In recent years, single-objective reinforcement learning (SORL) algorithms have received a significant amount of attention and seen some strong results. However, it is generally recognized that many practical problems have intrinsic multi-objective properties that cannot be easily handled by SORL algorithms. Although there have been many multi-objective reinforcement learning (MORL) algorithms proposed, there has been little recent exploration of the fundamental properties of the spaces we are learning in. In this paper, we perform a rigorous analysis of policy induced value functions and use the insights to distinguish three views of Pareto optimality. The results imply the convexity of the induced value function's range for stationary policies and suggest that any point of its Pareto front can be achieved by training a policy using linear scalarization (LS). We show the problem that leads to the suboptimal performance of LS can be solved by adding strongly concave terms to the immediate rewards, which motivates us to propose a new vector reward-based Q-learning algorithm, CAPQL. Combined with an actor-critic formulation, our algorithm achieves state-of-the-art performance on multiple MuJoCo tasks in the preference agnostic setting. Furthermore, we empirically show that, in contrast to other LS-based algorithms, our approach is significantly more stable, achieving similar results across various random seeds.

Continual Unsupervised Disentangling of Self-Organizing Representations

Zhiyuan Li,Xiajun Jiang,Ryan Missel,Prashnna Kumar Gyawali,Nilesh Kumar,Linwei Wang

Limited progress has been made in continual unsupervised learning of representations, especially in reusing, expanding, and continually disentangling learned semantic factors across data environments. We argue that this is because existing approaches treat continually-arrived data independently, without considering how they are related based on the underlying semantic factors. We address this by a new generative model describing a topologically-connected mixture of spike-and-slab distributions in the latent space, learned end-to-end in a continual fashion via principled variational inference. The learned mixture is able to automatically discover the active semantic factors underlying each data environment and to accumulate their relational structure based on that. This distilled knowledge of different data environments can further be used for generative replay and guiding continual disentangling of new semantic factors. We tested the presented method on a split version of 3DShapes to provide the first quantitative disentanglement evaluation of continually learned representations, and further demonstrated its ability to continually disentangle new representations in benchmark datasets.

Inducing Gaussian Process Networks

Alessandro Tibo,Thomas Dyhre Nielsen

Gaussian processes (GPs) are powerful but computationally expensive machine learning models, requiring an estimate of the kernel covariance matrix for every prediction. In large and complex domains, such as graphs, sets, or images, the choice of suitable kernel can also be non-trivial to determine, providing an additional obstacle to the learning task. Over the last decade, these challenges have resulted in significant advances being made in terms of scalability and expressivity, exemplified by, e.g., the use of inducing points and neural network kernel approximations.

In this paper, we propose inducing Gaussian process networks (IGN), a simple framework for simultaneously learning the feature space as well as the inducing points. The inducing points, in particular, are learned directly in the feature space, enabling a seamless representation of complex structured domains while also facilitating scalable gradient-based learning methods.

We consider both regression and (binary) classification tasks and report on experimental results for real-world data sets showing that IGNs provide significant advances over state-of-the-art methods. We also demonstrate how IGNs can be used to effectively model complex domains using neural network architectures.

Monotonicity and Double Descent in Uncertainty Estimation with Gaussian Processes

Liam Hodgkinson,Chris van der Heide,Fred Roosta,Michael W. Mahoney

The quality of many modern machine learning models improves as model complexity increases, an effect that has been quantified—for predictive performance—with the non-monotonic double descent learning curve. Here, we address the overarching question: is there an analogous theory of double descent for models which estimate uncertainty? We provide a partially affirmative and partially negative answer in the setting of Gaussian processes (GP). Under standard assumptions, we prove that higher model quality for optimally-tuned GPs (including uncertainty prediction) under marginal likelihood is realized for larger input dimensions, and therefore exhibits a monotone learning curve. After showing that marginal likelihood does not naturally exhibit double descent in the input dimension, we highlight related forms of posterior predictive loss that do. Finally, we verify empirically that our results hold for real data, beyond our considered assumptions, and explore unusual consequences involving synthetic covariates.

