallyouneed}.}

Graph Backup: Data Efficient Backup Exploiting Markovian Transitions

zhengyao jiang,Tianjun Zhang,Robert Kirk,Tim Rocktäschel,Edward Grefenstette

The successes of deep Reinforcement Learning (RL) are limited to settings where we have a large stream of online experiences, but applying RL in the data-efficient setting with limited access to online interactions is still challenging. A key to data-efficient RL is good value estimation, but current methods in this space fail to fully utilise the structure of the trajectory data gathered from the environment. In this paper, we treat the transition data of the MDP as a graph, and define a novel backup operator, Graph Backup, which exploits this graph structure for better value estimation. Compared to multi-step backup methods such as n-step Q-Learning and TD(λ), Graph Backup can perform counterfactual credit assignment and gives stable value estimates for a state regardless of which trajectory the state is sampled from. Our method, when combined with popular off-policy value-based methods, provides improved performance over one-step and multi-step methods on a suite of data-efficient RL benchmarks including MiniGrid, Minatar and Atari100K. We further analyse the reasons for this performance boost through a novel visualisation of the transition graphs of Atari games.

****

Linearised Implicit Variational Inference

Anshuk Uppal,Wouter Boomsma,Jes Frellsen

Bayesian neural networks (BNNs) are touted for robustness under data drift, resilience to overfitting and catastrophic forgetting whilst also producing actionable uncertainty estimates. In variational inference, these elegant properties are contingent on the expressivity of the variational approximation. Posteriors over parameters of large models are usually multimodal and highly correlated and hence cannot be well-approximated by simple, prescribed densities. We posit implicit variational distributions specified using differentiable generators are more flexible and propose a novel bound for training BNNs using such approximations (amortized neural samplers). The proposed bound uses an approximation of the variational distribution's entropy by locally linearising the generator. Unlike existing works, our method does not require a discriminator network and moves away from an unfavourable adversarial objective. Our formulation resembles normalizing flows but does not necessitate invertibility of the generator. Moreover, we use a differentiable numerical lower bound on the Jacobians of the generator, mitigating computational concerns. We report log-likelihoods on UCI datasets competitive with deep ensembles and test our method on out-of-distribution benchmarks.

Adversarial Driving Policy Learning by Misunderstanding the Traffic Flow

Dongkun Zhang,Jintao Xue,Jingke Wang,Yunkai Wang,Yuxiang Cui,Eryun Liu,Wei Jing,Rong Xiong,Junbo Chen,Yue Wang

Acquiring driving policies that can transfer to unseen environments is essential for driving in dense traffic flows. Adversarial training is a promising path to improve robustness under disturbances. Most prior works leverage few agents to induce driving policy's failures. However, we argue that directly implementing this training framework into dense traffic flow degrades transferability in unseen environments. In this paper, we propose a novel robust policy training framework that is capable of applying adversarial training based on a coordinated traff ic flow. We start by building up a coordinated traffic flow where agents are allowed to communicate Social Value Orientations (SVOs). Adversary emerges when the traffic flow misunderstands the SVO of driving agent. We utilize this property to formulate a minimax optimization problem where the driving policy maximizes its own reward and a spurious adversarial policy minimizes it. Experiments demonstrate that our adversarial training framework significantly improves zero-shot transfer performance of the driving policy in dense traffic flows compared to existing algorithms.

Differentiable and transportable structure learning

Jeroen Berrevoets,Nabeel Seedat,Fergus Imrie,Mihaela van der Schaar

Directed acyclic graphs (DAGs) encode a lot of information about a particular distribution in its structure. However, compute required to infer these structures is typically super-exponential in the number of variables, as inference requires a sweep of a combinatorially large space of potential structures. That is, until recent advances made it possible to search this space using a differentiable metric, drastically reducing search time. While this technique– named NOTEARS –is widely considered a seminal work in DAG-discovery, it concedes an important property in favour of differentiability: transportability. To be transportable, the structures discovered on one dataset must apply to another dataset from the same domain. In our paper, we introduce D-Struct which recovers transportability in the discovered structures through a novel architecture and loss function, while remaining completely differentiable. Because D-Struct remains differentiable, our method can be easily adopted in existing differentiable architectures, as was previously done with NOTEARS. In our experiments, we empirically validate D-Struct with respect to edge accuracy and structural Hamming distance in a variety of settings.

Distributed Inference and Fine-tuning of Large Language Models Over The Internet

Alexander Borzunov,Dmitry Baranchuk,Tim Dettmers,Max Ryabinin,Younes Belkada,Artem Chumachenko,Pavel Samygin,Colin Raffel

Large language models (LLMs) are useful in many NLP tasks and become more capable with size, scaling to over 100 billion parameters. With the release of BLOOM-176B and OPT-175B, everyone can download pretrained models of this scale. Still, using a pre-trained 100B+ model requires high-end hardware, making it inaccessible to most researchers. Recent studies in memory-efficient training (e.g. offloading) could alleviate these costs, but they do not cover important use cases of LLMs, such as autoregressive inference. In this work, we investigate methods for cost-efficient inference of large language models, comparing local and distributed strategies. We observe that a large enough model (100B+) could run efficiently on geodistributed devices in a consumer-grade network, for example by connecting existing compute resources of multiple research groups or pooling under-utilized compute from multiple cloud regions. To run LLMs in this unconventional setting, we develop a fault-tolerant algorithm for inferencing language models. We propose Petals - a decentralized system for running LLMs - and show that it can run BLOOM-176B over the Internet over $10\times$ faster than offloading for sequential generation. We evaluate the performance of our system in both simulated conditions and an actual distributed system spanning two continents. The design of Petals allows participants to inference, and fine-tune, or inference fine-tuned models simultaneously without affecting each other's results.

Association Rules in QUBO Samples and Where to Find Them

Tian Huang,Siong Thye Goh,Rick Siow Mong Goh,Tao Luo

There are sometimes strong associations between variables in the samples to a Quadratic Unconstrained Binary Optimization (QUBO) problem. A natural question arises to us: Are there any value in these association? We study max-cut problem and observe that association can be represented as rules to simplify QUBO problem. Classical and quantum annealers work better when the problem size is smaller. To effectively and efficiently find associations between variables, we adapt traditional association rule mining in the case of QUBO samples and propose a Fast A ssociation Rule Mining algorithm (FARM) specifically for mining QUBO samples. We also propose strategies and a workflow to select and apply promising rules and simplify QUBO problems. We evaluate our method on D-Wave Quantum Annealer as well as Fujitsu Digital Annealer. The experiments demonstrate the utility of FARM as a visualisation tool for understanding associations in QUBO samples. The results also demonstrate the potential of our method in closing the gap between samples and ground truth. The source code will be disclosed to the public if the manuscript is accepted.

Why adversarial training can hurt robust accuracy

Jacob Clarysse,Julia Hörrmann,Fanny Yang

Machine learning classifiers with high test accuracy often perform poorly under adversarial attacks. It is commonly believed that adversarial training alleviates this issue. In this paper, we demonstrate that, surprisingly, the opposite can be true for a natural class of perceptible perturbations --- even though adversarial training helps when enough data is available, it may in fact hurt robust generalization in the small sample size regime. We first prove this phenomenon for a high-dimensional linear classification setting with noiseless observations. Using intuitive insights from the proof, we could surprisingly find perturbations on standard image datasets for which this behavior persists. Specifically, it occurs for perceptible attacks that effectively reduce class information such as object occlusions or corruptions.

****

ExpressivE: A Spatio-Functional Embedding For Knowledge Graph Completion

Aleksandar Pavlovic,Emanuel Sallinger

Knowledge graphs are inherently incomplete. Therefore substantial research has been directed toward knowledge graph completion (KGC), i.e., predicting missing triples from the information represented in the knowledge graph (KG). KG embedding models (KGEs) have yielded promising results for KGC, yet any current KGE is incapable of: (1) fully capturing vital inference patterns (e.g., composition), (2) capturing prominent patterns jointly (e.g., hierarchy and composition), and (3) providing an intuitive interpretation of captured patterns. In this work, we propose ExpressivE, a fully expressive spatio-functional KGE that solves all these challenges simultaneously. ExpressivE embeds pairs of entities as points and relations as hyper-parallelograms in the virtual triple space $\mathbb{R}^{2d}$. This model design allows ExpressivE not only to capture a rich set of inference patterns jointly but additionally to display any supported inference pattern through the spatial relation of hyper-parallelograms, offering an intuitive and consistent geometric interpretation of ExpressivE embeddings and their captured patterns. Experimental results on standard KGC benchmarks reveal that ExpressivE is competitive with state-of-the-art KGEs and even significantly outperforms them on WN18RR.

FedPD: Defying data heterogeneity through privacy distillation

Zhiqin Brian Yang,Yonggang Zhang,Yu Zheng,Zhenheng TANG,Xiaowen Chu,Hao Peng,Bo Han

Model performance of federated learning (FL) typically suffers from data heterogeneity, i.e., data distribution varies with clients. Advanced works have already shown great potential for sharing client information to mitigate data heterogeneity. Yet, some literature shows a dilemma in preserving strong privacy and promoting model performance simultaneously. Revisiting the purpose of sharing information motivates us to raise the fundamental questions: Which part of the data is more critical for model generalization? Which part of the data is more privacy-sensitive? Can we solve this dilemma by sharing useful (for generalization) features and maintaining more sensitive data locally? Our work sheds light on data-dominated sharing and training, in a way that we decouple original training data into sensitive features and generalizable features. To be specific, we propose a \textbf{Fed}erated \textbf{P}rivacy \textbf{D}istillation framework named FedPD to alleviate the privacy-performance dilemma. Namely, FedPD keeps the distilled sensitive features locally and constructs a global dataset using shared general izable features in a differentially private manner. Accordingly, clients can perform local training on both the local and securely shared data for acquiring high model performance and avoiding the leakage of not distilled privacy. Theoretically, we demonstrate the superiority of the sharing-only useful feature strategy over sharing raw data. Empirically, we show the efficacy of FedPD in promoting performance with comprehensive experiments.

Harnessing Client Drift with Decoupled Gradient Dissimilarity

Zhenheng TANG,Yonggang Zhang,Shaohuai Shi,Xinmei Tian,Tongliang Liu,Bo Han,Xiaowen Chu

The performance of Federated learning (FL) typically suffers from client drift caused by heterogeneous data, where data distributions vary with clients. Recent studies show that the gradient dissimilarity between clients induced by the data distribution discrepancy causes the client drift. Thus, existing methods mainly focus on correcting the gradients. However, it is challenging to identify which client should (or not) be corrected. This challenge raises a series of questions: will the local training, without gradient correction, contribute to the server model's generalization of other clients' distributions? when the generalization contribution holds? how to address the challenge when it fails? To answer these questions, we analyze the generalization contribution of local training and conclude that the generalization contribution of local training is bounded by the conditional Wasserstein distance between clients' distributions. Thus, the key to promote generalization contribution is to leverage similar conditional distributions for local training. As collecting data distribution can cause privacy leakage, we propose decoupling the deep models, i.e., splitting into high-level models and low-level models, for harnessing client drift. Namely, high-level models are trained on shared feature distributions, causing promoted generalization contribution and alleviated gradient dissimilarity. Experimental results demonstrate that FL with decoupled gradient dissimilarity is robust to data heterogeneity.

SeKron: A Decomposition Method Supporting Many Factorization Structures

Marawan Gamal,Ali Mosleh,Marzieh S. Tahaei,Vahid Partovi Nia

While convolutional neural networks (CNNs) have become the de facto standard for most image processing and computer vision applications, their deployment on edge devices remains challenging. Tensor decomposition methods provide a means of compressing CNNs to meet the wide range of device constraints by imposing certain factorization structures on their convolution tensors. However, being limited to the small set of factorization structures presented by state-of-the-art decomposition approaches can lead to sub-optimal performance. We propose SeKron, a novel tensor decomposition method that offers a wide variety of factorization structures, using sequences of Kronecker products. By recursively finding approximating Kronecker factors, we arrive at optimal decompositions for each of the factorization structures. We show that SeKron is a flexible decomposition that generalizes widely used methods, such as Tensor-Train (TT), Tensor-Ring (TR), Canonical Polyadic (CP) and Tucker decompositions. Crucially, we derive an efficient convolution projection algorithm shared by all SeKron structures, leading to seamless compression of CNN models. We validate SeKron for model compression on both high-level and low-level computer vision tasks and find that it outperforms state-of-the-art decomposition methods.

Localized Randomized Smoothing for Collective Robustness Certification

Jan Schuchardt,Tom Wollschläger,Aleksandar Bojchevski,Stephan Günnemann

Models for image segmentation, node classification and many other tasks map a single input to multiple labels. By perturbing this single shared input (e.g. the image) an adversary can manipulate several predictions (e.g. misclassify several pixels). Collective robustness certification is the task of provably bounding the number of robust predictions under this threat model. The only dedicated method that goes beyond certifying each output independently is limited to strictly local models, where each prediction is associated with a small receptive field.

We propose a more general collective robustness certificate for all types of models. We further show that this approach is beneficial for the larger class of softly local models, where each output is dependent on the entire input but assigns different levels of importance to different input regions (e.g. based on their proximity in the image). The certificate is based on our novel localized randomized smoothing approach, where the random perturbation strength for different input regions is proportional to their importance for the outputs. Localized smoothing Pareto-dominates existing certificates on both image segmentation and node classification tasks, simultaneously offering higher accuracy and stronger certificates.

Learning Dictionaries over Datasets through Wasserstein Barycenters

Eduardo Fernandes Montesuma,Fred Maurice Ngole Mboula,Antoine Souloumiac

Dictionary learning consists of trying to represent objects in terms of basic elements (atoms) weighted by an importance factor (representation). Non-linear dictionary learning using optimal transport as a metric has been previously studied for normalized non-negative data on a fixed grid. We propose a new framework by using Wasserstein Dictionary Learning on datasets understood as empirical distributions. We leverage Wasserstein barycenters for learning a dictionary of virtual datasets and embeddings in a simplex. We apply our method for unsupervised domain adaptation, improving the state-of-the-art over 1.96% and 2.70%, respectively, and manifold learning of Gaussian distributions and color histograms.

****

Learning Interpretable Neural Discrete Representation for Time Series Classification

Etienne Le Naour,Ghislain Agoua,Nicolas Baskiotis,Vincent Guigue

Time series classification is a challenging research field with many real-life applications. Recent advances in deep learning have significantly improved the state of the art: recurrent or convolutional architectures allow automatic extraction of complex discriminating patterns that improve performance. Those approaches suffer from a lack of interpretability: the patterns are mapped into a high dimensional latent vector space, they are not representable in the time domain, and are often even not localizable. In this paper, we present a novel neural convolutional architecture that aims to provide a trade-off between interpretability and effectiveness based on the learning of a dictionary of discrete representations. The proposed model guarantees (1) that a small number of patterns are learned, and they are visualizable and interpretable (2) a shift equivariance property of the model associated with a time-consistency of the representation (3) a linear classifier over a limited number of patterns leading to an explainable decision. To ensure the robustness of the discrete representation, they are learned in an unsupervised process independently of the classification task. This allows further great performances in transfer learning. We present extensive experiments on the UCR benchmark wrt usual baselines. The interpretability of the model is illustrated empirically. The chosen trade-off results obviously in a decrease in performance compared to the state of the art. The performance drop is however limited and very dependent on the application domain. The experiments highlight the efficiency of the model for the transfer learning task, showing the robustness of the representations.

Representational Dissimilarity Metric Spaces for Stochastic Neural Networks

Lyndon Duong,Jingyang Zhou,Josue Nassar,Jules Berman,Jeroen Olieslagers,Alex H Williams

Quantifying similarity between neural representations---e.g. hidden layer activation vectors---is a perennial problem in deep learning and neuroscience research. Existing methods compare deterministic responses (e.g. artificial networks that lack stochastic layers) or averaged responses (e.g., trial-averaged firing rates in biological data). However, these measures of _deterministic_ representational similarity ignore the scale and geometric structure of noise, both of which play important roles in neural computation. To rectify this, we generalize previously proposed shape metrics (Williams et al. 2021) to quantify differences in _

stochastic_ representations. These new distances satisfy the triangle inequality, and thus can be used as a rigorous basis for many supervised and unsupervised analyses. Leveraging this novel framework, we find that the stochastic geometries of neurobiological representations of oriented visual gratings and naturalistic scenes respectively resemble untrained and trained deep network representations. Further, we are able to more accurately predict certain network attributes (e.g. training hyperparameters) from its position in stochastic (versus deterministic) shape space.

Hierarchical Prototypes for Unsupervised Dynamics Generalization in Model-Based Reinforcement Learning
Jiaxian Guo,Mingming Gong,Yali Du,Zhen Wang,Dacheng Tao
By incorporating the environment-specific factor into the dynamics prediction, model-based reinforcement learning (MBRL) is able to generalise to environments with diverse dynamics.In the majority of real-world scenarios, the environment-specific factor is not observable, so existing methods attempt to estimate it from historical transition segments. Nevertheless,earlier research was unable to identify distinct clusters for environment-specific factors learned from different environments, resulting in poor performance.
To address this issue,
We introduce a set of environmental prototypes to represent the environmental-specified representation for each environment. By encouraging learned environment-specific factors to resemble their assigned environmental prototypes more closely, the discrimination between factors estimated from distinct environments will be enhanced. To learn such prototypes, we first construct prototypes for each sampled trajectory and then hierarchically combine trajectory prototypes with similar semantics into one environmental prototype. Experiments demonstrate that environment-specific factors estimated by our method have superior clustering performance and can consistently improve MBRL's generalisation performance in six environments consistently.
****
Irregularity Reflection Neural Network for Time Series Forecasting
YoungJun Choo,Adrian Matias Chung Baek,Namhun Kim,Han-Gyun Woo
Time series forecasting is a long-standing challenge in a variety of industries, and deep learning stands as the mainstream paradigm for handling this forecasting problem. With recent success, representations of time series components (e.g., trend and seasonality) are also considered in the learning process of the models. However, the residual remains under explored due to difficulty in formulating its inherent complexity. In this study, we propose a novel Irregularity Reflection Neural Network (IRN) that reflect the residual for the time series forecasting. First, we redefine the residual as the irregularity and express it as a sum of individual, short regular waves considering the Fourier series in a micro perspective. Second, we design a module, based on the convolutional architectures to mimic the variables of the derived irregularity representation, named Irregularity Representation Block (IRB). IRN comprises IRB on top of a forecasting model to learn the irregularity representation of time series. Extensive experiments on multiple real-world datasets demonstrate that IRN outperforms the state-of-the-art benchmarks in time series forecasting tasks.
****
Sequential Learning of Neural Networks for Prequential MDL
Jorg Bornschein,Yazhe Li,Marcus Hutter
Minimum Description Length (MDL) provides a framework and an objective for principled model evaluation. It formalizes Occam's Razor and can be applied to data from non-stationary sources. In the prequential formulation of MDL, the objective is to minimize the cumulative next-step log-loss when sequentially going through the data and using previous observations for parameter estimation. It thus closely resembles a continual- or online-learning problem. In this study, we evaluate approaches for computing prequential description lengths for image classification datasets with neural networks. Considering the computational cost, we find that online-learning with rehearsal has favorable performance compared to the pr

eviously widely used block-wise estimation. We propose forward-calibration to better align the models predictions with the empirical observations and introduce replay-streams, a minibatch incremental training technique to efficiently implement approximate random replay while avoiding large in-memory replay buffers. As a result, we present description lengths for a suite of image classification datasets that improve upon previously reported results by large margins.

****

Relaxed Attention for Transformer Models

Timo Lohrenz,Björn Möller,Zhengyang Li,Tim Fingscheidt

The powerful modeling capabilities of all-attention-based transformer architectures often cause overfitting and - for natural language processing tasks - lead to an implicitly learned internal language model in the autoregressive transformer decoder complicating the integration of external language models. In this paper, we explore relaxed attention, a simple and easy-to-implement smoothing of the attention weights, yielding a two-fold improvement to the general transformer architecture: First, relaxed attention provides regularization when applied to the self-attention layers in the encoder. Second, we show that it naturally supports the integration of an external language model as it suppresses the implicitly learned internal language model by relaxing the cross attention in the decoder. We demonstrate the benefit of relaxed attention across several tasks with clear improvement in combination with recent benchmark approaches. Specifically, we exceed the former state-of-the-art performance of 26.90% word error rate on the largest public lip-reading LRS3 benchmark with a word error rate of 26.31%, as well as we achieve a top-performing BLEU score of 37.67 on the IWSLT14 (DE$\rightarrow$EN) machine translation task without external language models and virtually no additional model parameters. Code and models will be made publicly available.

****

SynBench: Task-Agnostic Benchmarking of Pretrained Representations using Synthetic Data

Ching-Yun Ko,Pin-Yu Chen,Jeet Mohapatra,Payel Das,Luca Daniel

Recent success in fine-tuning large models, that are pretrained on broad data at scale, on downstream tasks has led to a significant paradigm shift in deep learning, from task-centric model design to task-agnostic representation learning and task-specific fine-tuning. As the representations of pretrained models are used as a foundation for different downstream tasks, this paper proposes a new task-agnostic framework, \textit{SynBench}, to measure the quality of pretrained representations using synthetic data. We set up a reference by a theoretically-derived robustness-accuracy tradeoff of the class conditional Gaussian mixture. Given a pretrained model, the representations of data synthesized from the Gaussian mixture are used to compare with our reference to infer the quality. By comparing the ratio of area-under-curve between the raw data and their representations, SynBench offers a quantifiable score for robustness-accuracy performance benchmarking. Our framework applies to a wide range of pretrained models taking continuous data inputs and is independent of the downstream tasks and datasets. Evaluated with several pretrained vision transformer models, the experimental results show that our SynBench score well matches the actual linear probing performance of the pre-trained model when fine-tuned on downstream tasks. Moreover, our framework can be used to inform the design of robust linear probing on pretrained representations to mitigate the robustness-accuracy tradeoff in downstream tasks.