Fooling SHAP with Stealthily Biased Sampling

gabriel laberge,Ulrich Aïvodji,Satoshi Hara,Mario Marchand,Foutse Khomh

SHAP explanations aim at identifying which features contribute the most to the difference in model prediction at a specific input versus
a background distribution. Recent studies have shown that they can be manipulated by malicious adversaries to produce arbitrary desired
explanations. However, existing attacks focus solely on altering the black-box model itself. In this paper, we propose a complementary family
of attacks that leave the model intact and manipulate SHAP explanations using stealthily biased sampling of the data points used to approximate expectations w.r.t the background distribution. In the context of fairness audit, we show that our attack can reduce the importance of a sensitive feature when explaining the difference in outcomes between groups while remaining undetected. More precisely, experiments performed on real-world datasets showed that our attack could yield up to a 90\% relative decrease in amplitude of the sensitive feature attribution. These results highlight the manipulability of SHAP explanations and encourage auditors to treat them with skepticism.

Asynchronous Gradient Play in Zero-Sum Multi-agent Games
Ruicheng Ao,Shicong Cen,Yuejie Chi
Finding equilibria via gradient play in competitive multi-agent games has been attracting a growing amount of attention in recent years, with emphasis on designing efficient strategies where the agents operate in a decentralized and symmetric manner with guaranteed convergence. While significant efforts have been made in understanding zero-sum two-player matrix games, the performance in zero-sum multi-agent games remains inadequately explored, especially in the presence of delayed feedbacks, leaving the scalability and resiliency of gradient play open to questions. In this paper, we make progress by studying asynchronous gradient plays in zero-sum polymatrix games under delayed feedbacks. We first establish that the last iterate of entropy-regularized optimistic multiplicative weight updates (OMWU) method converges linearly to the quantal response equilibrium (QRE), the solution concept under bounded rationality, in the absence of delays. The linear convergence continues to hold even when the feedbacks are randomly delayed under mild statistical assumptions, albeit at a slower rate. Moving beyond random delays, we further demonstrate entropy-regularized OMWU with two-timescale learning rates enjoys faster last-iterate convergence under fixed delays, and continues to converge provably even when the delays are arbitrarily bounded. Our methods also lead to finite-time guarantees to approximate the Nash equilibrium (NE) by moderating the amount of regularization. To the best of our knowledge, this work is the first that aims to understand asynchronous gradient play in zero-sum polymatrix games under a wide range of delay assumptions.

Novel View Synthesis with Diffusion Models
Daniel Watson,William Chan,Ricardo Martin Brualla,Jonathan Ho,Andrea Tagliasacchi,Mohammad Norouzi
We present 3DiM (pronounced "three-dim"), a diffusion model for 3D novel view synthesis from as few as a single image. The core of 3DiM is an image-to-image diffusion model -- 3DiM takes a single reference view and their poses as inputs, and generates a novel view via diffusion. 3DiM can then generate a full 3D consistent scene following our novel stochastic conditioning sampler: the output frames of the scene are generated autoregressively, and during the reverse diffusion process of each individual frame, we select a random conditioning frame from the set of previous frames at each denoising step. We demonstrate that stochastic conditioning yields much more 3D consistent results compared to the naive sampling process which only conditions on a single previous frame. We compare 3DiMs to prior work on the SRN ShapeNet dataset, demonstrating that 3DiM's generated videos from a single view achieve much higher fidelity while being approximately 3D consistent. We also introduce a new evaluation methodology, 3D consistency scoring, to measure the 3D consistency of a generated object by training a neural field on the model's output views. 3DiMs are geometry free, do not rely on hyper-networks or test-time optimization for novel view synthesis, and allow a single mod

el to easily scale to a large number of scenes.