Learning topology-preserving data representations

Ilya Trofimov,Daniil Cherniavskii,Eduard Tulchinskii,Nikita Balabin,Evgeny Burnaev,Serguei Barannikov

We propose a method for learning topology-preserving data representations (dimensionality reduction). The method aims to provide topological similarity between the data manifold and its latent representation via enforcing the similarity in topological features (clusters, loops, 2D voids, etc.) and their localization. The core of the method is the minimization of the Representation Topology Divergence (RTD) between original high-dimensional data and low-dimensional representa

tion in latent space. RTD minimization provides closeness in topological features with strong theoretical guarantees.
We develop a scheme for RTD differentiation and apply it as a loss term for the autoencoder. The proposed method "RTD-AE" better preserves the global structure and topology of the data manifold than state-of-the-art competitors as measured by linear correlation, triplet distance ranking accuracy, and Wasserstein distance between persistence barcodes.
****
Interpreting Class Conditional GANs with Channel Awareness
Yingqing He,Zhiyi Zhang,Jiapeng Zhu,Yujun Shen,Qifeng Chen
Understanding the mechanism of generative adversarial networks (GANs) helps us better use GANs for downstream applications. Existing efforts mainly target interpreting unconditional models, leaving it less explored how a conditional GAN learns to render images regarding various categories. This work fills in this gap by investigating how a class conditional generator unifies the synthesis of multiple classes. For this purpose, we dive into the widely used class-conditional batch normalization (CCBN), and observe that each feature channel is activated at varying degrees given different categorical embeddings. To describe such a phenomenon, we propose channel awareness, which quantitatively characterizes how a single channel contributes to the final synthesis. Extensive evaluations and analyses on the BigGAN model pre-trained on ImageNet reveal that only a subset of channels is primarily responsible for the generation of a particular category, similar categories (e.g., cat and dog) usually get related to some same channels, and some channels turn out to share information across all classes. For good measure, our algorithm enables several novel applications with conditional GANs. Concretely, we achieve (1) versatile image editing via simply altering a single channel and manage to (2) harmoniously hybridize two different classes. We further verify that the proposed channel awareness shows promising potential in (3) segmenting the synthesized image and (4) evaluating the category-wise synthesis performance.
****
Escaping saddle points in zeroth-order optimization: two function evaluations suffice
Zhaolin Ren,Yujie Tang,Na Li
Zeroth-order methods are useful in solving black-box optimization and reinforcement learning problems in unknown environments. It uses function values to estimate the gradient. As optimization problems are often nonconvex, it is a natural question to understand how zeroth-order methods escape saddle points. In this paper, we consider zeroth-order methods, that at each iteration, may freely choose 2$m$ function evaluations where $m$ ranges from 1 to $d$, with $d$ denoting the problem dimension. We show that by adding an appropriate isotropic perturbation at each iteration, a zeroth-order algorithm based on $2m$ function evaluations per iteration can not only find $\epsilon$-second order stationary points polynomially fast, but do so using only $\tilde{O}(\frac{d}{\epsilon^{2.5}})$ function evaluations.
****
Vector Quantization and Shifting: Exploiting Latent Properties to Optimize Neural Codecs
Muhammet Balcilar,Bharath Bhushan Damodaran,Karam Naser,Franck Galpin,Pierre Hellier
End-to-end image/video codecs are getting competitive compared to traditional compression techniques that have been developed through decades of manual engineering efforts. These trainable codecs have many advantages over traditional techniques such as easy adaptation on perceptual distortion metrics and high performance on specific domains thanks to their learning ability. However, state of the art neural codecs do not take advantage of vector quantization technique and existence of gradient of entropy in decoding device. In this research, we propose some theoretical insights about these two properties (quantization and entropy gradient), and show that this can improve the performances of many off-the-shelf codecs. First, we prove that non-uniform quantization map on neural codec's latent

is not necessary. Thus, we improve the performance by using a predefined optimal uniform vector quantization map. Secondly, we theoretically show that gradient of entropy (available at decoder side) is correlated with the gradient of the reconstruction error (which is not available at decoder side). Thus, we use the former as a proxy in order to improve the compression performance. According to our results, we save between 2-4\% of rate for the same quality with this proposal, for various pre-trained methods.

Time-Myopic Go-Explore: Learning A State Representation for the Go-Explore Paradigm
Marc Höftmann,Jan Robine,Stefan Harmeling
Very large state spaces with a sparse reward signal are difficult to explore. The lack of a sophisticated guidance results in a poor performance for numerous reinforcement learning algorithms. In these cases, the commonly used random exploration is often not helpful. The literature shows that this kind of environments require enormous efforts to systematically explore large chunks of the state space. Learned state representations can help here to improve the search by providing semantic context and build a structure on top of the raw observations. In this work we introduce a novel time-myopic state representation that clusters temporal close states together while providing a time prediction capability between them. By adapting this model to the Go-Explore paradigm (Ecoffet et al., 2021b), we demonstrate the first learned state representation that reliably estimates novelty instead of using the hand-crafted representation heuristic. Our method shows an improved solution for the detachment problem which still remains an issue at the Go-Explore Exploration Phase. We provide evidence that our proposed method covers the entire state space with respect to all possible time trajectories — without causing disadvantageous conflict-overlaps in the cell archive. Analogous to native Go-Explore, our approach is evaluated on the hard exploration environments MontezumaRevenge, Gravitar and Frostbite (Atari) in order to validate its capabilities on difficult tasks. Our experiments show that time-myopic Go-Explore is an effective alternative for the domain-engineered heuristic while also being more general. The source code of the method is available on GitHub.

Mastering Spatial Graph Prediction of Road Networks
Sotiris Anagnostidis,Aurelien Lucchi,Thomas Hofmann
Accurately predicting road networks from satellite images requires a global understanding of the network topology. We propose to capture such high-level information by introducing a graph-based framework that simulates the addition of sequences of graph edges using a reinforcement learning (RL) approach. In particular, given a partially generated graph associated with a satellite image, an RL agent nominates modifications that maximize a cumulative reward. As opposed to standard supervised techniques that tend to be more restricted to commonly used surrogate losses, these rewards can be based on various complex, potentially non-continuous, metrics of interest. This yields more power and flexibility to encode problem-dependent knowledge. Empirical results on several benchmark datasets demonstrate enhanced performance and increased high-level reasoning about the graph topology when using a tree-based search. We further highlight the superiority of our approach under substantial occlusions by introducing a new synthetic benchmark dataset for this task.

Learning Probabilistic Topological Representations Using Discrete Morse Theory
Xiaoling Hu,Dimitris Samaras,Chao Chen
Accurate delineation of fine-scale structures is a very important yet challenging problem. Existing methods use topological information as an additional training loss, but are ultimately making pixel-wise predictions. In this paper, we propose a novel deep learning based method to learn topological/structural. We use discrete Morse theory and persistent homology to construct a one-parameter family of structures as the topological/structural representation space. Furthermore, we learn a probabilistic model that can perform inference tasks in such a topological/structural representation space. Our method generates true structures rath

er than pixel-maps, leading to better topological integrity in automatic segmentation tasks. It also facilitates semi-automatic interactive annotation/proofreading via the sampling of structures and structure-aware uncertainty.
****

Zero-Label Prompt Selection
Chonghua Liao,Yanan Zheng,Zhilin Yang
Natural language prompts have been shown to facilitate cross-task generalization for large language models. However, with no or limited labeled examples, the cross-task performance is highly sensitive to the choice of prompts, while selecting a high-performing prompt is challenging given the scarcity of labels. To address the issue, we propose a Zero-Label Prompt Selection (ZPS) method that selects prompts without any labeled data or gradient update. Specifically, given the candidate human-written prompts for a task, ZPS labels a set of unlabeled data with a prompt ensemble and uses the pseudo-labels for prompt selection. Experiments show that ZPS improves over prior methods by a sizeable margin in zero-label performance. We also extend ZPS to a few-shot setting and show its advantages over strong baselines such as prompt tuning and model tuning.

The Curious Case of Benign Memorization
Sotiris Anagnostidis,Gregor Bachmann,Lorenzo Noci,Thomas Hofmann
Despite the empirical advances of deep learning across a variety of learning tasks, our theoretical understanding of its success is still very restricted. One of the key challenges is the overparametrized nature of modern models, enabling complete overfitting of the data even if the labels are randomized, i.e. networks can completely \textit{memorize} all given patterns. While such a memorization capacity seems worrisome, in this work we show that under training protocols that include \textit{data augmentation}, neural networks learn to memorize entirely random labels in a benign way, i.e. they learn embeddings that lead to highly non-trivial performance under nearest neighbour probing. We demonstrate that deep models have the surprising ability to separate noise from signal by distributing the task of memorization and feature learning to different layers. As a result, only the very last layers are used for memorization, while preceding layers encode performant features which remain largely unaffected by the label noise. We explore the intricate role of the augmentations used for training and identify a memorization-generalization trade-off in terms of their diversity, marking a clear distinction to all previous works. Finally, we give a first explanation for the emergence of benign memorization by showing that \textit{malign} memorization under data augmentation is infeasible due to the insufficient capacity of the model for the increased sample size. As a consequence, the network is forced to leverage the correlated nature of the augmentations and as a result learns meaningful features. To complete the picture, a better theory of feature learning in deep neural networks is required to fully understand the origins of this phenomenon.

A Connection between One-Step Regularization and Critic Regularization in Reinforcement Learning
Benjamin Eysenbach,Matthieu Geist,Sergey Levine,Ruslan Salakhutdinov
As with any machine learning problem with limited data, effective offline RL algorithms require careful regularization to avoid overfitting. One-step methods perform regularization by doing just a single step of policy improvement, while critic regularization methods do many steps of policy improvement with a regularized objective. These methods appear distinct. One-step methods, such as advantage-weighted regression and conditional behavioral cloning, truncate policy iteration after just one step. This ``early stopping'' makes one-step RL simple and stable, but can limit its asymptotic performance. Critic regularization typically requires more compute but has appealing lower-bound guarantees. In this paper, we draw a close connection between these methods: applying a multi-step critic regularization method with a regularization coefficient of 1 yields the same policy as one-step RL. While practical implementations violate our assumptions and critic regularization is typically applied with smaller regularization coefficients

, our experiments nevertheless show that our analysis makes accurate, testable predictions about practical offline RL methods (CQL and one-step RL) with commonly-used hyperparameters. Our results that every problem can be solved with a single step of policy improvement, but rather that one-step RL might be competitive with critic regularization on RL problems that demand strong regularization.

Deep Class Conditional Gaussians for Continual Learning

Thomas L Lee,Amos Storkey

The current state of the art for continual learning with frozen, pre-trained embedding networks are simple probabilistic models defined over the embedding space, for example class conditional Gaussians. However, as of yet, in the task-incremental online setting, it has been an open question how to extend these methods to when the embedding function has to be learned from scratch. In this paper, we propose an empirical Bayesian framework that works by storing a fixed number of examples in memory which are used to calculate the posterior of the probabilistic model and a conditional marginal likelihood term used to fit the embedding function. The learning of the embedding function can be interpreted as using a variant of experience replay, which is a highly performative method for continual learning. As part of our framework, we decide which examples to store by selecting the subset that minimises the KL divergence between the true posterior and the posterior induced by the subset, which is shown to be necessary to achieve good performance. We demonstrate the performance of our method on a range of task-incremental online settings, including those with overlapping tasks which thus far have been under-explored. Our method outperforms all other methods, including several other replay-based methods, evidencing the potential of our approach.

Unbiased Supervised Contrastive Learning

Carlo Alberto Barbano,Benoit Dufumier,Enzo Tartaglione,Marco Grangetto,Pietro Gori

Many datasets are biased, namely they contain easy-to-learn features that are highly correlated with the target class only in the dataset but not in the true underlying distribution of the data. For this reason, learning unbiased models from biased data has become a very relevant research topic in the last years. In this work, we tackle the problem of learning representations that are robust to biases. We first present a margin-based theoretical framework that allows us to clarify why recent contrastive losses (InfoNCE, SupCon, etc.) can fail when dealing with biased data. Based on that, we derive a novel formulation of the supervised contrastive loss (ϵ-SupInfoNCE), providing more accurate control of the minimal distance between positive and negative samples.
Furthermore, thanks to our theoretical framework, we also propose FairKL, a new debiasing regularization loss, that works well even with extremely biased data. We validate the proposed losses on standard vision datasets including CIFAR10, CIFAR100, and ImageNet, and we assess the debiasing capability of FairKL with ϵ-SupInfoNCE, reaching state-of-the-art performance on a number of biased datasets, including real instances of biases "in the wild".

ReaKE: Contrastive Molecular Representation Learning with Chemical Synthetic Knowledge Graph

Yi Wang,Shuangjia Zheng,Jiahua Rao,Yunan Luo,Yuedong Yang

Molecular representation learning has demonstrated great promise in bridging machine learning and chemical science and in supporting novel chemical discoveries. State-of-the-art methods mostly employ graph neural networks (GNNs) with self-supervised learning (SSL) and extra chemical reaction knowledge to empower the learned embeddings. However, prior works ignore three major issues in modeling reaction data, that is abnormal energy flow, ambiguous embeddings, and sparse embedding space problems. To address these problems, we propose ReaKE, a chemical synthetic knowledge graph-driven pre-training framework for molecular representation learning. We first construct a large-scale chemical synthetic knowledge graph comprising reactants, products and reaction rules. We then propose triplet-level and graph-level contrastive learning strategies to jointly optimize the knowled ge graph and molecular embeddings. Representations learned by ReaKE can capture intermolecular relationships reflected in the semantic knowledge graph and molecular structures. By comparing with other state-of-the-art methods, we show that ReaKE can achieve competitive performance on the reaction prediction pretext task and the learned representations transfer well to various downstream tasks, including reaction classification, yield prediction, and molecule property prediction. Further visualization shows that the learned representations can capture the fine-grained differences both between reactions and between molecules.

Graph MLP-Mixer

Xiaoxin He,Bryan Hooi,Thomas Laurent,Adam Perold,Yann LeCun,Xavier Bresson

Graph Neural Networks (GNNs) have shown great potential in the field of graph representation learning. Standard GNNs define a local message-passing mechanism which propagates information over the whole graph domain by stacking multiple layers. This paradigm suffers from two major limitations, over-squashing and poor long-range dependencies, that can be solved using global attention but significantly increases the computational cost to quadratic complexity. In this work, we consider an alternative approach to overcome these structural limitations while keeping a low complexity cost. Motivated by the recent MLP-Mixer architecture introduced in computer vision, we propose to generalize this network to graphs. This GNN model, namely Graph MLP-Mixer, can make long-range connections without over-squashing or high complexity due to the mixer layer applied to the graph patches extracted from the original graph. As a result, this architecture exhibits promising results when comparing standard GNNs vs. Graph MLP-Mixers on benchmark graph datasets.

Learning to Register Unbalanced Point Pairs

Kanghee Lee,Junha Lee,Jaesik Park

Point cloud registration methods can effectively handle large-scale, partially overlapping point cloud pairs. Despite its practicality, matching the unbalanced pairs in terms of spatial extent and density has been overlooked and rarely studied. We present a novel method, dubbed UPPNet, for Unbalanced Point cloud Pair registration. We propose to incorporate a hierarchical framework that effectively finds inlier correspondences by gradually reducing search space. The proposed method first predicts subregions within target point cloud that are likely to be overlapped with query. Then following super-point matching and fine-grained refinement modules predict accurate inlier correspondences between the target and query. Additional geometric constraints are applied to refine the correspondences that satisfy spatial compatibility. The proposed network can be trained in an end-to-end manner, predicting the accurate rigid transformation with a single forward pass. To validate the efficacy of the proposed method, we create a carefully designed benchmark, named KITTI-UPP dataset, by augmenting the KITTI odometry dataset. Extensive experiments reveal that the proposed method not only outperforms state-of-the-art point cloud registration methods by large margins on KITTI-UPP benchmark, but also achieves competitive results on the standard pairwise registration benchmark including 3DMatch, 3DLoMatch, ScanNet, and KITTI, thus showing the applicability of our method on various datasets. The source code and dataset will be publicly released.

On Feature Diversity in Energy-based Models

Firas Laakom,Jenni Raitoharju,Alexandros Iosifidis,Moncef Gabbouj

Energy-based learning is a powerful learning paradigm that encapsulates various discriminative and generative approaches. An energy-based model (EBM) is typically formed of inner-model(s) that learn a combination of the different features to generate an energy mapping for each input configuration. In this paper, we focus on the diversity of the produced feature set. We extend the probably approximately correct (PAC) theory of EBMs and analyze the effect of redundancy reduction on the performance of EBMs. We derive generalization bounds for various learning contexts, i.e., regression, classification, and implicit regression, with different energy functions and we show that indeed reducing redundancy of the featu re set can consistently decrease the gap between the true and empirical expectation of the energy and boosts the performance of the model.

****

Physics Model-based Autoencoding for Magnetic Resonance Fingerprinting

Juyeon Heo,Pingfan Song,Weiyang Liu,Adrian Weller

Magnetic Resonance Fingerprinting (MRF) is a promising paradigm to achieve fast quantitative Magnetic Resonance Imaging (QMRI). However, current MRF methods suffer from slow imaging speeds and poor generalization performance on radio frequency pulse sequences generated with varied settings. To address this challenging task, we propose a novel model-based MRF method that learns better representations by integrating a fast and differentiable MRI physics model as causal regularization. The proposed approach adopts a supervised auto-encoder framework consisting of an encoder and a decoder, where the encoder predicts the target tissue properties (anti-causal task) and the decoder reconstructs the inputs (causal task). Specifically, the encoder embeds high-dimensional MRF time sequences to a low-dimensional tissue property space, while the decoder exploits an MRI physics model to reconstruct the input signals using the estimated tissue properties and associated MRI settings. The causal regularization induced by the decoder improves the generalization performance and uniform stability of the approach, leading to the best performance on tissue property estimation, outperforming state-of-the-art competing methods.

Compositional Prompt Tuning with Motion Cues for Open-vocabulary Video Relation Detection

Kaifeng Gao,Long Chen,Hanwang Zhang,Jun Xiao,Qianru Sun

Prompt tuning with large-scale pretrained vision-language models empowers open-vocabulary prediction trained on limited base categories, e.g., object classification and detection. In this paper, we propose compositional prompt tuning with motion cues: an extended prompt tuning paradigm for compositional predictions of video data. In particular, we present Relation Prompt (RePro) for Open-vocabulary Video Visual Relation Detection (Open-VidVRD), where conventional prompt tuning is easily biased to certain subject-object combinations and motion patterns. To this end, RePro addresses the two technical challenges of Open-VidVRD: 1) the prompt tokens should respect the two different semantic roles of subject and object, and 2) the tuning should account for the diverse spatiotemporal motion patterns of the subject-object compositions. Our RePro achieves a new state-of-the-art performance on two VidVRD benchmarks of not only the base training object and predicate categories, but also the unseen ones. Extensive ablations also demonstrate the effectiveness of the proposed compositional and multi-mode design of prompt. Code is available at https://github.com/Dawn-LX/OpenVoc-VidVRD.

Multi-objective optimization via equivariant deep hypervolume approximation

Jim Boelrijk,Bernd Ensing,Patrick Forré

Optimizing multiple competing objectives is a common problem across science and industry. The inherent inextricable trade-off between those objectives leads one to the task of exploring their Pareto front. A meaningful quantity for the purpose of the latter is the hypervolume indicator, which is used in Bayesian Optimization (BO) and Evolutionary Algorithms (EAs). However, the computational complexity for the calculation of the hypervolume scales unfavorably with increasing number of objectives and data points, which restricts its use in those common multi-objective optimization frameworks.

To overcome these restrictions, previous work has focused on approximating the hypervolume using deep learning. In this work, we propose a novel deep learning architecture to approximate the hypervolume function, which we call DeepHV. For better sample efficiency and generalization, we exploit the fact that the hypervolume is scale equivariant in each of the objectives as well as permutation invariant w.r.t. both the objectives and the samples, by using a deep neural network that is equivariant w.r.t. the combined group of scalings and permutations. We show through an ablation study that including these symmetries leads to significantly improved model accuracy.

We evaluate our method against exact, and approximate hypervolume methods in terms of accuracy, computation time, and generalization. We also apply and compare our methods to state-of-the-art multi-objective BO methods and EAs on a range of synthetic and real-world benchmark test cases. The results show that our methods are promising for such multi-objective optimization tasks.

Conditional Execution Of Cascaded Models Improves The Accuracy-Efficiency Trade-Off

Luzian Lebovitz,Lukas Cavigelli,Michele Magno,Lorenz K Muller

The compute effort required to perform inference on state-of-the-art deep learning models is ever growing. Practical applications are commonly limited to a certain cost per inference. Cascades of pretrained models with conditional execution address these requirements based on the intuition that some inputs are easy enough that they can be processed correctly by a small model allowing for an early exit. If the small model is not sufficiently confident in its prediction, the input is passed on to a larger model. The selection of the confidence threshold allows to trade off compute effort against accuracy. In this work, we explore the effective design of model cascades, and thoroughly evaluate the impact on the accuracy-compute trade-off. We find that they not only interpolate favorably between pretrained models, but that this trade-off curve commonly outperforms single models. This allows us to redefine most of the ImageNet Pareto front already with 2-model cascades, achieving an average reduction in compute effort at equal accuracy of almost 3.1x above 86% and more than 1.9x between 80% and 86% top-1 accuracy. We confirm the wide applicability and effectiveness of the method on the GLUE benchmark. We release the code to reproduce our experiments in the supplementary material and use only publicly available models and datasets.

Adversarial Text to Continuous Image Generation

Kilichbek Haydarov,Aashiq Muhamed,Jovana Lazarevic,Ivan Skorokhodov,Xiaoqian Shen,Chamuditha Jayanga Galappaththige,Mohamed Elhoseiny

Implicit Neural Representations (INR) provide a natural way to parametrize images as a continuous signal, using an MLP that predicts the RGB color at an (x, y) image location. Recently, it has been demonstrated that high-quality INR-decoders can be designed and integrated with Generative Adversarial Networks (GANs) to facilitate unconditional continuous image generation, that are no longer bounded to a spatial resolution. In this paper, we introduce HyperCGAN, a conceptually simple approach for Adversarial Text to Continuous Image Generation based on HyperNetworks, which are networks that produce parameters for another network. HyperCGAN utilizes HyperNetworks to condition an INR-based GAN model on text. In this setting, the generator and the discriminator weights are controlled by their corresponding HyperNetworks, which modulate weight parameters using the provided text query. We propose an effective Word-level hyper-modulation Attention operator, termed WhAtt, which encourages grounding words to independent pixels at input (x, y) coordinates. To the best of our knowledge, our work is the first that explores text-controllable continuous image generation. We conduct comprehensive experiments on the COCO 256x256, CUB 256x256, and the ArtEmis 256x256 benchmark which we introduce in this paper. HyperCGAN improves the performance of text-controllable image generators over the baselines while significantly reducing the gap between text-to-continuous and text-to-discrete image synthesis. Additionally, we show that HyperCGAN, when conditioned on text, retains the desired properties of continuous generative models (e.g., extrapolation outside of image boundaries, accelerated inference of low-resolution images, out-of-the-box superresolution).

Fine-grained Few-shot Recognition by Deep Object Parsing

Ruizhao Zhu,Pengkai Zhu,Samarth Mishra,Venkatesh Saligrama

We propose a new method for fine-grained few-shot recognition via deep object parsing. In our framework, an object is made up of K distinct parts and for each part, we learn a dictionary of templates, which is shared across all instances and categories. An object is parsed by estimating the locations of these K par ts and a set of active templates that can reconstruct the part features. We recognize test instances by comparing its active templates and the relative geometry of its part locations against those of the presented few-shot instances. Our method is end-to-end trainable to learn part templates on-top of a convolutional backbone. To combat visual distortions such as orientation, pose and size, we learn templates at multiple scales, and at test-time parse and match instances across these scales. We show that our method is competitive with the state-of-the-art, and by virtue of parsing enjoys interpretability as well.

****

Can Wikipedia Help Offline Reinforcement Learning?

Machel Reid,Yutaro Yamada,Shixiang Shane Gu

Fine-tuning reinforcement learning (RL) models has been challenging because of a lack of large scale off-the-shelf datasets as well as high variance in transferability among different environments. Recent work has looked at tackling offline RL from the perspective of sequence modeling with improved results as result of the introduction of the Transformer architecture. However, when the model is trained from scratch, it suffers from slow convergence speeds. In this paper, we look to take advantage of this formulation of reinforcement learning as sequence modeling and investigate the transferability of pre-trained sequence models on other domains (vision, language) when finetuned on offline RL tasks (control, games). To this end, we also propose techniques to improve transfer between these domains. Results show consistent performance gains in terms of both convergence speed and reward on a variety of environments, accelerating training by 3-6x and achieving state-of-the-art performance in a variety of tasks using Wikipedia-pretrained and GPT2 language models. We hope that this work not only brings light to the potentials of leveraging generic sequence modeling techniques and pre-trained models for RL, but also inspires future work on sharing knowledge between generative modeling tasks of completely different domains.

****

Lightweight Equivariant Graph Representation Learning for Protein Engineering

Bingxin Zhou,Outongyi Lv,Kai Yi,Xinye Xiong,Pan Tan,Liang Hong,Yu Guang Wang

This work tackles the issue of directed evolution in computational protein design that makes accurate predictions of the function of a protein mutant. We design a lightweight pre-training graph neural network model for multi-task protein representation learning from its 3D structure. Rather than reconstructing and optimizing the protein structure, the trained model recovers the amino acid types and key properties of the central residues from a given noisy three-dimensional local environment. On the prediction task for the higher-order mutants, where many amino acid sites of the protein are mutated, the proposed training strategy achieves remarkably higher performance by 20% improvement at the cost of requiring less than 1% of computational resources that are required by popular transformer-based state-of-the-art deep learning models for protein design.

****

DiffusER: Diffusion via Edit-based Reconstruction

Machel Reid,Vincent Josua Hellendoorn,Graham Neubig

In text generation, models that generate text from scratch one token at a time are currently the dominant paradigm. Despite being performant, these models lack the ability to revise existing text, which limits their usability in many practical scenarios. We look to address this, with DiffusER (Diffusion via Edit-based Reconstruction), a new edit-based generative model for text based on denoising diffusion models -- a class of models that use a Markov chain of denoising steps to incrementally generate data. DiffusER is not only a strong generative model in general, rivalling autoregressive models on several tasks spanning machine translation, summarization, and style transfer; it can also perform other varieties of generation that standard autoregressive models are not well-suited for. For instance, we demonstrate that DiffusER makes it possible for a user to condition generation on a prototype, or an incomplete sequence, and continue revising based on previous edit steps.

Modeling Temporal Data as Continuous Functions with Process Diffusion

Marin Biloš,Kashif Rasul,Anderson Schneider,Yuriy Nevmyvaka,Stephan Günnemann

Temporal data like time series are often observed at irregular intervals which is a challenging setting for the existing machine learning methods. To tackle this problem, we view such data as samples from some underlying continuous function. We then define a diffusion-based generative model that adds noise from a predefined stochastic process while preserving the continuity of the resulting underlying function. A neural network is trained to reverse this process which allows us to sample new realizations from the learned distribution. We define suitable stochastic processes as noise sources and introduce novel denoising and score-matching models on processes. Further, we show how to apply this approach to the multivariate probabilistic forecasting and imputation tasks. Through our extensive experiments, we demonstrate that our method outperforms previous models on synthetic and real-world datasets.

****

KeyCLD: Learning Constrained Lagrangian Dynamics in Keypoint Coordinates from Images

Rembert Daems,Jeroen Taets,Francis wyffels,Guillaume Crevecoeur

We present KeyCLD, a framework to learn Lagrangian dynamics from images. Learned keypoint representations derived from images are directly used as positional state vector for jointly learning constrained Lagrangian dynamics. KeyCLD is trained unsupervised end-to-end on sequences of images. Our method explicitly models the mass matrix, potential energy and the input matrix, thus allowing energy based control. We demonstrate learning of Lagrangian dynamics from images on the dm_control pendulum, cartpole and acrobot environments, wether they are unactuated, underactuated or fully actuated. Trained models are able to produce long-term video predictions, showing that the dynamics are accurately learned. Our method strongly outperforms recent works on learning Lagrangian or Hamiltonian dynamics from images. The benefits of including a Lagrangian prior and prior knowledge of a constraint function is further investigated and empirically evaluated.

****

DynaMS: Dyanmic Margin Selection for Efficient Deep Learning

Jiaxing Wang,Yong Li,Jingwei Zhuo,Xupeng Shi,WEIZHONG ZHANG,Lixing Gong,Tong Tao,Pengzhang Liu,Yongjun Bao,Weipeng Yan

The great success of deep learning is largely driven by training over-parameterized models on massive datasets. To avoid excessive computation, extracting and training only on the most informative subset is drawing increasing attention. Nevertheless, it is still an open question how to select such a subset on which the model trained generalizes on par with the full data. In this paper, we propose dynamic margin selection (DynaMS). DynaMS leverages the distance from candidate samples to the classification boundary to construct the subset, and the subset is dynamically updated during model training. We show that DynaMS converges with large probability, and for the first time show both in theory and practice that dynamically updating the subset can result in better generalization over previous works. To reduce the additional computation incurred by the selection, a light parameter sharing proxy (PSP) is designed. PSP is able to faithfully evaluate instances with respect to the current model, which is necessary for dynamic selection. Extensive analysis and experiments demonstrate the superiority of the proposed approach in data selection against many state-of-the-art counterparts on benchmark datasets.

TANGOS: Regularizing Tabular Neural Networks through Gradient Orthogonalization and Specialization

Alan Jeffares,Tennison Liu,Jonathan Crabbé,Fergus Imrie,Mihaela van der Schaar

Despite their success with unstructured data, deep neural networks are not yet a panacea for structured tabular data. In the tabular domain, their efficiency crucially relies on various forms of regularization to prevent overfitting and provide strong generalization performance. Existing regularization techniques include broad modelling decisions such as choice of architecture, loss functions, and optimization methods. In this work, we introduce Tabular Neural Gradient Orthogonalization and Specialization (TANGOS), a novel framework for regularization in the tabular setting built on latent unit attributions. The gradient attribution of an activation with respect to a given input feature suggests how the neuron attends to that feature, and is often employed to interpret the predictions of deep networks. In TANGOS, we take a different approach and incorporate neuron attributions directly into training to encourage orthogonalization and specialization of latent attributions in a fully-connected network. Our regularizer encourages neurons to focus on sparse, non-overlapping input features and results in a set of diverse and specialized latent units. In the tabular domain, we demonstrate that our approach can lead to improved out-of-sample generalization performance, outperforming other popular regularization methods. We provide insight into why our regularizer is effective and demonstrate that TANGOS can be applied jointly with existing methods to achieve even greater generalization performance.

How does Uncertainty-aware Sample-selection Help Decision against Action Noise?

Xingrui Yu,Bo Han,Ivor Tsang

Learning from imperfect demonstrations has become a vital problem in imitation learning (IL). Since the assumption of the collected demonstrations are optimal cannot always hold in real-world tasks, many previous works considers learning from a mixture of optimal and sub-optimal demonstrations. On the other hand, video records can be hands-down demonstrations in practice. Leveraging such demonstrations requires labors to output action for each frame. However, action noise always occurs when the labors are not domain experts, or meet confusing state frames. Previous IL methods can be vulnerable to such demonstrations with state-dependent action noise. To tackle this problem, we propose a robust learning paradigm called USN, which bridges Uncertainty-aware Sample-selection with Negative learning. First, IL model feeds forward all demonstration data and estimates its predictive uncertainty. Then, we select large-loss samples in the light of the uncertainty measures. Next, we update the model parameters with additional negative learning on the selected samples. Empirical results on Box2D tasks and Atari games demonstrate that USN improves the performance of state-of-the-art IL methods by more than 10% under a large portion of action noise.

Inversely Eliciting Numerical Reasoning in Language Models via Solving Linear Systems

Fan Zhou,Haoyu Dong,Qian Liu,Zhoujun Cheng,Shi Han,Dongmei Zhang

Numerical reasoning over natural language has been a long-standing goal for the research community. However, recent language models have proven difficult to reliably generalize to a broad range of numbers, although they have shown proficiency in reasoning over common and simple numbers. In this paper, we propose a novel method to elicit and exploit the numerical reasoning knowledge hidden in pre-trained language models using simple anchor numbers. Concretely, we first leverage simple numbers as anchors to probe the implicitly inferred arithmetic expressions from language models, and then explicitly apply the expressions on complex numbers to get corresponding answers. To inversely elicit arithmetic expressions, we transform and formulate the task as an analytically solvable linear system. Experimental results on several numerical reasoning benchmarks demonstrate that our approach is highly effective. More importantly, our approach works in the inference phase without extra model training, making it highly portable and achieving significant and consistent performance benefits across a variety of language models in zero-shot, few-shot, and fine-tuning scenarios.

Model-based Causal Bayesian Optimization

Scott Sussex,Anastasia Makarova,Andreas Krause

How should we intervene on an unknown structural equation model to maximize a downstream variable of interest? This setting, also known as causal Bayesian optimization (CBO), has important applications in medicine, ecology, and manufacturing. Standard Bayesian optimization algorithms fail to effectively leverage the underlying causal structure. Existing CBO approaches assume noiseless measurements and do not come with guarantees. We propose the {\em model-based causal Bayesian optimization algorithm (MCBO)} that learns a full system model instead of only modeling intervention-reward pairs. MCBO propagates epistemic uncertainty about the causal mechanisms through the graph and trades off exploration and exploitation via the optimism principle. We bound its cumulative regret, and obtain the first non-asymptotic bounds for CBO. Unlike in standard Bayesian optimization, our acquisition function cannot be evaluated in closed form, so we show how the reparameterization trick can be used to apply gradient-based optimizers. The resulting practical implementation of MCBO compares favorably with state-of-the-art approaches empirically.

Targeted Attacks on Timeseries Forecasting

Yuvaraj Govindarajulu,Avinash Amballa,Pavan Kulkarni,Manojkumar Parmar

Real-world deep learning models built for Time Series Forecasting are used in several critical applications from medical devices to the security domain. Many previous works have shown how deep learning models are prone to adversarial attacks and studied their vulnerabilities. However, the vulnerabilities of time series models for forecasting due to adversarial inputs are not extensively studied. While attack on a forecasting model might be intended to deteriorate the performance of the model, it is more effective, if the attack is focused on a specific impact on the model's output. In this paper, we propose a novel formulation of Directional, Amplitudinal, and Temporal targeted adversarial attacks on time series forecasting models. These targeted attacks create a specific impact or hide a potential high-impact area on the forecasting output. We use the existing adversarial attack techniques from the computer vision domain and adapt them for time series. Additionally, we propose a modified version of the Auto Projected Gradient Descent attack for targeted attacks. We explore the impact of the proposed targeted attacks against untargeted attacks. We use KS-Tests to statistically prove the impact of the attack. Our experimental results demonstrate how targeted attacks on time series models are practical and are more powerful in terms of statistical similarity. It is, hence difficult to detect through statistical methods. We believe that this work opens a new paradigm in the time series forecasting domain and is an important consideration for developing better defenses.

QuAFL: Federated Averaging Made Asynchronous and Communication-Efficient

Hossein Zakerinia,Shayan Talaei,Giorgi Nadiradze,Dan Alistarh

Federated Learning (FL) is an emerging paradigm to enable the large-scale distributed training of machine learning models, while still providing privacy guarantees.

In this work, we address two of the main practical challenges when scaling federated optimization to large node counts: the need for tight synchronization between the central authority and individual computing nodes, and the large communication cost of transmissions between the central server and clients.

Specifically, we present a new variant of the classic federated averaging (FedAvg) algorithm, which supports both asynchronous communication and communication compression. We provide a new analysis technique showing that, in spite of these system relaxations, our algorithm can provide similar convergence to FedAvg in some parameter regimes.

On the experimental side, we show that our algorithm ensures fast convergence for standard federated tasks.

Random Matrix Analysis to Balance between Supervised and Unsupervised Learning under the Low Density Separation Assumption

Vasilii Feofanov,Malik Tiomoko,Aladin Virmaux

We propose a theoretical framework to analyze semi-supervised classification under the low density separation assumption in a high-dimensional regime. In particular, we introduce QLDS, a linear classification model, where the low density separation assumption is implemented via quadratic margin maximization.

The algorithm has an explicit solution with rich theoretical properties, and we show that particular cases of our algorithm are the least-square support vector machine in the supervised case, the spectral clustering in the fully unsupervised regime, and a class of semi-supervised graph-based approaches. As such, QLDS e stablishes a smooth bridge between these supervised and unsupervised learning methods. Using recent advances in the random matrix theory, we formally derive a theoretical evaluation of the classification error in the asymptotic regime.

As an application, we derive a hyperparameter selection policy that finds the best balance between the supervised and the unsupervised terms of our learning criterion.

Finally, we provide extensive illustrations of our framework, as well as an experimental study on several benchmarks to demonstrate that QLDS, while being computationally more efficient, improves over cross-validation for hyperparameter selection, indicating a high promise of the usage of random matrix theory for semi-supervised model selection.

Learning to Solve Constraint Satisfaction Problems with Recurrent Transformer

Zhun Yang,Adam Ishay,Joohyung Lee

Constraint satisfaction problems (CSPs) are about finding values of variables that satisfy the given constraints. We show that Transformer extended with recurrence is a viable approach to learning to solve CSPs in an end-to-end manner, having clear advantages over state-of-the-art methods such as Graph Neural Networks, SATNet, and some neuro-symbolic models. With the ability of Transformer to handle visual input, the proposed Recurrent Transformer can straightforwardly be applied to visual constraint reasoning problems while successfully addressing the symbol grounding problem. We also show how to leverage deductive knowledge of discrete constraints in the Transformer's inductive learning to achieve sample-efficient learning and semi-supervised learning for CSPs.

MARLlib: Extending RLlib for Multi-agent Reinforcement Learning

Siyi Hu,Yifan Zhong,Minquan Gao,Weixun Wang,Hao Dong,Zhihui Li,Xiaodan Liang,Yaodong Yang,Xiaojun Chang

Despite the fast development of multi-agent reinforcement learning (MARL) methods, there is a lack of commonly-acknowledged baseline implementation and evaluation platforms. As a result, an urgent need for MARL researchers is to develop an integrated library suite, similar to the role of RLlib in single-agent RL, that delivers reliable MARL implementation and replicable evaluation in various bechmarks. To fill such a research gap, in this paper, we propose Multi-Agent RLlib (MARLlib), a comprehensive MARL algorithm library that facilitates RLlib for solving multi-agent problems. With a novel design of agent-level distributed dataflow, MARLlib manages to unify tens of algorithms, including different types of independent learning, centralized critic, and value decomposition methods; this leads to a highly composable integration of MARL algorithms that are not possible to unify before. Furthermore, MARLlib goes beyond current work by integrating diverse environment interfaces and providing flexible parameter sharing strategies; this allows to create versatile solutions to cooperative, competitive, and mixed tasks with minimal code modifications for end users. A plethora of experiments are conducted to substantiate the correctness of our implementation, based on which we further derive new insights on the relationship between the performance and the design of algorithmic components. With MARLlib, we expect researchers to be able to tackle broader real-world multi-agent problems with trustworthy solutions. Our code\footnote{\url{https://github.com/ICLR2023Paper4242/MARLlib}} and documentation\footnote{\url{https://iclr2023marllib.readthedocs.io/}} are released for reference.

Improving the imputation of missing data with Markov Blanket discovery

Yang Liu,Anthony Constantinou

The process of imputation of missing data typically relies on generative and regression models. These approaches often operate on the unrealistic assumption that all of the data features are directly related with one another, and use all of the available features to impute missing values. In this paper, we propose a novel Markov Blanket discovery approach to determine the optimal feature set for a given variable by considering both observed variables and missingness of partially observed variables to account for systematic missingness. We then incorporat e this method to the learning process of the state-of-the-art MissForest imputation algorithm, such that it informs MissForest which features to consider to impute missing values, depending on the variable the missing value belongs to. Experiments across different case studies and multiple imputation algorithms show that the proposed solution improves imputation accuracy, both under random and systematic missingness.

Boosting the Cycle Counting Power of Graph Neural Networks with I^2-GNNs
Yinan Huang,Xingang Peng,Jianzhu Ma,Muhan Zhang

Message Passing Neural Networks (MPNNs) are a widely used class of Graph Neural Networks (GNNs). The limited representational power of MPNNs inspires the study of provably powerful GNN architectures. However, knowing one model is more powerful than another gives little insight about what functions they can or cannot express. It is still unclear whether these models are able to approximate specific functions such as counting certain graph substructures, which is essential for applications in biology, chemistry and social network analysis. Motivated by this, we propose to study the counting power of Subgraph MPNNs, a recent and popular class of powerful GNN models that extract rooted subgraphs for each node, assign the root node a unique identifier and encode the root node's representation within its rooted subgraph. Specifically, we prove that Subgraph MPNNs fail to count more-than-4-cycles at node level, implying that node representations cannot correctly encode the surrounding substructures like ring systems with more than four atoms. To overcome this limitation, we propose I^2-GNNs to extend Subgraph MPNNs by assigning different identifiers for the root node and its neighbors in each subgraph. I^2-GNNs' discriminative power is shown to be strictly stronger than Subgraph MPNNs and partially stronger than the 3-WL test. More importantly, I^2-GNNs are proven capable of counting all 3, 4, 5 and 6-cycles, covering common substructures like benzene rings in organic chemistry, while still keeping linear complexity. To the best of our knowledge, it is the first linear-time GNN model that can count 6-cycles with theoretical guarantees. We validate its counting power in cycle counting tasks and demonstrate its competitive performance in molecular prediction benchmarks.