DM-NeRF: 3D Scene Geometry Decomposition and Manipulation from 2D Images
Bing WANG,Lu Chen,Bo Yang

In this paper, we study the problem of 3D scene geometry decomposition and manipulation from 2D views. By leveraging the recent implicit neural representation techniques, particularly the appealing neural radiance fields, we introduce an object field component to learn unique codes for all individual objects in 3D space only from 2D supervision. The key to this component is a series of carefully designed loss functions to enable every 3D point, especially in non-occupied space, to be effectively optimized even without 3D labels. In addition, we introduce an inverse query algorithm to freely manipulate any specified 3D object shape in the learned scene representation. Notably, our manipulation algorithm can explicitly tackle key issues such as object collisions and visual occlusions. Our method, called DM-NeRF, is among the first to simultaneously reconstruct, decompose, manipulate and render complex 3D scenes in a single pipeline. Extensive experiments on three datasets clearly show that our method can accurately decompose all 3D objects from 2D views, allowing any interested object to be freely manipulated in 3D space such as translation, rotation, size adjustment, and deformation.

Robust Neural ODEs via Contractivity-promoting Regularization
Liang Xu,Muhammad Zakwan,Giancarlo Ferrari-Trecate

Neural networks can be fragile to input noise and adversarial attacks. In this work, we consider Neural Ordinary Differential Equations (NODEs) – a family of continuous-depth neural networks represented by dynamical systems - and propose to use contraction theory to improve their robustness. A dynamical system is contractive if two trajectories starting from different initial conditions converge to each other exponentially fast. Contractive NODEs can enjoy increased robustness as slight perturbations of the features do not cause a significant change in the output. Contractivity can be induced during training by using a regularization term involving the Jacobian of the system dynamics. To reduce the computational burden, we show that it can also be promoted using carefully selected weight regularization terms for a class of NODEs with slope-restricted activation functions, including convolutional networks commonly used in image classification. The performance of the proposed regularizers is illustrated through benchmark image classification tasks on MNIST and FashionMNIST datasets, where images are corrupted by different kinds of noise and attacks.

Analyzing the Effects of Classifier Lipschitzness on Explainers
Zulqarnain Khan,Aria Masoomi,Davin Hill,Jennifer Dy

Machine learning methods are getting increasingly better at making predictions, but at the same time they are also becoming more complicated and less transparent. As a result, explainers are often relied on to provide interpretability to these \textit{black-box} prediction models. As crucial diagnostics tools, it is important that these explainers themselves are reliable. In this paper we focus on one particular aspect of reliability, namely that an explainer should give similar explanations for similar data inputs. We formalize this notion by introducing and defining \textit{explainer astuteness}, analogous to astuteness of classifiers. Our formalism is inspired by the concept of \textit{probabilistic Lipschitzness}, which captures the probability of local smoothness of a function. For a variety of explainers (e.g., SHAP, RISE, CXPlain), we provide lower bound guarantees on the astuteness of these explainers given the Lipschitzness of the prediction function. These theoretical results imply that locally smooth prediction functions lend themselves to locally robust explanations. We evaluate these results empirically on simulated as well as real datasets.

Complex-Target-Guided Open-Domain Conversation based on offline reinforcement learning
Haibo Huang,Ying Tan,Haoxing Zhang,Lei Yu

Previous target-guided open-domain dialogue systems mostly take one keyword as the target, which has great limitations and cannot characterize the dialogue target well. In this paper, we introduce a new target representation model which uses a verb-noun pair to represent a complex-target. To this end, we implement a new dialogue guide procedure with Verb graph and Noun graph construction, dialogue encoder, verb-noun choose model and response generator. Machine metrics and human evaluation both show that our model outperforms previous target-guided dialogue system. In addition, different from previous target-guided dialogue systems which use online reinforcement learning to make decisions, we integrate an offline reinforcement learning method to gradually reduce the training time with a high performance.

Trading Information between Latents in Hierarchical Variational Autoencoders
Tim Z. Xiao,Robert Bamler

Variational Autoencoders (VAEs) were originally motivated as probabilistic generative models in which one performs approximate Bayesian inference. The proposal of β-VAEs breaks this interpretation and generalizes VAEs to application domains beyond generative modeling (e.g., representation learning, clustering, or lossy data compression) by introducing an objective function that allows practitioners to trade off between the information content ("bit rate") of the latent representation and the distortion of reconstructed data. In this paper, we reconsider this rate/distortion trade-off in the context of hierarchical VAEs, i.e., VAEs with more than one layer of latent variables. We propose a method to control each layer's contribution to the rate independently. We identify the most general class of inference models to which our proposed method is applicable, and we derive theoretical bounds on the performance of downstream tasks as functions of the individual layers' rates. Our experiments demonstrate that the proposed method allows us to better tune hierarchical VAEs for a diverse set of practical use cases.