Energy Consumption-Aware Tabular Benchmarks for Neural Architecture Search
Pedram Bakhtiarifard,Christian Igel,Raghavendra Selvan

The demand for large-scale computational resources for Neural Architecture Search (NAS) has been lessened by tabular benchmarks for NAS. Evaluating NAS strategies is now possible on extensive search spaces and at a moderate computational cost. But so far, NAS has mainly focused on maximising performance on some hold-out validation/test set. However, energy consumption is a partially conflicting objective that should not be neglected. We hypothesise that constraining NAS to include the energy consumption of training the models could reveal a sub-space of undiscovered architectures that are more computationally efficient with a smaller carbon footprint. To support the hypothesis, an existing tabular benchmark for NAS is augmented with the energy consumption of each architecture. We then perform multi-objective optimisation that includes energy consumption as an additional objective. We demonstrate the usefulness of multi-objective NAS for uncovering the trade-off between performance and energy consumption as well as for finding more energy-efficient architectures. The updated tabular benchmark is open-sourced to encourage the further exploration of energy consumption-aware NAS.

Fundamental Limits in Formal Verification of Message-Passing Neural Networks
Marco Sälzer,Martin Lange

Output reachability and adversarial robustness are among the most relevant safety properties of neural networks.
We show that in the context of Message Passing Neural Networks (MPNN), a common Graph Neural Network (GNN) model,
formal verification is impossible. In particular, we show that output reachability of graph-classifier MPNN,
working over graphs of unbounded size, non-trivial degree and sufficiently expre

ssive node labels, cannot be verified formally: there is no algorithm that answers correctly (with yes or no), given an MPNN, whether there exists some valid input to the MPNN such that the corresponding output satisfies a given specification. However, we also show that output reachability and adversarial robustness of node-classifier MPNN can be verified formally when a limit on the degree of input graphs is given a priori. We discuss the implications of these results, for the purpose of obtaining a complete picture of the principle possibility to formally verify GNN, depending on the expressiveness of the involved GNN models and input-output specifications.

Score Matching via Differentiable Physics

Benjamin Holzschuh,Simona Vegetti,Nils Thuerey

Diffusion models based on stochastic differential equations (SDEs) gradually perturb a data distribution $p(\mathbf{x})$ over time by adding noise to it. A neural network is trained to approximate the score $\nabla_\mathbf{x} \log p_t(\mathbf{x})$ at time t, which can be used to reverse the corruption process. In this paper, we focus on learning the score field that is associated with the time evolution according to a physics operator in the presence of natural non-deterministic physical processes like diffusion. A decisive difference to previous methods is that the SDE underlying our approach transforms the state of a physical system to another state at a later time. For that purpose, we replace the drift of the underlying SDE formulation with a differentiable simulator or a neural network approximation of the physics. At the core of our method, we optimize the so-called probability flow ODE to fit a training set of simulation trajectories inside an ODE solver and solve the reverse-time SDE for inference to sample plausible trajectories that evolve towards a given end state. We demonstrate the competitiveness of our approach for different challenging inverse problems.

QUIC-FL: : Quick Unbiased Compression for Federated Learning

Ran Ben-Basat,Shay Vargaftik,Amit Portnoy,Gil Einziger,Yaniv Ben-Itzhak,Michael Mitzenmacher

Distributed Mean Estimation (DME) is a fundamental building block in communication efficient federated learning. In DME, clients communicate their lossily compressed gradients to the parameter server, which estimates the average and updates the model.

State of the art DME techniques apply either unbiased quantization methods, resulting in large estimation errors, or biased quantization methods, where unbiasing the result requires that the server decodes each gradient individually, which markedly slows the aggregation time.

In this paper, we propose QUIC-FL, a DME algorithm that achieves the best of all worlds. QUIC-FL is unbiased, offers fast aggregation time, and is competitive with the most accurate (slow aggregation) DME techniques. To achieve this, we formalize the problem in a novel way that allows us to use standard solvers to design near-optimal unbiased quantization schemes.

FedMEKT: Split Multimodal Embedding Knowledge Transfer in Federated Learning

Huy Quang Le,Minh N. H. Nguyen,Choong Seon Hong

Federated Learning (FL) enables a decentralized machine-learning paradigm to collaboratively train a generalized global model without sharing users' private data. However, most existing FL approaches solely utilize single-modal data, thus limiting the systems for exploiting valuable multimodal data in future personalized applications. Furthermore, most FL methods still rely on the labeled data at the client side, which is limited in real-world applications due to the inability of data self-annotation from users. To leverage the representations from different modalities in FL, we propose a novel multimodal FL framework with a semi-supervised learning setting. Specifically, we develop the split multimodal embedding knowledge transfer mechanism in federated learning, namely, FedMEKT, which en ables the personalized and generalized multimodal representations exchange between server and clients using a small multimodal proxy dataset. Hence, FedMEKT iteratively updates the generalized encoders from the collaborative embedding knowledge of each client, such as modality-averaging representations. Thereby, a generalized encoder could guide personalized encoders to enhance the generalization abilities of client models; afterward, personalized classifiers could be trained using the proxy labeled data to perform supervised tasks. Through the extensive experiments on three multimodal human activity recognition tasks, we demonstrate that FedMEKT achieves superior performance in both local and global encoder models on linear evaluation and guarantees user privacy for personal data and model parameters.

Short-Term Memory Convolutions

Grzegorz Stefa■ski,Krzysztof Arendt,Pawe■ Daniluk,Bart■omiej Jasik,Artur Szumaczuk

The real-time processing of time series signals is a critical issue for many real-life applications. The idea of real-time processing is especially important in audio domain as the human perception of sound is sensitive to any kind of disturbance in perceived signals, especially the lag between auditory and visual modalities. The rise of deep learning (DL) models complicated the landscape of signal processing. Although they often have superior quality compared to standard DSP methods, this advantage is diminished by higher latency. In this work we propose novel method for minimization of inference time latency and memory consumption, called Short-Term Memory Convolution (STMC) and its transposed counterpart. The main advantage of STMC is the low latency comparable to long short-term memory (LSTM) networks. Furthermore, the training of STMC-based models is faster and more stable as the method is based solely on convolutional neural networks (CNNs). In this study we demonstrate an application of this solution to a U-Net model for a speech separation task and GhostNet model in acoustic scene classification (ASC) task. In case of speech separation we achieved a 5-fold reduction in inference time and a 2-fold reduction in latency without affecting the output quality. The inference time for ASC task was up to 4 times faster while preserving the original accuracy.

End-to-End Speech Synthesis Based on Deep Conditional Schrödinger Bridges

Shoule Wu,Ziqiang Shi

Speech synthesis plays an important role in human-computer interaction. Existing methods mainly employ traditional two-stage pipeline, e.g. text-to-speech and vocoder. In this paper, we propose a system called Schr\"on, which can generate speech waves in an end-to-end mamaner by solving Schr\"odinger bridge problems (SBP). In order to make SBP suitable for speech synthesis, we generalize SBP from two aspects. The first generalization makes it possible to accept condition variables, which are used to control the generated speech, and the second generalization allows it to handle variable-size input. Besides these two generalizations, we propose two techniques to fill the large information gap between text and speech waveforms for generating high-quality voice. The first technique is to use a text-mel joint representation as the conditional input of the conditional SBP. The second one is to use a branch network for the generation of mel scores as a regularization, so that the text features will not be degenerated. Experimental results show that Schr\"on achieves state-of-the-art MOS of 4.52 on public data set LJSpeech. Audio samples are available at https://schron.github.io/.

LexMAE: Lexicon-Bottlenecked Pretraining for Large-Scale Retrieval

Tao Shen,Xiubo Geng,Chongyang Tao,Can Xu,Xiaolong Huang,Binxing Jiao,Linjun Yang,Daxin Jiang

In large-scale retrieval, the lexicon-weighting paradigm, learning weighted sparse representations in vocabulary space, has shown promising results with high quality and low latency. Despite it deeply exploiting the lexicon-representing capability of pre-trained language models, a crucial gap remains between language modeling and lexicon-weighting retrieval -- the former preferring certain or low-

entropy words whereas the latter favoring pivot or high-entropy words -- becoming the main barrier to lexicon-weighting performance for large-scale retrieval. To bridge this gap, we propose a brand-new pre-training framework, lexicon-bottlenecked masked autoencoder (LexMAE), to learn importance-aware lexicon representations. Essentially, we present a lexicon-bottlenecked module between a normal language modeling encoder and a weakened decoder, where a continuous bag-of-words bottleneck is constructed to learn a lexicon-importance distribution in an unsupervised fashion. The pre-trained LexMAE is readily transferred to the lexicon-weighting retrieval via fine-tuning. On the ad-hoc retrieval benchmark, MS-Marco, it achieves 42.6% MRR@10 with 45.8 QPS for the passage dataset and 44.4% MRR@100 with 134.8 QPS for the document dataset, by a CPU machine. And LexMAE shows state-of-the-art zero-shot transfer capability on BEIR benchmark with 12 datasets.

A GNN-Guided Predict-and-Search Framework for Mixed-Integer Linear Programming
Qingyu Han,Linxin Yang,Qian Chen,Xiang Zhou,Dong Zhang,Akang Wang,Ruoyu Sun,Xiaodong Luo
Mixed-integer linear programming (MILP) is widely employed for modeling combinatorial optimization problems. In practice, similar MILP instances with only coefficient variations are routinely solved, and machine learning (ML) algorithms are capable of capturing common patterns across these MILP instances. In this work, we combine ML with optimization and propose a novel predict-and-search framework for efficiently identifying high-quality feasible solutions. Specifically, we first utilize graph neural networks to predict the marginal probability of each variable, and then search for the best feasible solution within a properly defined ball around the predicted solution. We conduct extensive experiments on public datasets, and computational results demonstrate that our proposed framework achieves 51.1% and 9.9% performance improvements to MILP solvers SCIP and Gurobi on primal gaps, respectively.
****
Parameter Averaging for SGD Stabilizes the Implicit Bias towards Flat Regions
Atsushi Nitanda,Ryuhei Kikuchi,Shugo Maeda
Stochastic gradient descent is a workhorse for training deep neural networks due to its excellent generalization performance. Several studies demonstrated this success is attributed to the implicit bias of the method that prefers a flat minimum and developed new methods based on this perspective. Recently, Izmailov et al. (2018) empirically observed that an averaged stochastic gradient descent with a large step size can bring out the implicit bias more effectively and can converge more stably to a flat minimum than the vanilla stochastic gradient descent. In our work, we theoretically justify this observation by showing that the averaging scheme improves the bias-optimization tradeoff coming from the stochastic gradient noise: a large step size amplifies the bias but makes convergence unstable, and vice versa. Specifically, we show that the averaged stochastic gradient descent can get closer to a solution of a penalized objective on the sharpness than the vanilla stochastic gradient descent using the same step size under certain conditions. In experiments, we verify our theory and demonstrate this learning scheme significantly improves performance.
****
On Explaining Neural Network Robustness with Activation Path
Ziping Jiang
Despite their verified performance, neural networks are prone to be misled by maliciously designed adversarial examples. This work investigates the robustness of neural networks from the activation pattern perspective. We find that despite the complex structure of the deep neural network, most of the neurons provide locally stable contributions to the output, while the minority, which we refer to as float neurons, can greatly affect the prediction. We decompose the computational graph of the neural network into the fixed path and float path and investigate their role in generating adversarial examples. Based on our analysis, we categorize the vulnerable examples into Lipschitz vulnerability and float neuron vulnerability. We show that the boost of robust accuracy from randomized smoothing is the result of correcting the latter. We then propose an SC-RFP (smoothed clas

sifier with repressed float path) to further reduce the instability of the float neurons and show that our result can provide a higher certified radius as well as accuracy.

****

Flareon: Stealthy Backdoor Injection via Poisoned Augmentation

Tianrui Qin,Xitong Gao,Xianghuan He,Yiren Zhao,Kejiang Ye,Cheng-zhong Xu

Open software supply chain attacks, once successful, can exact heavy costs in mission-critical applications. As open-source ecosystems for deep learning flourish and become increasingly universal, they present attackers previously unexplored avenues to code-inject malicious backdoors in deep neural network models. This paper proposes Flareon, a simple, stealthy, mostly-free, and yet effective backdoor injection payload that specifically targets the data augmentation pipeline with motion-based triggers. Flareon neither alters ground-truth labels, nor modifies the training loss objective, nor does it assume prior knowledge of the victim model architecture and training hyperparameters. By learning multiple triggers for targets simultaneously, it can even produce models that learn target-conditional (or ``any2any'') backdoors. Model trained under Flareon exhibits higher attack success rates for any target choices and better clean accuracies than competing attacks that not only seize greater capabilities, but also assume more restrictive attack targets. We also demonstrate the effectiveness of Flareon against recent defenses. Flareon is fully open-source and available online to the deep learning community.

Dimensionless instance segmentation by learning graph representations of point clouds

Robert Kiewisz,Tristan Bepler

Point clouds are an increasingly common spatial data modality, being produced by sensors used in robotics and self-driving cars, and as natural intermediate representations of objects in microscopy and other bioimaging domains (e.g., cell locations over time, or filaments, membranes, or organelle boundaries in cryo-electron micrographs or tomograms). However, semantic and instance segmentation of this data remains challenging due to the complex nature of objects in point clouds. Especially in bioimaging domains where objects are often large and can be intersecting or overlapping. Furthermore, methods for operating on point clouds should not be sensitive to the specific orientation or translation of the point cloud, which is often arbitrary. Here, we frame the point cloud instance segmentation problem as a graph learning problem in which we seek to learn a function that accepts the point cloud as input and outputs a probability distribution over neighbor graphs in which connected components of the graph correspond to individual object instances. We introduce the Dimensionless Instance Segmentation Transformer (DIST), a deep neural network for spatially invariant instance segmentation of point clouds to solve this point cloud-to-graph problem. DIST uses an SO(n) invariant transformer layer architecture to operate on point clouds of arbitrary dimension and outputs, for each pair of points, the probability that an edge exists between them in the instance graph. We then decode the most likely set of instances using a graph cut. We demonstrate the power of DIST for the segmentation of biomolecules in cryo-electron micrographs and tomograms, far surpassing existing methods for membrane and filament segmentation in empirical evaluation. DIST also applies to scene and object understanding, performing competitively on the ScanNetV2 3D instance segmentation challenge. We anticipate that DIST will underpin a new generation of methods for point cloud segmentation in bioimaging and that our general model and approach will provide useful insights for point cloud segmentation methods in other domains.

****

Structure by Architecture: Structured Representations without Regularization

Felix Leeb,Giulia Lanzillotta,Yashas Annadani,Michel Besserve,Stefan Bauer,Bernhard Schölkopf

We study the problem of self-supervised structured representation learning using autoencoders for downstream tasks such as generative modeling. Unlike most methods which rely on matching an arbitrary, relatively unstructured, prior distribu tion for sampling, we propose a sampling technique that relies solely on the independence of latent variables, thereby avoiding the trade-off between reconstruction quality and generative performance typically observed in VAEs. We design a novel autoencoder architecture capable of learning a structured representation without the need for aggressive regularization. Our structural decoders learn a hierarchy of latent variables, thereby ordering the information without any additional regularization or supervision. We demonstrate how these models learn a representation that improves results in a variety of downstream tasks including generation, disentanglement, and extrapolation using several challenging and natural image datasets.

Understanding Neural Coding on Latent Manifolds by Sharing Features and Dividing Ensembles

Martin Bjerke,Lukas Schott,Kristopher T Jensen,Claudia Battistin,David A. Klindt,Benjamin Adric Dunn

Systems neuroscience relies on two complementary views of neural data, characterized by single neuron tuning curves and analysis of population activity. These two perspectives combine elegantly in neural latent variable models that constrain the relationship between latent variables and neural activity, modeled by simple tuning curve functions. This has recently been demonstrated using Gaussian processes, with applications to realistic and topologically relevant latent manifolds. Those and previous models, however, missed crucial shared coding properties of neural populations. We propose $\textit{feature sharing}$ across neural tuning curves which significantly improves performance and helps optimization. We also propose a solution to the $\textit{ensemble detection}$ problem, where different groups of neurons, i.e., ensembles, can be modulated by different latent manifolds. Achieved through a soft clustering of neurons during training, this allows for the separation of mixed neural populations in an unsupervised manner. These innovations lead to more interpretable models of neural population activity that train well and perform better even on mixtures of complex latent manifolds. Finally, we apply our method on a recently published grid cell dataset, and recover distinct ensembles, infer toroidal latents and predict neural tuning curves in a single integrated modeling framework.

Learning Fast and Slow for Time Series Forecasting

Quang Pham,Chenghao Liu,Doyen Sahoo,Steven Hoi

Despite the recent success of deep learning for time series forecasting, these methods are not scalable for many real-world applications where data arrives sequentially. Training deep neural forecasters on the fly is notoriously challenging because of their limited ability to adapt to non-stationary environments and remember old knowledge. We argue that the fast adaptation capability of deep neural networks is critical and successful solutions require handling changes to both new and recurring patterns effectively. In this work, inspired by the Complementary Learning Systems (CLS) theory, we propose Fast and Slow learning Network (FSNet) as a novel framework to address the challenges of online forecasting. Particularly, FSNet improves the slowly-learned backbone by dynamically balancing fast adaptation to recent changes and retrieving similar old knowledge. FSNet achieves this mechanism via an interaction between two novel complementary components: (i) a per-layer adapter to support fast learning from individual layers, and (ii) an associative memory to support remembering, updating, and recalling repeating events. Extensive experiments on real and synthetic datasets validate FSNet's efficacy and robustness to both new and recurring patterns. Our code is publicly available at: \url{https://github.com/salesforce/fsnet/}.

Perturbation Defocusing for Adversarial Defense

HENG YANG,Ke Li

Recent research indicates adversarial attacks are likely to deceive neural systems, including large-scale, pre-trained language models. Given a natural sentence, an attacker replaces a subset of words to fool objective models. To defend against adversarial attacks, existing works aim to reconstruct the adversarial exam ples. However, these methods show limited defense performance on the adversarial examples whilst also damaging the clean performance on natural examples. To achieve better defense performance, our finding indicates that the reconstruction of adversarial examples is not necessary. More specifically, we inject non-toxic perturbations into adversarial examples, which can disable almost all malicious perturbations. In order to minimize performance sacrifice, we employ an adversarial example detector to distinguish and repair detected adversarial examples, which alleviates the mis-defense on natural examples. Our experimental results on three datasets, two objective models and a variety of adversarial attacks show that the proposed method successfully repairs up to ~ 97% correctly identified adversarial examples with ≤~ 2% performance sacrifice. We provide an anony-mus demonstration of adversarial detection and repair based on our work.

Accuracy Boosters: Epoch-Driven Mixed-Mantissa Block Floating-Point for DNN Training

Simla Burcu Harma,Canberk Sönmez,Babak Falsafi,Martin Jaggi,Yunho Oh

The unprecedented growth in DNN model complexity, size and the amount of training data have led to a commensurate increase in demand for computing and a search for minimal encoding. Recent research advocates Hybrid Block Floating-Point (HBFP) as a technique that minimizes silicon provisioning in accelerators by converting the majority of arithmetic operations in training to 8-bit fixed-point. In this paper, we perform a full-scale exploration of the HBFP design space including minimal mantissa encoding, varying block sizes, and mixed mantissa bit-width across layers and epochs. We propose Accuracy Boosters, an epoch-driven mixed-mantissa HBFP that uses 6-bit mantissa only in the last epoch and converts 99.7% of all arithmetic operations in training to 4-bit mantissas. Accuracy Boosters enable reducing silicon provisioning for an HBFP training accelerator by 16.98× as compared to FP32, while preserving or outperforming FP32 accuracy.

Compressing multidimensional weather and climate data into neural networks

Langwen Huang,Torsten Hoefler

Weather and climate simulations produce petabytes of high-resolution data that are later analyzed by researchers in order to understand climate change or severe weather. We propose a new method of compressing this multidimensional weather and climate data: a coordinate-based neural network is trained to overfit the data, and the resulting parameters are taken as a compact representation of the original grid-based data. While compression ratios range from 300x to more than 3,000x, our method outperforms the state-of-the-art compressor SZ3 in terms of weighted RMSE, MAE. It can faithfully preserve important large scale atmosphere structures and does not introduce significant artifacts.

When using the resulting neural network as a 790x compressed dataloader to train the WeatherBench forecasting model, its RMSE increases by less than 2%. The three orders of magnitude compression democratizes access to high-resolution climate data and enables numerous new research directions.

Guess the Instruction! Flipped Learning Makes Language Models Stronger Zero-Shot Learners

Seonghyeon Ye,Doyoung Kim,Joel Jang,Joongbo Shin,Minjoon Seo

Meta-training, which fine-tunes the language model (LM) on various downstream tasks by maximizing the likelihood of the target label given the task instruction and input instance, has improved the zero-shot task generalization performance. However, meta-trained LMs still struggle to generalize to challenging tasks containing novel labels unseen during meta-training. In this paper, we propose Flipped Learning, an alternative method of meta-training which trains the LM to generate the task instruction given the input instance and label. During inference, the LM trained with Flipped Learning, referred to as FLIPPED, selects the label option that is most likely to generate the task instruction. On 14 tasks of the BIG-bench benchmark, the 11B-sized FLIPPED outperforms zero-shot T0-11B (Sanh et al, 2021) and even a 16 times larger 3-shot GPT-3 (175B) (Brown et al, 2020) on average by 8.4% and 9.7% points, respectively. FLIPPED gives particularly large improvements on tasks with unseen labels, outperforming T0-11B by up to +20% average F1 score. This indicates that the strong task generalization of FLIPPED comes from improved generalization to novel labels. We release our code at github.com/seonghyeonye/Flipped-Learning.

Probabilistic Imputation for Time-series Classification with Missing Data

Hyunsu Kim,SeungHyun Kim,Eunggu Yun,Hwangrae Lee,Jaehun Lee,Juho Lee

Multivariate time series data available for real-world applications typically contain a significant amount of missing values. A dominant approach for the classification with such missing values is to heuristically impute the missing values with specific values (zero, mean, values of adjacent time-steps) or learnable parameters. However, these simple strategies do not take the data generative process into account, and more importantly, do not effectively capture the uncertainty in prediction due to the multiple possibilities for the missing values. In this paper, we propose a novel probabilistic framework for classification with multivariate time series data with missing values. Our model consists of two parts; a deep generative model for missing value imputation and a classifier. Extending the existing deep generative models to better capture structures of time-series data, our deep generative model part is trained to impute the missing values in multiple plausible ways, effectively modeling the uncertainty of the imputation. The classifier part takes the time series data along with the imputed missing values and classifies signals, and is trained to capture the predictive uncertainty due to the multiple possibilities of imputations. Importantly, we show that na\"ively combining the generative model and the classifier could result in trivial solutions where the generative model does not produce meaningful imputations. To resolve this, we present a novel regularization technique that can promote the model to produce useful imputation values that actually help classification. Through extensive experiments on real-world time series data with missing values, we demonstrate the effectiveness of our method.

****

Timing is Everything: Learning to Act Selectively with Costly Actions and Budgetary Constraints

David Henry Mguni,Aivar Sootla,Juliusz Krzysztof Ziomek,Oliver Slumbers,Zipeng Dai,Kun Shao,Jun Wang

Many real-world settings involve costs for performing actions; transaction costs in financial systems and fuel costs being common examples. In these settings, performing actions at each time step quickly accumulates costs leading to vastly suboptimal outcomes. Additionally, repeatedly acting produces wear and tear and ultimately, damage. Determining when to act is crucial for achieving successful outcomes and yet, the challenge of efficiently learning to behave optimally when actions incur minimally bounded costs remains unresolved. In this paper, we introduce a reinforcement learning (RL) framework named Learnable Impulse Control Reinforcement Algorithm (LICRA), for learning to optimally select both when to act and which actions to take when actions incur costs. At the core of LICRA is a nested structure that combines RL and a form of policy known as impulse control which learns to maximise objectives when actions incur costs. We prove that LICRA, which seamlessly adopts any RL method, converges to policies that optimally select when to perform actions and their optimal magnitudes. We then augment LICRA to handle problems in which the agent can perform at most $k < \infty$ actions and more generally, faces a budget constraint. We show LICRA learns the optimal value function and ensures budget constraints are satisfied almost surely.
We demonstrate empirically LICRA’s superior performance against benchmark RL methods in OpenAI gym’s Lunar Lander and in Highway environments and a variant of the Merton portfolio problem within finance.

Multi-Head State Space Model for Sequence Modeling

Yassir Fathullah,Chunyang Wu,Yuan Shangguan,Junteng Jia,Wenhan Xiong,Jay Mahadeokar,Chunxi Liu,Yangyang Shi,Ozlem Kalinli,Mike Seltzer,Mark Gales

Recently, state space models (SSMs) have shown promising results on sequence modeling tasks. However, a potential challenge of existing works is that SSMs are usually introduced or initialized in a homogeneous way, encouraging the model to only capture similar temporal dynamics on different features. In this paper, we propose a multi-head state space model (MSSM), in which parallel heads are introduced to learn different temporal dynamics on sequence data. Furthermore, we propose a novel variant of the Transformer, referred to as the Stateformer, which combines MSSMs with attention. Experiments on large-scale automatic speech recognition (ASR) and language modeling tasks show the MSSM outperforming a range of attention-based baselines. The Stateformer further improves performance, achieving the state-of-the-art performance on the LibriSpeech ASR task.

A Weight Variation-Aware Training Method for Hardware Neuromorphic Chips
Min-Hye Oh
Hardware neuromorphic chips that mimic the biological nervous systems have recently attracted significant attention due to their ultra-low power and parallel computation. However, the inherent variability of nano-scale synaptic devices causes a weight perturbation and performance drop of neural networks. This paper proposes a training method to find weight with robustness to intrinsic device variability. A stochastic weight characteristic incurred by device inherent variability is considered during training. We investigate the impact of weight variation on both Spiking Neural Network (SNN) and standard Artificial Neural Network (ANN) with different architectures including fully connected, convolutional neural network (CNN), VGG, and ResNet on MNIST, CIFAR-10, and CIFAR-100. Experimental results show that a weight variation-aware training method (WVAT) can dramatically minimize the performance drop on weight variability by exploring a flat loss landscape. When there are weight perturbations, WVAT yields 85.21% accuracy of VGG-5 on CIFAR-10, reducing accuracy degradation by more than 1/10 compared with SGD. Finally, WVAT is easy to implement on various architectures with little computational overhead.

Semantic Prior for Weakly Supervised Class-Incremental Segmentation
Subhankar Roy,Riccardo Volpi,Gabriela Csurka,Diane Larlus
Class-incremental semantic image segmentation assumes multiple model updates, each enriching the model to segment new categories. This is typically carried out by providing pixel-level manual annotations for all new objects, limiting the adoption of such methods. Approaches which solely require image-level labels offer an attractive alternative, yet, such annotations lack crucial information about the location and boundary of new objects. In this paper we argue that, since classes represent not just indices but semantic entities, the conceptual relationships between them can provide valuable information that should be leveraged. We propose a weakly supervised approach that leverages such semantic relations in order to transfer some cues from the previously learned classes into the new ones, complementing the supervisory signal from image-level labels. We validate our approach on a number of continual learning tasks, and show how even a simple pairwise interaction between classes can significantly improve the segmentation mask quality of both old and new classes. We show these conclusions still hold for longer and, hence, more realistic sequences of tasks and for a challenging few-shot scenario.
****
A Mutual Information Duality Algorithm for Multi-Agent Specialization
Stefan Juang,Qiyang Cao,Yuan Zhou,Ruochen Liu,Nevin Zhang,Elvis S. Liu
The social behavior change in a population has long been studied as an essential component of multi-agent learning. The learning of behavioral change not only involves reinforcement learning (RL), but also be measured against the general population with mutual information (MI). The combination of RL and MI led us to derive MI optimizations from policy gradient. With MI as multi-agent's optimization objective, we discover that the dual properties of MI can result in distinctly different population behaviors. From MI maximization that maximizes the stability of a population to MI minimization that enables specialization among the agen

ts, the dual of MI creates a significant change in a population's behavioral properties. In this paper, we propose a minimax formulation of MI (M\&M) that enables agents specialization with stable regularization. Empirically we evaluated M\&M against the prior SOTA MARL framework, and analyze the social behavior change in performance, diversity, and the stability of their social graphs.

DeCap: Decoding CLIP Latents for Zero-Shot Captioning via Text-Only Training
Wei Li,Linchao Zhu,Longyin Wen,Yi Yang

Large-scale pre-trained multi-modal models (e.g., CLIP) demonstrate strong zero-shot transfer capability in many discriminative tasks, e.g., image classification. Their adaptation to zero-shot image-conditioned text generation tasks has drawn increasing interest. Prior arts approach to zero-shot captioning by either utilizing the existing large language models (e.g., GPT-2) or pre-training the encoder-decoder network in an end-to-end manner. However, the large language models may not generate sensible descriptions due to the task discrepancy between captioning and language modeling, while the end-to-end pre-training requires paired data and extensive computational resources. In this work, we propose a simple framework, named DeCap, for zero-shot captioning. We introduce a lightweight visual-aware language decoder. This decoder is both data-efficient and computation-efficient: 1) it only requires the \textit{text} data for training, easing the burden on the collection of paired data. 2) it does not require end-to-end training. When trained with text-only data, the decoder takes the text embedding extracted from the off-the-shelf CLIP encoder as a prefix embedding. The challenge is that the decoder is trained on the text corpus but at the inference stage, it needs to generate captions based on visual inputs. Though the CLIP text embedding and the visual embedding are correlated, the \textit{modality gap} issue is widely observed in multi-modal contrastive models that prevents us from directly taking the visual embedding as the prefix embedding. We propose a training-free mechanism to reduce the modality gap. We project the visual embedding into the CLIP text embedding space, while the projected embedding retains the information of the visual input. Taking the projected embedding as the prefix embedding, the decoder generates high-quality descriptions that match the visual input. The experiments show that DeCap outperforms other zero-shot captioning methods and unpaired captioning methods by a large margin on the typical image captioning benchmarks, i.e., MSCOCO and NoCaps. We apply DeCap to video captioning and achieve state-of-the-art zero-shot performance on MSR-VTT and ActivityNet-Captions. The code is available at https://github.com/dhg-wei/DeCap.

Biological Factor Regulatory Neural Network
Xinnan Dai,Caihua Shan,Jie Zheng,Xiaoxiao Li,Dongsheng Li

Genes are fundamental for analyzing biological systems and many recent works proposed to utilize gene expression for various biological tasks by deep learning models. Despite their promising performance, it is hard for deep neural networks to provide biological insights for humans due to their black-box nature. Recently, some works integrated biological knowledge with neural networks to improve the transparency and performance of their models. However, these methods can only incorporate partial biological knowledge, leading to suboptimal performance. In this paper, we propose the Biological Factor Regulatory Neural Network (BFReg-NN), a generic framework to model relations among biological factors in cell systems. BFReg-NN starts from gene expression data and is capable of merging most existing biological knowledge into the model, including the regulatory relations among genes or proteins (e.g., gene regulatory networks (GRN), protein-protein interaction networks (PPI)) and the hierarchical relations among genes, proteins and pathways (e.g., several genes/proteins are contained in a pathway). Moreover, BFReg-NN also has the ability to provide new biologically meaningful insights because of its white-box characteristics. Experimental results on different gene expression-based tasks verify the superiority of BFReg-NN compared with baselines. Our case studies also show that the key insights found by BFReg-NN are consistent with the biological literature.

Preserving Semantics in Textual Adversarial Attacks
David Herel,Hugo Cisneros,Tomas Mikolov
Adversarial attacks in NLP challenge the way we look at language models. The goal of this kind of adversarial attack is to modify the input text to fool a classifier while maintaining the original meaning of the text. Although most existing adversarial attacks claim to fulfill the constraint of semantics preservation, careful scrutiny shows otherwise. We show that the problem lies in the text encoders used to determine the similarity of adversarial examples, specifically in the way they are trained. Unsupervised training methods make these encoders more susceptible to problems with antonym recognition. To overcome this, we introduce a simple, fully supervised sentence embedding technique called Semantics-Preserving-Encoder (SPE). The results show that our solution minimizes the variation in the meaning of the adversarial examples generated. It also significantly improves the overall quality of adversarial examples, as confirmed by human evaluators. Furthermore, it can be used as a component in any existing attack to speed up its execution while maintaining similar attack success.

Unbiased Decisions Reduce Regret: Adversarial Optimism for the Bank Loan Problem
Elena Gal,Shaun Singh,Aldo Pacchiano,Benjamin Walker,Terry Lyons,Jakob Nicolaus Foerster
In many real world settings binary classification decisions are made based on limited data in near real-time, e.g. when assessing a loan application. We focus on a class of these problems that share a common feature that the true label is only observed when a data point is assigned a positive label by a learner, e.g. we only learn of an outcome of \emph{accepted} loan applications. In this setting, sometimes referred to as the Bank Loan Problem (BLP) in the literature, the labelled training set suffers from accumulating bias since it is created by learners past decisions.
Prior work mitigates the consequences of this bias by injecting optimism into the model to allow the learner to correct self-reinforcing false rejections. This reduces long term regret but comes at the cost of a higher false acceptance rate.
We introduce \emph{adversarial optimism} (AdOpt) to directly address the bias in the training set using \emph{adversarial domain adaptation}. The goal of AdOpt is to learn an unbiased but informative representation of past data, by reducing the distributional shift between the set of \textit{accepted} data points and all data points seen thus far. AdOpt integrates classification made using this debiased representation of the data with the recently proposed \emph{pseudo-label optimism}(PLOT) method to increase the rate of correct decisions at every timestep.
AdOpt significantly exceeds state-of-the-art performance on a set of challenging BLP benchmark problems.
****
That Label's got Style: Handling Label Style Bias for Uncertain Image Segmentation
Kilian Zepf,Eike Petersen,Jes Frellsen,Aasa Feragen
Segmentation uncertainty models predict a distribution over plausible segmentations for a given input, which they learn from the annotator variation in the training set. However, in practice these annotations can differ systematically in the way they are generated, for example through the use of different labeling tools. This results in datasets that contain both data variability and differing label styles. In this paper, we demonstrate that applying state-of-the-art segmentation uncertainty models on such datasets can lead to model bias caused by the different label styles. We present an updated modelling objective conditioning on labeling style for aleatoric uncertainty estimation, and modify two state-of-the-art-architectures for segmentation uncertainty accordingly. We show with extensive experiments that this method reduces label style bias, while improving segmentation performance, increasing the applicability of segmentation uncertainty models in the wild. We curate two datasets, with annotations in different label styles, which we will make publicly available along with our code upon publication

Holistic Adversarially Robust Pruning
Qi Zhao,Christian Wressnegger
Neural networks can be drastically shrunk in size by removing redundant parameters. While crucial for the deployment on resource-constraint hardware, oftentimes, compression comes with a severe drop in accuracy and lack of adversarial robustness. Despite recent advances, counteracting both aspects has only succeeded for moderate compression rates so far. We propose a novel method, HARP, that copes with aggressive pruning significantly better than prior work. For this, we consider the network holistically. We learn a global compression strategy that optimizes how many parameters (compression rate) and which parameters (scoring connections) to prune specific to each layer individually. Our method fine-tunes an existing model with dynamic regularization, that follows a step-wise incremental function balancing the different objectives. It starts by favoring robustness before shifting focus on reaching the target compression rate and only then handles the objectives equally. The learned compression strategies allow us to maintain the pre-trained model’s natural accuracy and its adversarial robustness for a reduction by 99% of the network’s original size. Moreover, we observe a crucial influence of non-uniform compression across layers. The implementation of HARP is publicly available at https://intellisec.de/research/harp.

PASHA: Efficient HPO and NAS with Progressive Resource Allocation
Ondrej Bohdal,Lukas Balles,Martin Wistuba,Beyza Ermis,Cedric Archambeau,Giovanni Zappella
Hyperparameter optimization (HPO) and neural architecture search (NAS) are methods of choice to obtain the best-in-class machine learning models, but in practice they can be costly to run. When models are trained on large datasets, tuning them with HPO or NAS rapidly becomes prohibitively expensive for practitioners, even when efficient multi-fidelity methods are employed. We propose an approach to tackle the challenge of tuning machine learning models trained on large datasets with limited computational resources. Our approach, named PASHA, extends ASHA and is able to dynamically allocate maximum resources for the tuning procedure depending on the need. The experimental comparison shows that PASHA identifies well-performing hyperparameter configurations and architectures while consuming significantly fewer computational resources than ASHA.

Thinking fourth dimensionally: Treating Time as a Random Variable in EBMs
Omer Yair,Tomer Michaeli
Recent years have seen significant progress in techniques for learning high-dimensional distributions. Many modern methods, from diffusion models to Energy-Based-Models (EBMs), adopt a coarse-to-fine approach. This is often done by introducing a series of auxiliary distributions that gradually change from the data distribution to some simple distribution (e.g. white Gaussian noise). Methods in this category separately learn each auxiliary distribution (or transition between pairs of consecutive distributions) and then use the learned models sequentially to generate samples. In this paper, we offer a simple way to generalize this idea by treating the ``time'' index of the series as a random variable and framing the problem as that of learning a single joint distribution of "time" and samples. We show that this joint distribution can be learned using any existing EBM method and that it allows achieving improved results. As an example, we demonstrate this approach using contrastive divergence (CD) in its most basic form. On CIFAR-10 and CelebA (32×32), this method outperforms previous CD-based methods in terms of inception and FID scores.

Diversity of Generated Unlabeled Data Matters for Few-shot Hypothesis Adaptation
Ruijiang Dong,Feng Liu,Haoang Chi,Tongliang Liu,Mingming Gong,Gang Niu,Masashi Sugiyama,Bo Han
Generating unlabeled data has been recently shown to help address the few-shot hypothesis adaptation (FHA) problem, where we aim to train a classifier for the t

arget domain with a few labeled target-domain data and a well-trained source-domain classifier (i.e., a source hypothesis), for the additional information of the highly-compatible unlabeled data. However, the generated data of the existing methods are extremely similar or even the same. The strong dependency among the generated data will lead the learning to fail. In this paper, we propose a diversity-enhancing generative network (DEG-Net) for the FHA problem, which can generate diverse unlabeled data with the help of a kernel independence measure: the Hilbert-Schmidt independence criterion (HSIC). Specifically, DEG-Net will generate data via minimizing the HSIC value (i.e., maximizing the independence) among the semantic features of the generated data. By DEG-Net, the generated unlabeled data are more diverse and more effective for addressing the FHA problem. Experimental results show that the DEG-Net outperforms existing FHA baselines and further verifies that generating diverse data plays an important role in addressing the FHA problem.

StableDR: Stabilized Doubly Robust Learning for Recommendation on Data Missing Not at Random

Haoxuan Li,Chunyuan Zheng,Peng Wu

In recommender systems, users always choose the favorite items to rate, which leads to data missing not at random and poses a great challenge for unbiased evaluation and learning of prediction models. Currently, the doubly robust (DR) methods have been widely studied and demonstrate superior performance. However, in this paper, we show that DR methods are unstable and have unbounded bias, variance, and generalization bounds to extremely small propensities. Moreover, the fact that DR relies more on extrapolation will lead to suboptimal performance. To address the above limitations while retaining double robustness, we propose a stabilized doubly robust (StableDR) learning approach with a weaker reliance on extrapolation. Theoretical analysis shows that StableDR has bounded bias, variance, and generalization error bound simultaneously under inaccurate imputed errors and arbitrarily small propensities. In addition, we propose a novel learning approach for StableDR that updates the imputation, propensity, and prediction models cyclically, achieving more stable and accurate predictions. Extensive experiments show that our approaches significantly outperform the existing methods.

Variational Causal Dynamics: Discovering Modular World Models from Interventions

Anson Lei,Bernhard Schölkopf,Ingmar Posner

Latent world models allow agents to reason about complex environments with high-dimensional observations. However, adapting to new environments and effectively leveraging previous knowledge remain significant challenges. We present variational causal dynamics (VCD), a structured world model that exploits the invariance of causal mechanisms across environments to achieve fast and modular adaptation. By causally factorising a transition model, VCD is able to identify reusable components across different environments. This is achieved by combining causal discovery and variational inference to learn a latent representation and transition model jointly in an unsupervised manner. Specifically, we optimise the evidence lower bound jointly over a representation model and a transition model structured as a causal graphical model. In evaluations on simulated environments with state and image observations, we show that VCD is able to successfully identify causal variables, and to discover consistent causal structures across different environments. Moreover, given a small number of observations in a previously unseen, intervened environment, VCD is able to identify the sparse changes in the dynamics and to adapt efficiently. In doing so, VCD significantly extends the capabilities of the current state-of-the-art in latent world models while also comparing favourably in terms of prediction accuracy.

Query The Agent: Improving Sample Efficiency Through Epistemic Uncertainty Estimation

Julian Alverio,Boris Katz,Andrei Barbu

Curricula for goal-conditioned reinforcement learning agents typically rely on poor estimates of the agent's epistemic uncertainty or fail to consider the agent s' epistemic uncertainty altogether, resulting in poor sample efficiency. We propose a novel algorithm, Query The Agent (QTA), which significantly improves sample efficiency by estimating the agent's epistemic uncertainty throughout the state space and setting goals in highly uncertain areas. Encouraging the agent to collect data in highly uncertain states allows the agent to improve its estimation of the value function rapidly. QTA utilizes a novel technique for estimating epistemic uncertainty, Predictive Uncertainty Networks (PUN), to allow QTA to assess the agent's uncertainty in all previously observed states. We demonstrate that QTA offers decisive sample efficiency improvements over preexisting methods.

Differentiable Logic Programming for Probabilistic Reasoning

Tuo Xu,Lei Zou

This paper studies inductive logic programming for probabilistic reasoning. The key problems, i.e. learning rule structures and learning rule weights, have been extensively studied with traditional discrete searching methods as well as recent neural-based approaches. In this paper, we present a new approach called Differentiable Logic Programming (DLP), which provides a flexible framework for learning first-order logical rules for reasoning. We propose a continuous version of optimization problem for learning high-quality rules as a proxy and generalize rule learning and forward chaining algorithms in a differentiable manner, which enables us to efficiently learn rule structures and weights via gradient-based methods. Theoretical analysis and empirical results show effectiveness of our approach.