VC Theoretical Explanation of Double Descent
Eng Hock Lee,Vladimir Cherkassky

There has been growing interest in generalization performance of large multilayer neural networks that can be trained to achieve zero training error, while generalizing well on test data. This regime is known as ‘second descent’ and it appears to contradict the conventional view that optimal model complexity should reflect an optimal balance between underfitting and overfitting, i.e., the bias-variance tradeoff.

This paper presents a VC-theoretical analysis of double descent and shows that it can be fully explained by classical VC-generalization bounds. We illustrate an application of analytic VC-bounds for modeling double descent for classification problems, using empirical results for several learning methods, such as SVM, Least Squares, and Multilayer Perceptron classifiers. In addition, we discuss several reasons for the misinterpretation of VC-theoretical results in Deep Learning community.

Enhance Local Consistency for Free: A Multi-Step Inertial Momentum Approach
Yixing Liu,Yan Sun,Li Shen,Baoyuan Wu,Zhengtao Ding,Dacheng Tao

Federated learning (FL), as a collaborative distributed training paradigm with several edge computing devices under the coordination of a centralized server, is plagued by inconsistent local stationary points due to the heterogeneity of the local partial participation clients, which precipitates the local client-drifts problems and sparks off the unstable and slow convergence, especially on the aggravated heterogeneous dataset. To address these issues, we propose a novel federated learning algorithm, named FedMIM, which adopts the multi-step inertial momentum on the edge devices and enhances the local consistency for free during the training to improve the robustness of the heterogeneity. Specifically, we incorporate the weighted global gradient estimations as the inertial correction terms to guide both the local iterates and stochastic gradient estimation, which can reckon the global objective optimization on the edges' heterogeneous dataset nat urally and maintain the demanding consistent iteration locally. Theoretically, we show that FedMIM achieves the $\mathcal{O}\big({1}/{\sqrt{SKT}}\big)$ convergence rate with a linear speedup property with respect to the number of selected clients S and proper local interval K in each communication round under the nonconvex setting. Empirically, we conduct comprehensive experiments on various real-world datasets and demonstrate the efficacy of the proposed FedMIM against several state-of-the-art baselines.

SYNG4ME: Model Evaluation using Synthetic Test Data

Boris van Breugel,Nabeel Seedat,Fergus Imrie,Mihaela van der Schaar

Model evaluation is a crucial step in ensuring reliable machine learning systems. Currently, predictive models are evaluated on held-out test data, quantifying aggregate model performance. Limitations of available test data make it challenging to evaluate model performance on small subgroups or when the environment changes. Synthetic test data provides a unique opportunity to address this challenge; instead of evaluating predictive models on real data, we propose to use synthetic data. This brings two advantages. First, supplementing and increasing the amount of evaluation data can lower the variance of model performance estimates compared to evaluation on the original test data. This is especially true for local performance evaluation in low-density regions, e.g. minority or intersectional groups. Second, generative models can be conditioned as to induce a shift in the synthetic data distribution, allowing us to evaluate how supervised models could perform in different target settings. In this work, we propose SYNG4ME: an automated suite of synthetic data generators for model evaluation. By generating smart synthetic data sets, data practitioners have a new tool for exploring how supervised models may perform on subgroups of the data, and how robust methods are to distributional shifts. We show experimentally that SYNG4ME achieves more accurate performance estimates compared to using the test data alone.

Take One Gram of Neural Features, Get Enhanced Group Robustness

Simon Roburin,Charles Corbière,Gilles Puy,Nicolas THOME,Mathieu Aubry,Renaud Marlet,Patrick Perez

Predictive performance of machine learning models trained with empirical risk minimization (ERM) can degrade considerably under distribution shifts. In particular, the presence of spurious correlations in training datasets leads ERM-trained models to display high loss when evaluated on minority groups not presenting such correlations in test sets. Extensive attempts have been made to develop methods improving worst-group robustness. However, they require group information for each training input or at least, a validation set with group labels to tune their hyperparameters, which may be expensive to get or unknown a priori. In this paper, we address the challenge of improving group robustness without group annotations during training. To this end, we propose to partition automatically the training dataset into groups based on Gram matrices of features extracted from an identification model and to apply robust optimization based on these pseudo-groups. In the realistic context where no group labels are available, our experiments show that our approach not only improves group robustness over ERM but also outperforms all recent baselines.