****

Rewiring with Positional Encodings for GNNs

Rickard Brüel Gabrielsson,Mikhail Yurochkin,Justin Solomon

Several recent works use positional encodings to extend the receptive fields of graph neural network (GNN) layers equipped with attention mechanisms. These techniques, however, extend receptive fields to the complete graph, at substantial computational cost and risking a change in the inductive biases of conventional GNNs, or require complex architecture adjustments. As a conservative alternative, we use positional encodings to expand receptive fields to r-hop neighborhoods. More specifically, our method augments the input graph with additional nodes/edges and uses positional encodings as node and/or edge features. We thus modify graphs before inputting them to a downstream GNN model, instead of modifying the model itself. This makes our method model-agnostic, i.e. compatible with any existing GNN architectures. We also provide examples of positional encodings that are lossless with a one-to-one map between the original and the modified graphs. We demonstrate that extending receptive fields via positional encodings and a virtual fully-connected node significantly improves GNN performance and alleviates over-squashing using small r. We obtain improvements on a variety of models and datasets, and reach state-of-the-art performance using traditional GNNs or graph Transformers.

****

Feed-Forward Latent Domain Adaptation

Ondrej Bohdal,Da Li,Shell Xu Hu,Timothy Hospedales

We study the highly practical but comparatively under-studied problem of latent-domain adaptation, where a source model should be adapted to a target dataset that contains a mixture of unlabelled domain-relevant and domain-irrelevant examples. Furthermore, motivated by the requirements for data privacy and the need for embedded and resource-constrained devices of all kinds to adapt to local data distributions, we focus on the setting of feed-forward source-free domain adaptation, where adaptation should not require access to the source dataset, and also be back propagation-free. Our solution is to meta-learn a network capable of embedding the mixed-relevance target dataset and dynamically adapting inference for target examples using cross-attention. The resulting framework leads to consistent improvement on strong ERM baselines. We also show that our framework sometimes even improves on the upper bound of domain-supervised adaptation, where only domain-relevant instances are provided for adaptation. This suggests that human annotated domain labels may not always be optimal, and raises the possibility o f doing better through automated instance selection.

Sampling-based inference for large linear models, with application to linearised Laplace

Javier Antoran,Shreyas Padhy,Riccardo Barbano,Eric Nalisnick,David Janz,José Miguel Hernández-Lobato

Large-scale linear models are ubiquitous throughout machine learning, with contemporary application as surrogate models for neural network uncertainty quantification; that is, the linearised Laplace method. Alas, the computational cost associated with Bayesian linear models constrains this method's application to small networks, small output spaces and small datasets. We address this limitation by introducing a scalable sample-based Bayesian inference method for conjugate Gaussian multi-output linear models, together with a matching method for hyperparameter (regularisation) selection. Furthermore, we use a classic feature normalisation method (the g-prior) to resolve a previously highlighted pathology of the linearised Laplace method. Together, these contributions allow us to perform linearised neural network inference with ResNet-18 on CIFAR100 (11M parameters, 100 output dimensions × 50k datapoints) and with a U-Net on a high-resolution tomographic reconstruction task (2M parameters, 251k output dimensions).

Defending against Adversarial Audio via Diffusion Model

Shutong Wu,Jiongxiao Wang,Wei Ping,Weili Nie,Chaowei Xiao

Deep learning models have been widely used in commercial acoustic systems in recent years. However, adversarial audio examples can cause abnormal behaviors for those acoustic systems, while being hard for humans to perceive. Various methods, such as transformation-based defenses and adversarial training, have been proposed to protect acoustic systems from adversarial attacks, but they are less effective against adaptive attacks. Furthermore, directly applying the methods from the image domain can lead to suboptimal results because of the unique properties of audio data. In this paper, we propose an adversarial purification-based defense pipeline, AudioPure, for acoustic systems via off-the-shelf diffusion models. Taking advantage of the strong generation ability of diffusion models, AudioPure first adds a small amount of noise to the adversarial audio and then runs the reverse sampling step to purify the noisy audio and recover clean audio. AudioPure is a plug-and-play method that can be directly applied to any pretrained classifier without any fine-tuning or re-training. We conduct extensive experiments on the speech command recognition task to evaluate the robustness of AudioPure. Our method is effective against diverse adversarial attacks (e.g. L2 or L∞-norm). It outperforms the existing methods under both strong adaptive white-box and black-box attacks bounded by L2 or L∞-norm (up to +20% in robust accuracy). Besides, we also evaluate the certified robustness for perturbations bounded by L2-norm via randomized smoothing. Our pipeline achieves a higher certified accuracy than baselines.

****

Text-Guided Diffusion Image Style Transfer with Contrastive Loss Fine-tuning

Serin Yang,Hyunmin Hwang,Jong Chul Ye

Recently, diffusion models have demonstrated superior performance in text-guided image style transfer. However, there exists fundamental trade-off between transforming styles and maintaining content in diffusion models. Although a simple remedy would be using deterministic sampling scheme such as denoising diffusion implicit model (DDIM) that guarantees the perfect reconstruction, it requires the computationally expensive fining-tuning of the diffusion models. To address this, here we present a text-guided sampling scheme using a patch-wise contrastive loss fine-tuning. By exploiting the contrastive loss between the samples and the original images, our diffusion model can generate an image with the same semantic content as the source image. Experimental results demonstrate that our approach outperforms the existing methods while maintaining content and requiring no additional training on the diffusion model.

****

FedProp: Cross-client Label Propagation for Federated Semi-supervised Learning

Jonathan Scott,Michelle Yeo,Christoph H Lampert

Federated learning (FL) allows multiple clients to jointly train a machine learning model in such a way that no client has to share their data with any other participating party. In the supervised setting, where all client data is fully labeled, FL has been widely adopted for learning tasks that require data privacy. However, it is an ongoing research question how to best perform federated learning in a semi-supervised setting, where the clients possess data that is only partially labeled or even completely unlabeled. In this work, we propose a new method, FedProp, that follows a manifold-based approach to semi-supervised learning (SSL). It estimates the data manifold jointly from the data of multiple clients and computes pseudo-labels using cross-client label propagation. To avoid that clients have to share their data with anyone, FedProp employs two cryptographically secure yet highly efficient protocols: multi-party Hamming distance computation and secure aggregation. Experiments on three standard benchmarks show that FedProp achieves higher classification accuracy than previous federated SSL methods. Furthermore, as a pseudo-label-based technique, FedProp is complementary to other federated SSL approaches, in particular consistency-based ones. We demonstrate experimentally that further accuracy gains are possible by combining both.

****

Gated Inference Network: Inferencing and Learning State-Space Models

Hamidreza Hashempoor,Wan Choi

State-space models (SSMs) perform predictions by learning the underlying dynamics of observed sequence. We propose a new SSM in both high and low dimensional observation space, which utilizes Bayesian filtering-smoothing to model system’s dynamics more accurately than RNN-based SSMs and can be learned in an end-to-end manner. The designed architecture, which we call the Gated Inference Network (GIN), is able to integrate the uncertainty estimates and learn the complicated dynamics of the system that enables us to perform estimation and imputation tasks in both data presence and absence. The proposed model uses the GRU cells into its structure to complete the data flow, while avoids expensive computations and potentially unstable matrix inversions. The GIN is able to deal with any time-series data and gives us a strong robustness to handle the observational noise. In the numerical experiments, we show that the GIN reduces the
uncertainty of estimates and outperforms its counterparts , LSTMs, GRUs and variational approaches.

Theoretical Characterization of the Generalization Performance of Overfitted Meta-Learning

Peizhong Ju,Yingbin Liang,Ness Shroff

Meta-learning has arisen as a successful method for improving training performance by training over many similar tasks, especially with deep neural networks (DNNs). However, the theoretical understanding of when and why overparameterized models such as DNNs can generalize well in meta-learning is still limited. As an initial step towards addressing this challenge, this paper studies the generalization performance of overfitted meta-learning under a linear regression model with Gaussian features. In contrast to a few recent studies along the same line, our framework allows the number of model parameters to be arbitrarily larger than the number of features in the ground truth signal, and hence naturally captures the overparameterized regime in practical deep meta-learning. We show that the overfitted min ℓ_2-norm solution of model-agnostic meta-learning (MAML) can be beneficial, which is similar to the recent remarkable findings on "benign overfitting" and "double descent" phenomenon in the classical (single-task) linear regression. However, due to the uniqueness of meta-learning such as task-specific gradient descent inner training and the diversity/fluctuation of the ground-truth signals among training tasks, we find new and interesting properties that do not exist in single-task linear regression. We first provide a high-probability upper bound (under reasonable tightness) on the generalization error, where certain terms decrease when the number of features increases. Our analysis suggests that benign overfitting is more significant and easier to observe when the noise and the diversity/fluctuation of the ground truth of each training task are la rge. Under this circumstance, we show that the overfitted min ℓ_2-norm solution can achieve an even lower generalization error than the underparameterized solution.

Cold Posteriors through PAC-Bayes

Konstantinos Pitas,Julyan Arbel

We investigate the cold posterior effect through the lens of PAC-Bayes generalization bounds. We argue that in the non-asymptotic setting, when the number of training samples is (relatively) small, discussions of the cold posterior effect should take into account that approximate Bayesian inference does not readily provide guarantees of performance on out-of-sample data. Instead, out-of-sample error is better described through a generalization bound. In this context, we explore the connections of the ELBO objective from variational inference and the PAC-Bayes objectives. We note that, while the ELBO and PAC-Bayes objectives are similar, the latter objectives naturally contain a temperature parameter λ which is not restricted to be $\lambda=1$. For both simplified regression and realistic classification tasks, in the case of Laplace approximations to the posterior, we show how this PAC-Bayesian interpretation of the temperature parameter captures important aspects of the cold posterior effect.

Training language models to summarize narratives improves brain alignment

Khai Loong Aw,Mariya Toneva

Building systems that achieve a deeper understanding of language is one of the central goals of natural language processing (NLP). Towards this goal, recent works have begun to train language models on narrative datasets which require extracting the most critical information by integrating across long contexts. However, it is still an open question whether these models are learning a deeper understanding of the text, or if the models are simply learning a heuristic to complete the task. This work investigates this further by turning to the one language processing system that truly understands complex language: the human brain. We show that training language models for deeper narrative understanding results in richer representations that have improved alignment to human brain activity. We further find that the improvements in brain alignment are larger for character names than for other discourse features, which indicates that these models are learning important narrative elements. Taken together, these results suggest that this type of training can indeed lead to deeper language understanding. These findings have consequences both for cognitive neuroscience by revealing some of the significant factors behind brain-NLP alignment, and for NLP by highlighting that understanding of long-range context can be improved beyond language modeling.

VQ-TR: Vector Quantized Attention for Time Series Forecasting

Kashif Rasul,Umang Gupta,Hena Ghonia,Yuriy Nevmyvaka

Modern time series datasets can easily contain hundreds or thousands of temporal time points, however, Transformer based models scale poorly to the size of the sequence length constraining their context size in the seq-to-seq setting. In this work, we introduce VQ-TR which maps large sequences to a discrete set of latents representations as part of the Attention module. This allows us to attend over larger context windows with linear complexity with respect to the sequence length. We compare this method with other competitive deep learning and classical univariate probabilistic models and highlight its performance using both probabilistic and point forecasting metrics on a variety of open datasets from different domains.

****

Local KL Convergence Rate for Stein Variational Gradient Descent with Reweighted Kernel

Xunpeng Huang,Hanze Dong,Cong Fang

We study convergence properties of Stein Variational Gradient Descent (SVGD) algorithm for sampling from a non-normalized probabilistic distribution $p_*({x})\propto\exp(-f_*({x}))$. Compared with Kernelized Stein Discrepancy (KSD) convergence analyzed in previous literature, KL convergence as a more convincing criter ion can better explain the effectiveness of SVGD in real-world applications. In the population limit, SVGD performs smoothed gradient descent with kernel integral operator. Notably, SVGD with smoothing kernels suffers from gradient vanishing in low-density areas, which makes the error term between smoothed gradient and Wasserstein gradient not controllable. In this context, we introduce a reweighted kernel to amplify the smoothed gradient in low-density areas, which leads to a bounded error term to Wasserstein gradient. When the $p_*({x})$ satisfies log-Sobolev inequality, we develop the convergence rate for SVGD in KL divergence with the reweighted kernel. Our analysis points out the defects of conventional smoothing kernels in SVGD and provides the convergence rate for SVGD in KL divergence.

****

A Decomposition Based Dual Projection Model for Multivariate Time Series Forecasting and Anomaly Detection

Peng Zhang,Qin Xie,Jaesik Choi

Efficient anomaly detection and diagnosis in multivariate time series data is of great importance for various application areas. Forecasting of long-sequence time series is an important problem to prepare for future changes. An accurate prediction can help to detect anomaly events beforehand and make better decisions. It seems that one has to use more complex structures for deep learning models to get better performance, e.g., the recent surge of Transformer variants for time series modeling. However, such complex architectures require a large amount of training data and extensive computing resources. In addition, many of the considerations behind such architectures do not hold for time series applications. The objective of this study is to re-consider the effectiveness of deep learning architectures for efficient and accurate time series forecasting and anomaly detection. A model with direct projections is proposed, and it outperforms existing Transformer based models in most cases by a significant margin. The new decomposition based dual projection (DBDP) model consists of an anchored global profile and a varied number of decomposed seasonal local profiles of the time series for better forecasting performance. In addition to forecasting, a non-contrastive self-supervised learning approach, we propose to include a contrastive learning module in the DBDPC model for better forecasting performance and robustness. Finally, we apply the DBDP and DBDPC models to forecasting based time series anomaly detection and achieve superior performance over the latest SoTA models. These results demonstrate the effectiveness of the several key considerations behind the DBDP and DBDPC models, which also encourages the development of new architectures for time series applications.

FedHPO-Bench: A Benchmark Suite for Federated Hyperparameter Optimization

Zhen WANG,Weirui Kuang,Ce Zhang,Bolin Ding,Yaliang Li

Hyperparameter optimization (HPO) is crucial for machine learning algorithms to achieve satisfactory performance. Its research progress has been boosted by existing HPO benchmarks. Nonetheless, existing efforts in benchmarking all focus on HPO for traditional centralized learning while ignoring federated learning (FL), a promising paradigm for collaboratively learning models from dispersed data. In this paper, we first identify some uniqueness of HPO for FL algorithms from various aspects. Due to this uniqueness, existing HPO benchmarks no longer satisfy the need to compare HPO methods in the FL setting. To facilitate the research of HPO in the FL setting, we propose and implement a benchmark suite FedHPO-Bench that incorporates comprehensive FedHPO problems, enables flexible customization of the function evaluations, and eases continuing extensions. We also conduct extensive experiments based on FedHPO-Bench to provide the community with more insights into FedHPO. We open-sourced FedHPO-Bench at https://github.com/FedHPO-Bench/FedHPO-Bench-ICLR23.

CCT: Cross-consistency training for Clone Detection and Code Search Tasks

Nikita Sorokin,Dmitry Abulkhanov,Valentin Malykh

Clone detection is a well known task, which could be formulated on any programming language. Although to the best of our knowledge there is no cross-lingual clo ne detection task formulated. In this work we formulate such a task alongside with a specific training procedure CCT for a deep leaning language model. This procedure allows CCT-trained model to outperform the existing approaches on POJ-104 benchmark with result of 95.67\% MAP and on newly created cross-lingual clone detection benchmark XCD. Moreover, CCT model shows new state of the art results in code search task AdvTest 47.15\% MRR.

Robust Explanation Constraints for Neural Networks

Matthew Robert Wicker,Juyeon Heo,Luca Costabello,Adrian Weller

Post-hoc explanation methods are used with the intent of providing insights about neural networks and are sometimes said to help engender trust in their outputs. However, popular explanations methods have been found to be fragile to minor perturbations of input features or model parameters. Relying on constraint relaxation techniques from non-convex optimization, we develop a method that upper-bounds the largest change an adversary can make to a gradient-based explanation via bounded manipulation of either the input features or model parameters. By propagating a compact input or parameter set as symbolic intervals through the forwards and backwards computations of the neural network we can formally certify the robustness of gradient-based explanations. Our bounds are differentiable, hence we can incorporate provable explanation robustness into neural network training. Empirically, our method surpasses the robustness provided by previous heuristic approaches. We find that our training method is the only method able to learn neural networks with certificates of explanation robustness across all six datasets tested.

Cyclophobic Reinforcement Learning

Stefan Sylvius Wagner,Peter Arndt,Jan Robine,Stefan Harmeling

In environments with sparse rewards finding a good inductive bias for exploration is crucial to the agent’s success. However, there are two competing goals: novelty search and systematic exploration. While existing approaches such as curiousity- driven exploration find novelty, they sometimes do not systematically explore the whole state space, akin to depth-first-search vs breadth-first-search. In this paper, we propose a new intrinsic reward that is cyclophobic, i.e. it does not reward novelty, but punishes redundancy by avoiding cycles. Augmenting the cyclophobic intrinsic reward with a sequence of hierarchical representations based on the agent’s cropped observations we are able to achieve excellent results in the MiniGrid and MiniHack environments. Both are particularly hard, as they require complex interactions with different objects in order to be solved. Detailed comparisons with previous approaches and thorough ablation studies show that our newly proposed cyclophobic reinforcement learning is vastly more efficient than other state of the art methods.

Emergent collective intelligence from massive-agent cooperation and competition

Hanmo Chen,Stone Tao,Jiaxin Chen,Weihan Shen,Xihui Li,Sikai Cheng,Xiaolong Zhu,Xiu Li

Inspired by organisms evolving through cooperation and competition between different populations on Earth, we study the emergence of artificial collective intelligence through massive-agent reinforcement learning. To this end, We propose a new massive-agent reinforcement learning environment, Lux, where dynamic and massive agents in two teams scramble for limited resources and fight off the darkness. In Lux, we build our agents through the standard reinforcement learning algorithm in curriculum learning phases and leverage centralized control via a pixel-to-pixel policy network. As agents co-evolve through self-play, we observe several stages of intelligence, from the acquisition of atomic skills to the development of group strategies. Since these learned group strategies arise from individual decisions without an explicit coordination mechanism, we claim that artificial collective intelligence emerges from massive-agent cooperation and competition. We further analyze the emergence of various learned strategies through metrics and ablation studies, aiming to provide insights for reinforcement learning implementations in massive-agent environments.

Offline Reinforcement Learning via High-Fidelity Generative Behavior Modeling

Huayu Chen,Cheng Lu,Chengyang Ying,Hang Su,Jun Zhu

In offline reinforcement learning, weighted regression is a common method to ensure the learned policy stays close to the behavior policy and to prevent selecting out-of-sample actions. In this work, we show that due to the limited distributional expressivity of policy models, previous methods might still select unseen actions during training, which deviates from their initial motivation. To address this problem, we adopt a generative approach by decoupling the learned policy into two parts: an expressive generative behavior model and an action evaluation model. The key insight is that such decoupling avoids learning an explicitly parameterized policy model with a closed-form expression. Directly learning the behavior policy allows us to leverage existing advances in generative modeling, such as diffusion-based methods, to model diverse behaviors. As for action evaluation, we combine our method with an in-sample planning technique to further avoid selecting out-of-sample actions and increase computational efficiency. Experimental results on D4RL datasets show that our proposed method achieves competitive or superior performance compared with state-of-the-art offline RL methods, especially in complex tasks such as AntMaze. We also empirically demonstrate that our method can successfully learn from a heterogeneous dataset containing multiple distinctive but similarly successful strategies, whereas previous unimodal policies fail.

GraphVF: Controllable Protein-Specific 3D Molecule Generation with Variational Flow

Fang Sun,Zhihao Zhan,Hongyu Guo,Ming Zhang,Jian Tang

Designing molecules that bind to specific target proteins is a fundamental task in drug discovery. Recent generative models leveraging geometrical constraints imposed by proteins and molecules have shown great potential in generating protein-specific 3D molecules. Nevertheless, these existing methods fail to generate 3D molecules with 2D skeletal curtailments, which encode pharmacophoric patterns essential to drug potency. To cope with this challenge, we propose GraphVF, which seamlessly integrates geometrical and skeletal restraints into a variational flow framework, where the former is captured through a flow transformation and the latter is encoded by an amortized factorized Gaussian. We empirically verify that our method achieves state-of-the-art performance on protein-specific 3D molecule generation in terms of binding affinity and some other drug properties. In particular, it represents the first controllable geometry-aware, protein-specific molecule generation method, which enables creating 3D molecules with specified chemical sub-structures or drug properties.

Graph Neural Networks as Gradient Flows: understanding graph convolutions via energy

Francesco Di Giovanni,James Rowbottom,Benjamin Paul Chamberlain,Thomas Markovich,Michael M. Bronstein

Gradient flows are differential equations that minimize an energy functional and constitute the main descriptors of physical systems. We apply this formalism to Graph Neural Networks (GNNs) to develop new frameworks for learning on graphs as well as provide a better theoretical understanding of existing ones. We derive GNNs as a gradient flow equation of a parametric energy that provides a physics-inspired interpretation of GNNs as learning particle dynamics in the feature space. In particular, we show that in graph convolutional models (GCN), the positive/negative eigenvalues of the channel mixing matrix correspond to attractive/repulsive forces between adjacent features. We rigorously prove how the channel-mixing can learn to steer the dynamics towards low or high frequencies, which allows to deal with heterophilic graphs. We show that the same class of energies is decreasing along a larger family of GNNs; albeit not gradient flows, they retain their inductive bias. We experimentally evaluate an instance of the gradient flow framework that is principled, more efficient than GCN, and achieves competiti ve performance on graph datasets of varying homophily often outperforming recent baselines specifically designed to target heterophily.

CogVideo: Large-scale Pretraining for Text-to-Video Generation via Transformers

Wenyi Hong,Ming Ding,Wendi Zheng,Xinghan Liu,Jie Tang

In this work, we present CogVideo, a 9B-parameter transformer for text-to-video generation. The CogVideo model has been trained by inheriting a pretrained text-to-image model, CogView2, which significantly reduces the training cost and alleviates the problem of scarcity and weak relevance. We also propose a multi-frame-rate training strategy for better aligning text and video clips. CogVideo achieves state-of-the-art performance in machine evaluation and outperforms publicly available models by a large margin in human evaluation. Its codes and model are also publicly available at https://github.com/THUDM/CogVideo.

Revisit Finetuning strategy for Few-Shot Learning to Transfer the Emdeddings

Heng Wang,Tan Yue,Xiang Ye,Zihang He,Bohan Li,Yong Li

Few-Shot Learning (FSL) aims to learn a simple and effective bias on limited novel samples. Recently, many methods have been focused on re-training a randomly initialized linear classifier to adapt it to the novel features extracted by the pre-trained feature extractor (called Linear-Probing-based methods). These methods typically assumed the pre-trained feature extractor was robust enough, i.e., finetuning was not needed, and hence the pre-trained feature extractor does not change on the novel samples. However, the unchanged pre-trained feature extractor will distort the features of novel samples because the robustness assumption may not hold, especially on the out-of-distribution samples. To extract the undistorted features, we designed Linear-Probing-Finetuning with Firth-Bias (LP-FT-FB) to yield an accurate bias on the limited samples for better finetuning the pre-trained feature extractor, providing stronger transferring ability. In LP-FT-FB, we further proposed inverse Firth Bias Reduction (i-FBR) to regularize the over-parameterized feature extractor on which FBR does not work well.■The proposed i-FBR effectively alleviates the over-fitting problem of the feature extractor in the process of finetuning and helps extract undistorted novel features. To show the effectiveness of the designed LP-FT-FB, we conducted a lot of experiments on the commonly used FSL datasets under different backbones, including in-domain and cross-domain FSL tasks. The experimental results show that the proposed FT-LP-FB outperforms the SOTA FSL methods. The code is available at https://github.com/whzyf951620/LinearProbingFinetuningFirthBias.

Scalable Multi-Modal Continual Meta-Learning

Bin Wu,Shangsong Liang,Qiang Zhang

This paper focuses on continual meta-learning, where few-shot tasks are sequentially available and sampled from a non-stationary distribution. Motivated by this challenging setting, many works have been developed with a mixture of meta-knowledge to cope with the heterogeneity and a dynamically changing number of components to capture incremental information. However, the underlying assumption of mutual exclusiveness among mixture components prevents sharing meta-knowledge across different clusters of tasks. Moreover, the existing incremental methods only rely on the prior to determine whether to increase meta-knowledge, where the unlimited increase would lead to parameter inefficiency. In our work, we propose a Scalable Multi-Modal Continual Meta-Learning (SMM-CML) algorithm. It employs a multi-modal premise that not only encourages different clusters of tasks to share meta-knowledge but also maintains their diversity. Moreover, to capture the incremental information, our algorithm uses Indian Buffet Process (IBP) as a prior number of components and proposes a sparsity method based on evidential theory to filter out the components without receiving support information directly from tasks. Thus we can learn the posterior number of components to avoid parameter inefficiency and reduce computational consumption. Experiments show SMM-CML outperforms SOTA baselines, which illustrates the effectiveness of our multi-modal meta-knowledge, and confirms that our algorithm can learn the really need meta-knowledge from tasks.

Optimizing Spca-based Continual Learning: A Theoretical Approach

Chunchun Yang,Malik Tiomoko,Zengfu Wang

Catastrophic forgetting and the stability-plasticity dilemma are two major obstacles to continual learning. In this paper we first propose a theoretical analysis of a SPCA-based continual learning algorithm using high dimensional statistics. Second, we design OSCL (Optimized Spca-based Continual Learning) which builds on a flexible task optimization based on the theory. By optimizing a single task, catastrophic forgetting can be prevented theoretically. While optimizing multi-tasks, the trade-off between integrating knowledge from the new task and retaining previous knowledge of the old task can be achieved by assigning appropriate weights to corresponding tasks in compliance with the objectives. Experimental results confirm that the various theoretical conclusions are robust to a wide range of data distributions. Besides, several applications on synthetic and real data show that the proposed method while being computationally efficient, achieves comparable results with some state of the art.

Value Memory Graph: A Graph-Structured World Model for Offline Reinforcement Learning

Deyao Zhu,Li Erran Li,Mohamed Elhoseiny

Reinforcement Learning (RL) methods are typically applied directly in environments to learn policies. In some complex environments with continuous state-action spaces, sparse rewards, and/or long temporal horizons, learning a good policy in the original environments can be difficult. Focusing on the offline RL setting, we aim to build a simple and discrete world model that abstracts the original environment. RL methods are applied to our world model instead of the environment data for simplified policy learning. Our world model, dubbed Value Memory Graph (VMG), is designed as a directed-graph-based Markov decision process (MDP) of which vertices and directed edges represent graph states and graph actions, separately. As state-action spaces of VMG are finite and relatively small compared to the original environment, we can directly apply the value iteration algorithm on VMG to estimate graph state values and figure out the best graph actions. VMG is trained from and built on the offline RL dataset. Together with an action translator that converts the abstract graph actions in VMG to real actions in the original environment, VMG controls agents to maximize episode returns. Our experiments on the D4RL benchmark show that VMG can outperform state-of-the-art offline RL methods in several tasks, especially when environments have sparse rewards and long temporal horizons. Code is available at https://github.com/TsuTikgiau/ValueMemoryGraph

CAKE: CAusal and collaborative proxy-tasKs lEarning for Semi-Supervised Domain Adaptation

Wenqiao Zhang,CHANGSHUO LIU,Can Cui,Beng Chin Ooi

Semi-supervised domain adaptation (SSDA) adapts a learner to a new domain by effectively utilizing source domain data and a few labeled target samples. It is a practical yet under-investigated research topic. In this paper, we analyze the SSDA problem from two perspectives that have previously been overlooked, and correspondingly decompose it into two \emph{key subproblems}: \emph{robust domain adaptation (DA) learning} and \emph{maximal cross-domain data utilization}. \textbf{(i)} From a causal theoretical view, a robust DA model should distinguish the invariant ``concept'' (key clue to image label) from the nuisance of confounding factors across domains. To achieve this goal, we propose to generate \emph{concept-invariant samples} to enable the model to classify the samples through causal intervention, yielding improved generalization guarantees; \textbf{(ii)} Based on the robust DA theory, we aim to exploit the maximal utilization of rich source domain data and a few labeled target samples to boost SSDA further. Consequently, we propose a collaboratively debiasing learning framework that utilizes two complementary semi-supervised learning (SSL) classifiers to mutually exchange their unbiased knowledge, which helps unleash the potential of source and target domain training data, thereby producing more convincing pseudo-labels. Such ob tained labels facilitate cross-domain feature alignment and duly improve the invariant concept learning. In our experimental study, we show that the proposed model significantly outperforms SOTA methods in terms of effectiveness and generalisability on SSDA datasets.

RulE: Neural-Symbolic Knowledge Graph Reasoning with Rule Embedding
Xiaojuan Tang,Song-Chun Zhu,Yitao Liang,Muhan Zhang

Knowledge graph (KG) reasoning is an important problem for knowledge graphs. It predicts missing links by reasoning on existing facts. Knowledge graph embedding (KGE) is one of the most popular methods to address this problem. It embeds entities and relations into low-dimensional vectors and uses the learned entity/relation embeddings to predict missing facts. However, KGE only uses zeroth-order (propositional) logic to encode existing triplets (e.g., ``Alice is Bob's wife."); it is unable to leverage first-order (predicate) logic to represent generally applicable logical \textbf{rules} (e.g., ``$\forall x,y \colon x ~\text{is}~ y\text{'s wife} \rightarrow y ~\text{is}~ x\text{'s husband}$''). On the other hand, traditional rule-based KG reasoning methods usually rely on hard logical rule inference, making it brittle and hardly competitive with KGE. In this paper, we propose RulE, a novel and principled framework to represent and model logical rules and triplets. RulE jointly represents entities, relations and logical rules in a unified embedding space. By learning an embedding for each logical rule, RulE can perform logical rule inference in a soft way and give a confidence score to each grounded rule, similar to how KGE gives each triplet a confidence score. Compared to KGE alone, RulE allows injecting prior logical rule information into the embedding space, which improves the generalization of knowledge graph embedding. Besides, the learned confidence scores of rules improve the logical rule inference process by softly controlling the contribution of each rule, which alleviates the brittleness of logic. We evaluate our method with link prediction tasks. Experimental results on multiple benchmark KGs demonstrate the effectiveness of RulE.

Sampling-free Inference for Ab-Initio Potential Energy Surface Networks
Nicholas Gao,Stephan Günnemann

Recently, it has been shown that neural networks not only approximate the ground-state wave functions of a single molecular system well but can also generalize to multiple geometries. While such generalization significantly speeds up training, each energy evaluation still requires Monte Carlo integration which limits the evaluation to a few geometries. In this work, we address the inference shortcomings by proposing the Potential learning from ab-initio Networks (PlaNet) framework, in which we simultaneously train a surrogate model in addition to the neural wave function. At inference time, the surrogate avoids expensive Monte-Carlo integration by directly estimating the energy, accelerating the process from hours to milliseconds. In this way, we can accurately model high-resolution multi-dimensional energy surfaces for larger systems that previously were unobtainable via neural wave functions. Finally, we explore an additional inductive bias by introducing physically-motivated restricted neural wave function models. We implement such a function with several additional improvements in the new PESNet++ model. In our experimental evaluation, PlaNet accelerates inference by 7 orders of magnitude for larger molecules like ethanol while preserving accuracy. Compared to previous energy surface networks, PESNet++ reduces energy errors by up to 74%.

Hidden Schema Networks
Ramses J Sanchez,Lukas Alexander Conrads,Pascal Welke,Kostadin Cvejoski,Cesar Ojeda

Most modern language models infer representations that, albeit powerful, lack both compositionality and semantic interpretability. Starting from the assumption that a large proportion of semantic content is necessarily relational, we introduce a neural language model that discovers networks of symbols (schemata) from text datasets. Using a variational autoencoder (VAE) framework, our model encodes sentences into sequences of symbols (composed representation), which correspond to the nodes visited by biased random walkers on a global latent graph. We first demonstrate that the model is able to uncover ground-truth graphs from artificially generated datasets of random token sequences. Next we leverage pretrained BERT and GPT-2 language models as encoder and decoder, respectively, to train our model on language modelling and commonsense knowledge generation tasks. Qualitatively, the model is able to infer schema networks whose nodes (symbols) can be interpreted as encoding different aspects of natural language (as e.g. topics, sentiments). Quantitatively, our results show that the model successfully interprets the encoded symbol sequences, as it achieves state-of-the-art scores on VAE language modeling benchmarks. Source code to reproduce all experiments is provided with the supplementary material.

$\mathscr{N}$-WL: A New Hierarchy of Expressivity for Graph Neural Networks

Qing Wang,Dillon Ze Chen,Asiri Wijesinghe,Shouheng Li,Muhammad Farhan

The expressive power of Graph Neural Networks (GNNs) is fundamental for understanding their capabilities and limitations, i.e., what graph properties can or cannot be learnt by a GNN. Since standard GNNs have been characterised to be upper-bounded by the Weisfeiler-Lehman (1-WL) algorithm, recent attempts concentrated on developing more expressive GNNs in terms of the k-WL hierarchy, a well-established framework for graph isormorphism tests. In this work we show that, contrary to the widely accepted view, the k-WL hierarchy is not well-suited for measuring expressive GNNs. This is due to limitations that are inherent to high-dimensional WL algorithms such as the lack of a natural interpretation and high computational costs, which makes it difficult to draw any firm conclusions about the expressive power of GNNs beyond 1-WL. Thus, we propose a novel hierarchy of graph isomorphism tests, namely Neighbourhood WL ($\mathscr{N}$-WL), and also establish a new theorem on the equivalence of expressivity between induced connected subgraphs and induced subgraphs within this hierarchy. Further, we design a GNN model upon $\mathscr{N}$-WL, Graph Neighbourhood Neural Network (G3N), and empirically verify its expressive power on synthetic and real-world benchmarks.

Learning Input-agnostic Manipulation Directions in StyleGAN with Text Guidance

Yoonjeon Kim,Hyunsu Kim,Junho Kim,Yunjey Choi,Eunho Yang

With the advantages of fast inference and human-friendly flexible manipulation, image-agnostic style manipulation via text guidance enables new applications that were not previously available. The state-of-the-art text-guided image-agnostic manipulation method embeds the representation of each channel of StyleGAN independently in the Contrastive Language-Image Pre-training (CLIP) space, and provides it in the form of a Dictionary to quickly find out the channel-wise manipulation direction during inference time. However, in this paper we argue that this dictionary which is constructed by controlling single channel individually is limited to accommodate the versatility of text guidance since the collective and interactive relation among multiple channels are not considered. Indeed, we show that it fails to discover a large portion of manipulation directions that can be found by existing methods, which manually manipulates latent space without texts. To alleviate this issue, we propose a novel method that learns a Dictionary, whose entry corresponds to the representation of a single channel, by taking into account the manipulation effect coming from the interaction with multiple other channels. We demonstrate that our strategy resolves the inability of previous methods in finding diverse known directions from unsupervised methods and unknown directions from random text while maintaining the real-time inference speed and disentanglement ability.

End-to-end Invariance Learning with Relational Inductive Biases in Multi-Object Robotic Manipulation

Davide Mambelli,Frederik Träuble,Stefan Bauer,Bernhard Schölkopf,Francesco Locatello

Although reinforcement learning has seen remarkable progress over the last years, solving robust dexterous object-manipulation tasks in multi-object settings re mains a challenge. In this paper, we focus on models that can learn manipulation tasks in fixed multi-object settings \emph{and} extrapolate this skill zero-shot without any drop in performance when the number of objects changes. We consider the generic task of moving a single cube out of a set to a goal position. We find that previous approaches, which primarily leverage attention and graph neural network-based architectures, do not exhibit this invariance when the number of input objects changes while scaling as K^2. We analyse effects on generalization of different relational inductive biases and then propose an efficient plug-and-play module that overcomes these limitations. Besides exceeding performances in their training environment, we show that our approach, which scales linearly in K, allows agents to extrapolate and generalize zero-shot to any new object number.

****

DAVA: Disentangling Adversarial Variational Autoencoder

Benjamin Estermann,Roger Wattenhofer

The use of well-disentangled representations offers many advantages for downstream tasks, e.g. an increased sample efficiency, or better interpretability.

However, the quality of disentangled interpretations is often highly dependent on the choice of dataset-specific hyperparameters, in particular the regularization strength.

To address this issue, we introduce DAVA, a novel training procedure for variational auto-encoders. DAVA completely alleviates the problem of hyperparameter selection.

We compare DAVA to models with optimal hyperparameters.

Without any hyperparameter tuning, DAVA is competitive on a diverse range of commonly used datasets.

Underlying DAVA, we discover a necessary condition for unsupervised disentanglement, which we call PIPE.

We demonstrate the ability of PIPE to positively predict the performance of downstream models in abstract reasoning.

We also thoroughly investigate correlations with existing supervised and unsupervised metrics. The code is available at https://github.com/besterma/dava.

TDR-CL: Targeted Doubly Robust Collaborative Learning for Debiased Recommendations

Haoxuan Li,Yan Lyu,Chunyuan Zheng,Peng Wu

Bias is a common problem inherent in recommender systems, which is entangled with users' preferences and poses a great challenge to unbiased learning. For debiasing tasks, the doubly robust (DR) method and its variants show superior performance due to the double robustness property, that is, DR is unbiased when either imputed errors or learned propensities are accurate.

However, our theoretical analysis reveals that DR usually has a large variance. Meanwhile, DR would suffer unexpectedly large bias and poor generalization caused by inaccurate imputed errors and learned propensities, which usually occur in practice. In this paper, we propose a principled approach that can effectively reduce the bias and variance simultaneously for existing DR approaches when the error imputation model is misspecified. In addition, we further propose a novel semi-parametric collaborative learning approach that decomposes imputed errors into parametric and nonparametric parts and updates them collaboratively, resulting in more accurate predictions. Both theoretical analysis and experiments demonstrate the superiority of the proposed methods compared with existing debiasing methods.

****

DeepGRAND: Deep Graph Neural Diffusion

Khang Nguyen,Nong Minh Hieu,Tan Minh Nguyen,Nguyen Duy Khuong,Vinh Duc NGUYEN

We propose the Deep Graph Neural Diffusion (DeepGRAND), a class of continuous-depth graph neural networks based on the diffusion process on graphs. DeepGRAND leverages a data-dependent scaling term and a perturbation to the graph diffusivity to make the real part of all eigenvalues of the diffusivity matrix become negative, which ensures two favorable theoretical properties: (i) the node represent ation does not exponentially converge to a constant vector as the model depth increases, thus alleviating the over-smoothing issue; (ii) the stability of the model is guaranteed by controlling the norm of the node representation. Compared to the baseline GRAND, DeepGRAND mitigates the accuracy drop-off with increasing depth and improves the overall accuracy of the model. We empirically corroborate the advantage of DeepGRAND over many existing graph neural networks on various graph deep learning benchmark tasks.

Learning Discrete Representation with Optimal Transport Quantized Autoencoders

Xiaoyu Bie,Dexiong Chen,Xiaodong Cun,Xi SHEN

Vector quantized variational autoencoder (VQ-VAE) has recently emerged as a powerful generative model for learning discrete representations. Like other vector quantization methods, one key challenge of training VQ-VAE comes from the codebook collapse, i.e. only a fraction of codes are used, limiting its reconstruction qualities. To this end, VQ-VAE often leverages some carefully designed heuristics during the training to use more codes. In this paper, we propose a simple yet effective approach to overcome this issue through optimal transport, which regularizes the quantization by explicitly assigning equal number of samples to each code. The proposed approach, named OT-VAE, enforces the full utilization of the codebook while not requiring any heuristics. We empirically validate our approach on three different data modalities: images, speech, and 3D human motions. For all the modalities, OT-VAE shows better reconstruction with higher perplexity than other VQ-VAE variants on several datasets. In particular, OT-VAE achieves state-of-the-art results on the AIST++ dataset for 3D dance generation. Our code will be released upon publication.

How to Keep Cool While Training

Martin Trimmel,Mihai Zanfir,Richard Hartley,Cristian Sminchisescu

Modern classification neural networks are notoriously prone to being overly confident in their predictions. With multiple calibration methods having been proposed so far, there has been noteworthy progress in reducing this overconfidence. However, to the best of our knowledge, prior methods have exclusively focused on the factors that affect calibration, leaving open the reverse question of how (mis)calibration impacts network training. Aiming for a better understanding of this interplay, we propose a temperature-based Cooling method for calibrating classification neural networks during training. Cooling has a substantial effect on the gradients and reduces the need for a learning rate schedule. We investigate different variants of Cooling, with the simplest one, last layer Cooling, being also the best-performant one, improving network performance on a range of datasets, network architectures, and hyperparameter settings.

Learning System Dynamics from Sensory Input under Optimal Control Principles

Oumayma Bounou,Jean Ponce,Justin Carpentier

Identifying the underlying dynamics of actuated physical systems from sensory input is of high interest in control, robotics, and engineering in general. In the context of control problems, existing approaches decouple the construction of the feature space where the dynamics identification process occurs from the target control tasks, potentially leading to a mismatch between feature and real state spaces: the systems may not be controllable in feature space, and synthesized controls may not be applicable in the state space. Borrowing from the Koopman formalism, we propose instead to learn an embedding of both the states and con- trols in feature spaces where the dynamics are linear, and to include the target control task in the learning objective in the form of a differentiable and robust optimal control problem. We validate this approach with simulation experiments of systems with non-linear dynamics, demonstrating that the controls obtained in feature space can be used to drive the corresponding physical systems and that the learned model can serve for future state prediction.

Dual Algorithmic Reasoning

Danilo Numeroso,Davide Bacciu,Petar Veli■kovi■

Neural Algorithmic Reasoning is an emerging area of machine learning which seeks to infuse algorithmic computation in neural networks, typically by training neural models to approximate steps of classical algorithms. In this context, much of the current work has focused on learning reachability and shortest path graph algorithms, showing that joint learning on similar algorithms is beneficial for generalisation. However, when targeting more complex problems, such "similar" algorithms become more difficult to find. Here, we propose to learn algorithms by exploiting duality of the underlying algorithmic problem. Many algorithms solve optimisation problems. We demonstrate that simultaneously learning the dual definition of these optimisation problems in algorithmic learning allows for better learning and qualitatively better solutions. Specifically, we exploit the max-flow min-cut theorem to simultaneously learn these two algorithms over synthetically generated graphs, demonstrating the effectiveness of the proposed approach. We then validate the real-world utility of our dual algorithmic reasoner by deploying it on a challenging brain vessel classification task, which likely depends on the vessels’ flow properties. We demonstrate a clear performance gain when using our model within such a context, and empirically show that learning the max-flow and min-cut algorithms together is critical for achieving such a result.

Lmser-pix2seq: Learning Stable Sketch Representations For Sketch Healing
Tengjie Li,Sicong Zang,Shikui Tu,Lei Xu

Sketch healing aims to recreate a complete sketch from the corrupted one. The sparse and abstract nature of the sketch makes it challenging due to the difficulty in learning. The features extracted from the corrupted sketch may be inconsistent with the ones from the corresponding full sketch. In this paper, we present Lmser-pix2seq to learn stable sketch representations against the missing information by employing a Least mean square error reconstruction (Lmser) block, which falls into encoder-decoder paradigm. Taking as input a corrupted sketch, the Lmser encoder computes the embeddings of structural patterns of the input, while the decoder reconstructs the complete sketch from the embeddings. We build bi-directional skip connections between the encoder and the decoder in our Lmser block. The feedback connections enable recurrent paths to receive more information about the reconstructed sketch produced by the decoder, which helps the encoder extract stable sketch features. The features captured by the Lmser block are eventually fed into a recurrent neural network decoder to recreate the sketches. Experimental results show that our Lmser-pix2seq outperforms the state-of-the-art methods in sketch healing, especially when the sketches are heavily masked or corrupted.

Toward Effective Deep Reinforcement Learning for 3D Robotic Manipulation: End-to-End Learning from Multimodal Raw Sensory Data
Samyeul Noh,Hyun Myung

Sample-efficient reinforcement learning (RL) methods capable of learning directly from raw sensory data without the use of human-crafted representations would open up real-world applications in robotics and control. Recent advances in visual RL have shown that learning a latent representation together with existing RL algorithms closes the gap between state-based and image-based training. However, image-based training is still significantly sample-inefficient with respect to learning in 3D continuous control problems (for example, robotic manipulation) compared to state-based training. In this study, we propose an effective model-free off-policy RL method for 3D robotic manipulation that can be trained in an end-to-end manner from multimodal raw sensory data obtained from a vision camera and a robot's joint encoders, without the need for human-crafted representations. Notably, our method is capable of learning a latent multimodal representation and a policy in an efficient, joint, and end-to-end manner from multimodal raw sensory data. Our method, which we dub MERL: Multimodal End-to-end Reinforcement Learning, results in a simple but effective approach capable of significantly outperforming both current state-of-the-art visual RL and state-based RL methods with respect to sample efficiency, learning performance, and training stability in relation to 3D robotic manipulation tasks from DeepMind Control.

****

Domain Generalisation via Domain Adaptation: An Adversarial Fourier Amplitude Approach

Minyoung Kim,Da Li,Timothy Hospedales

We tackle the domain generalisation (DG) problem by posing it as a domain adaptation (DA) task where we adversarially synthesise the worst-case `target' domain and adapt a model to that worst-case domain, thereby improving the model’s robustness. To synthesise data that is challenging yet semantics-preserving, we generate Fourier amplitude images and combine them with source domain phase images, exploiting the widely believed conjecture from signal processing that amplitude spectra mainly determines image style, while phase data mainly captures image semantics. To synthesise a worst-case domain for adaptation, we train the classifier and the amplitude generator adversarially. Specifically, we exploit the maximum classifier discrepancy (MCD) principle from DA that relates the target domain performance to the discrepancy of classifiers in the model hypothesis space. By Bayesian hypothesis modeling, we express the model hypothesis space effectively as a posterior distribution over classifiers given the source domains, making adversarial MCD minimisation feasible. On the DomainBed benchmark including the large-scale DomainNet dataset, the proposed approach yields significantly improved domain generalisation performance over the state-of-the-art.

Improving Generative Flow Networks with Path Regularization

Anh Do,Duy Dinh,Tan Minh Nguyen,Nguyen Duy Khuong,Stanley Osher,Nhat Ho

Generative Flow Networks (GFlowNets) are recently proposed models for learning stochastic policies that generate compositional objects by sequences of actions with the probability proportional to a given reward function. The central problem of GFlowNets is to improve their exploration and generalization. In this work, we propose a novel path regularization method based on optimal transport theory that places prior constraints on the underlying structure of the GFlowNets. The prior is designed to help the GFlowNets better discover the latent structure of the target distribution or enhance its ability to explore the environment in the context of active learning. The path regularization controls the flow in GFlowNets to generate more diverse and novel candidates via maximizing the optimal transport distances between two forward policies or to improve the generalization via minimizing the optimal transport distances. In addition, we derive an efficient implementation of the regularization by finding its closed form solutions in specific cases and a meaningful upper bound that can be used as an approximation to minimize the regularization term. We empirically demonstrate the advantage of our path regularization on a wide range of tasks, including synthetic hypergrid environment modeling, discrete probabilistic modeling, and biological sequence design.

Confidential-PROFITT: Confidential PROof of FaIr Training of Trees

Ali Shahin Shamsabadi,Sierra Calanda Wyllie,Nicholas Franzese,Natalie Dullerud,Sébastien Gambs,Nicolas Papernot,Xiao Wang,Adrian Weller

Post hoc auditing of model fairness suffers from potential drawbacks: (1) auditing may be highly sensitive to the test samples chosen; (2) the model and/or its training data may need to be shared with an auditor thereby breaking confidentiality. We address these issues by instead providing a certificate that demonstrates that the learning algorithm itself is fair, and hence, as a consequence, so too is the trained model. We introduce a method to provide a confidential proof of fairness for training, in the context of widely used decision trees, which we term Confidential-PROFITT. We propose novel fair decision tree learning algorithms along with customized zero-knowledge proof protocols to obtain a proof of fairness that can be audited by a third party. Using zero-knowledge proofs enables us to guarantee confidentiality of both the model and its training data. We show empirically that bounding the information gain of each node with respect to the sensitive attributes reduces the unfairness of the final tree. In extensive experiments on the COMPAS, Communities and Crime, Default Credit, and Adult datasets, we demonstrate that a company can use Confidential-PROFITT to certify the fai rness of their decision tree to an auditor in less than 2 minutes, thus indicating the applicability of our approach. This is true for both the demographic parity and equalized odds definitions of fairness. Finally, we extend Confidential-PROFITT to apply to ensembles of trees.

Consolidator: Mergable Adapter with Group Connections for Visual Adaptation

Tianxiang Hao,Hui Chen,Yuchen Guo,Guiguang Ding

Recently, transformers have shown strong ability as visual feature extractors, surpassing traditional convolution-based models in various scenarios. However, the success of vision transformers largely owes to their capacity to accommodate numerous parameters. As a result, new challenges for adapting a well-trained transformer to downstream tasks arise. On the one hand, classic fine-tuning tunes all parameters in a huge model for every downstream task and thus easily falls into an overfitting situation, leading to inferior performance. On the other hand, on resource-limited devices, fine-tuning stores a full copy of all parameters and thus is usually impracticable for the shortage of storage space. However, few works have focused on how to efficiently and effectively transfer knowledge in a vision transformer. Existing methods did not dive into the properties of visual features, leading to inferior performance. Moreover, some of them bring heavy inference cost though benefiting storage. To tackle these problems, we propose consolidator to achieve efficient transfer learning for large vision models. Our consolidator modifies the pre-trained model with the addition of a small set of tunable parameters to temporarily store the task-specific knowledge while freezing the backbone model during adaptation. Motivated by the success of group-wise convolution, we adopt grouped connections across the features extracted by fully connected layers to construct tunable parts in a consolidator. To further enhance the model's capacity to transfer knowledge under a constrained storage budget and keep inference efficient, we consolidate the parameters in two stages: 1. between adaptation and storage, and 2. between loading and inference. On a series of downstream visual tasks, our consolidator can reach up to 7.56 better accuracy than full fine-tuning with merely 0.35% parameters, and outperform state-of-the-art parameter-efficient tuning methods by a clear margin. Code is available at github.

Statistical Theory of Differentially Private Marginal-based Data Synthesis Algorithms

Ximing Li,Chendi Wang,Guang Cheng

Marginal-based methods achieve promising performance in the synthetic data competition hosted by the National Institute of Standards and Technology (NIST).

To deal with high-dimensional data, the distribution of synthetic data is represented by a probabilistic graphical model (e.g., a Bayesian network), while the raw data distribution is approximated by a collection of low-dimensional marginals.

Differential privacy (DP) is guaranteed by introducing random noise to each low-dimensional marginal distribution.

Despite its promising performance in practice, the statistical properties of marginal-based methods are rarely studied in the literature.

In this paper, we study DP data synthesis algorithms based on Bayesian networks (BN) from a statistical perspective. We establish a rigorous accuracy guarantee for BN-based algorithms, where the errors are measured by the total variation (TV) distance or the L^2 distance.

Related to downstream machine learning tasks, an upper bound for the utility error of the DP synthetic data is also derived. To complete the picture, we establish a lower bound for TV accuracy that holds for every ϵ-DP synthetic data generator.

Homotopy-based training of NeuralODEs for accurate dynamics discovery

Joon-Hyuk Ko,Hankyul Koh,Nojun Park,Wonho Jhe

Conceptually, Neural Ordinary Differential Equations (NeuralODEs) pose an attractive way to extract dynamical laws from time series data, as they are natural ex tensions of the traditional differential equation-based modeling paradigm of the physical sciences. In practice, NeuralODEs display long training times and suboptimal results, especially for longer duration data where they may fail to fit the data altogether. While methods have been proposed to stabilize NeuralODE training, many of these involve placing a strong constraint on the functional form the trained NeuralODE can take that the actual underlying governing equation does not guarantee satisfaction. In this work, we present a novel NeuralODE training algorithm that leverages tools from the chaos and mathematical optimization communities -- synchronization and homotopy optimization -- for a breakthrough in tackling the NeuralODE training obstacle. We demonstrate architectural changes are unnecessary for effective NeuralODE training. Compared to the conventional training methods, our algorithm achieves drastically lower loss values without any changes to the model architectures. Experiments on both simulated and real systems with complex temporal behaviors demonstrate NeuralODEs trained with our algorithm are able to accurately capture true long term behaviors and correctly extrapolate into the future.

Transformers with Multiresolution Attention Heads
Tan Minh Nguyen,Tho Tran Huu,Tam Minh Nguyen,Minh Pham,Nhat Ho,Stanley Osher

We propose the Transformer with Multiresolution-head Attention (MrsFormer), a class of efficient transformers inspired by the multiresolution approximation (MRA) for approximating a signal f using wavelet bases. MRA decomposes a signal into components that lie on orthogonal subspaces at different scales. Similarly, MrsFormer decomposes the attention heads in the multi-head attention into fine-scale and coarse-scale heads, modeling the attention patterns between tokens and between groups of tokens. Computing the attention heads in MrsFormer requires significantly less computation and memory footprint compared to the standard softmax transformer with multi-head attention. We analyze and validate the advantage of MrsFormer over the standard transformers on a wide range of applications including image and time series classification.

Anti-Symmetric DGN: a stable architecture for Deep Graph Networks
Alessio Gravina,Davide Bacciu,Claudio Gallicchio

Deep Graph Networks (DGNs) currently dominate the research landscape of learning from graphs, due to their efficiency and ability to implement an adaptive message-passing scheme between the nodes. However, DGNs are typically limited in their ability to propagate and preserve long-term dependencies between nodes, i.e., they suffer from the over-squashing phenomena. As a result,
we can expect them to under-perform, since different problems require to capture interactions at different (and possibly large) radii in order to be effectively solved. In this work, we present Anti-Symmetric Deep Graph Networks (A-DGNs), a framework for stable and non-dissipative DGN design, conceived through the lens of ordinary differential equations. We give theoretical proof that our method is stable and non-dissipative, leading to two key results: long-range information between nodes is preserved, and no gradient vanishing or explosion occurs in training. We empirically validate the proposed approach on several graph benchmarks, showing that A-DGN yields to improved performance and enables to learn effectively even when dozens of layers are used.

Contrastive Learning for Unsupervised Domain Adaptation of Time Series
Yilmazcan Ozyurt,Stefan Feuerriegel,Ce Zhang

Unsupervised domain adaptation (UDA) aims at learning a machine learning model using a labeled source domain that performs well on a similar yet different, unlabeled target domain. UDA is important in many applications such as medicine, where it is used to adapt risk scores across different patient cohorts. In this paper, we develop a novel framework for UDA of time series data, called CLUDA. Specifically, we propose a contrastive learning framework to learn contextual representations in multivariate time series, so that these preserve label information for the prediction task. In our framework, we further capture the variation in t he contextual representations between source and target domain via a custom nearest-neighbor contrastive learning. To the best of our knowledge, ours is the first framework to learn domain-invariant, contextual representation for UDA of time series data. We evaluate our framework using a wide range of time series datasets to demonstrate its effectiveness and show that it achieves state-of-the-art performance for time series UDA.

Model-Based Decentralized Policy Optimization

Hao Luo,Jiechuan Jiang,Zongqing Lu

Decentralized policy optimization has been commonly used in cooperative multi-agent tasks. However, since all agents are updating their policies simultaneously, from the perspective of individual agents, the environment is non-stationary, resulting in it being hard to guarantee monotonic policy improvement. To help the policy improvement be stable and monotonic, we propose model-based decentralized policy optimization (MDPO), which incorporates a latent variable function to help construct the transition and reward function from an individual perspective. We theoretically analyze that the policy optimization of MDPO is more stable than model-free decentralized policy optimization. Moreover, due to non-stationarity, the latent variable function is varying and hard to be modeled. We further propose a latent variable prediction method to reduce the error of latent variable function, which theoretically contributes to the monotonic policy improvement. Empirically, MDPO can indeed obtain superior performance than model-free decentralized policy optimization in a variety of cooperative multi-agent tasks.

Online Low Rank Matrix Completion

Soumyabrata Pal,Prateek Jain

We study the problem of online low-rank matrix completion with M users, N items and T rounds. In each round, the algorithm recommends one item per user, for which it gets a (noisy) reward sampled from a low-rank user-item preference matrix. The goal is to design a method with sub-linear regret (in T) and nearly optimal dependence on M and N. The problem can be easily mapped to the standard multi-armed bandit problem where each item is an independent arm, but that leads to poor regret as the correlation between arms and users is not exploited. On the other hand, exploiting the low-rank structure of reward matrix is challenging due to non-convexity of the low-rank manifold. We first demonstrate that the low-rank structure can be exploited using a simple explore-then-commit (ETC) approach that ensures a regret of $O(\mathsf{polylog} (\mathsf{M}+\mathsf{N}) \mathsf{T}^{2/3})$. That is, roughly only $\mathsf{polylog} (\mathsf{M}+\mathsf{N})$ item recommendations are required per user to get a non-trivial solution. We then improve our result for the rank-1 setting which in itself is quite challenging and encapsulates some of the key issues. Here, we propose OCTAL (Online Collaborative filTering using iterAtive user cLustering) that guarantees nearly optimal regret of $O(\mathsf{polylog} (\mathsf{M}+\mathsf{N}) \mathsf{T}^{1/2})$. OCTAL is based on a novel technique of clustering users that allows iterative elimination of items and leads to a nearly optimal minimax rate.

Modality Complementariness: Towards Understanding Multi-modal Robustness

Siting Li,Chenzhuang Du,Yu Huang,Longbo Huang,Hang Zhao

Along with the success of multi-modal learning, the robustness of multi-modal learning is receiving attention due to real-world safety concerns. Multi-modal models are anticipated to be more robust due to the possible redundancy between modalities. However, some empirical results have offered contradictory conclusions. In this paper, we point out an essential factor that causes this discrepancy: The difference in the amount of modality-wise complementary information. We provide an information-theoretical analysis of how the modality complementariness affects the multi-modal robustness. Based on the analysis, we design a metric for quantifying how complementary the modalities are to others and propose an effective pipeline to calculate our metric. Experiments on carefully-designed synthetic data verify our theory. Further, we apply our metric to real-world multi-modal datasets and reveal their property. To our best knowledge, we are the first to identify modality complementariness as an important factor affecting multi-modal robustness.

Effective Offline Reinforcement Learning via Conservative State Value Estimation

Liting Chen,Jie Yan,Lu Wang,Qingwei Lin,Dongmei Zhang,Saravan Rajmohan,Thomas Moscibroda

Offline RL promises to learn effective policies from static experience datasets without further interaction, which expect to perform well in the online environment. However, it faces up to a major challenge of value over-estimation introduced by the distributional drift between the dataset and the current learned policy, which leads to learning failure in practice. The common approach is to add a penalty term to reward or value estimation in the Bellman iterations, which has given rise to a number of successful algorithms such as CQL. Meanwhile, to avoid extrapolation on unseen states, existing methods focus on conservative Q-function estimation. In this paper, we propose CSVE, a new approach that directly imposes penalty on out-of-distribution states. We prove that for the evaluated policy, our conservative state value estimation satisfies: (1) over the state distribution that samples penalizing states, it lower bounds the true values in expectation, and (2) over the marginal state distribution of data, it is no more than the true values in expectation plus a constant decided by sampling error. Further, we develop a practical actor-critic algorithm in which the critic does the conservative value estimation by additionally sampling and penalizing the states 'around' the dataset, while the actor applies advantage weighted updates to improve the policy. We evaluate in classic continual control tasks of D4RL, showing that our method performs better than the conservative Q-function learning methods (e.g., CQL) and is strongly competitive among recent SOTA methods.

ChemAlgebra : Algebraic Reasoning on Chemical Reactions

Andrea Valenti,Davide Bacciu,Antonio Vergari

While showing impressive performance on various kinds of learning tasks, it is yet unclear whether deep learning models have the ability to robustly tackle reasoning tasks. Measuring the robustness of reasoning in machine learning models is challenging as one needs to provide a task that cannot be easily shortcut by exploiting spurious statistical correlations in the data, while operating on complex objects and constraints. To address this issue, we propose ChemAlgebra, a benchmark for measuring the reasoning capabilities of deep learning models through the prediction of stoichiometrically-balanced chemical reactions. ChemAlgebra requires manipulating sets of complex discrete objects – molecules represented as formulas or graphs – under algebraic constraints such as the mass preservation principle. We believe that ChemAlgebra can serve as a useful test bed for the next generation of machine reasoning models and as a promoter of their development.

A Primal-Dual Framework for Transformers and Neural Networks

Tan Minh Nguyen,Tam Minh Nguyen,Nhat Ho,Andrea L. Bertozzi,Richard Baraniuk,Stanley Osher

Self-attention is key to the remarkable success of transformers in sequence modeling tasks including many applications in natural language processing and computer vision. Like neural network layers, these attention mechanisms are often developed by heuristics and experience. To provide a principled framework for constructing attention layers in transformers, we show that the self-attention corresponds to the support vector expansion derived from a support vector regression problem, whose primal formulation has the form of a neural network layer. Using our framework, we derive popular attention layers used in practice and propose two new attentions: 1) the Batch Normalized Attention (Attention-BN) derived from the batch normalization layer and 2) the Attention with Scaled Head (Attention-SH) derived from using less training data to fit the SVR model. We empirically demonstrate the advantages of the Attention-BN and Attention-SH in reducing head redundancy, increasing the model's accuracy, and improving the model's efficiency in a variety of practical applications including image and time-series classifi

cation.

Explaining RL Decisions with Trajectories
Shripad Vilasrao Deshmukh,Arpan Dasgupta,Balaji Krishnamurthy,Nan Jiang,Chirag Agarwal,Georgios Theocharous,Jayakumar Subramanian

Explanation is a key component for the adoption of reinforcement learning (RL) in many real-world decision-making problems. In the literature, the explanation is often provided by saliency attribution to the features of the RL agent's state. In this work, we propose a complementary approach to these explanations, particularly for offline RL, where we attribute the policy decisions of a trained RL agent to the trajectories encountered by it during training. To do so, we encode trajectories in offline training data individually as well as collectively (encoding a set of trajectories). We then attribute policy decisions to a set of trajectories in this encoded space by estimating the sensitivity of the decision with respect to that set. Further, we demonstrate the effectiveness of the proposed approach in terms of quality of attributions as well as practical scalability in diverse environments that involve both discrete and continuous state and action spaces such as grid-worlds, video games (Atari) and continuous control (MuJoCo). We also conduct a human study on a simple navigation task to observe how their understanding of the task compares with data attributed for a trained RL policy.

Keypoint Matching via Random Network Consensus
Siyan Dong,Shuzhe Wang,Daniel Barath,Juho Kannala,Marc Pollefeys,Baoquan Chen

Visual description, detection, and matching of keypoints in images are fundamental components of many computer vision problems, such as camera tracking and (re)localization. Recently, learning-based feature extractors on top of convolutional neural networks (CNNs) have achieved state-of-the-art performance. In this paper, we further explore the usage of CNN and present a new approach that ensembles randomly initialized CNNs without any training. Our observation is that the CNN architecture inherently extracts features with certain extents of robustness to viewpoint/illumination changes and thus, it can be regarded as visual descriptors. Consequently, randomized CNNs serve as descriptor extractors and a subsequent consensus mechanism detects keypoints using them. Such description and detection pipeline can be used to match keypoints in images and achieves higher generalization ability than the state-of-the-art methods in our experiments.