LMC: Fast Training of GNNs via Subgraph Sampling with Provable Convergence

Zhihao Shi,Xize Liang,Jie Wang

The message passing-based graph neural networks (GNNs) have achieved great success in many real-world applications.

However, training GNNs on large-scale graphs suffers from the well-known neighbor explosion problem, i.e., the exponentially increasing dependencies of nodes with the number of message passing layers. Subgraph-wise sampling methods---a promising class of mini-batch training techniques---discard messages outside the mini-batches in backward passes to avoid the neighbor explosion problem at the expense of gradient estimation accuracy. This poses significant challenges to their convergence analysis and convergence speeds, which seriously limits their reliable real-world applications. To address this challenge, we propose a novel subgra ph-wise sampling method with a convergence guarantee, namely Local Message Compensation (LMC). To the best of our knowledge, LMC is the {\it first} subgraph-wise sampling method with provable convergence. The key idea of LMC is to retrieve the discarded messages in backward passes based on a message passing formulation of backward passes. By efficient and effective compensations for the discarded messages in both forward and backward passes, LMC computes accurate mini-batch gradients and thus accelerates convergence. We further show that LMC converges to first-order stationary points of GNNs. Experiments on large-scale benchmark tasks demonstrate that LMC significantly outperforms state-of-the-art subgraph-wise sampling methods in terms of efficiency.

DEEPER-GXX: DEEPENING ARBITRARY GNNS
Lecheng Zheng,Dongqi Fu,Ross Maciejewski,Jingrui He

Recently, motivated by real applications, a major research direction in graph neural networks (GNNs) is to explore deeper structures.

For instance, the graph connectivity is not always consistent with the label distribution (e.g., the closest neighbors of some nodes are not from the same category). In this case, GNNs need to stack more layers, in order to find the same categorical neighbors in a longer path for capturing the class-discriminative information. However, two major problems hinder the deeper GNNs to obtain satisfactory performance, i.e., vanishing gradient and over-smoothing. On one hand, stacking layers makes the neural network hard to train as the gradients of the first few layers vanish. Moreover, when simply addressing vanishing gradient in GNNs, we discover the shading neighbors effect (i.e., stacking layers inappropriately distorts the non-IID information of graphs and degrade the performance of GNNs). On the other hand, deeper GNNs aggregate much more information from common neighbors such that individual node representations share more overlapping features, which makes the final output representations not discriminative (i.e., overly smoothed). In this paper, for the first time, we address both problems to enable deeper GNNs, and propose Deeper-GXX, which consists of the Weight-Decaying Graph Residual Connection module (WDG-ResNet) and Topology-Guided Graph Contrastive Loss (TGCL). Extensive experiments on real-world data sets demonstrate that Deeper-GXX outperforms state-of-the-art deeper baselines.

Music-to-Text Synaesthesia: Generating Descriptive Text from Music Recordings
Zhihuan Kuang,Shi Zong,Jianbing Zhang,Jiajun Chen,Hongfu Liu

In this paper, we consider a novel research problem, music-to-text synaesthesia. Different from the classical music tagging problem that classifies a music recording into pre-defined categories, the music-to-text synaesthesia aims to generate descriptive texts from music recordings for further understanding. Although this is a new and interesting application to the machine learning community, to our best knowledge, the existing music-related datasets do not contain the semantic description on music recordings and cannot serve the music-to-text synaesthesia task. In light of this, we collect a new dataset that contains 1,955 aligned pairs of classical music recordings and text descriptions. Based on this, we build a computational model to generate sentences that can describe the content of the music recording. To tackle the highly non-discriminative classical music, we design a group topology-preservation loss in our computational model, which considers more samples as a group reference and preserves the relative topology among different samples. Extensive experimental results qualitatively and quantitatively demonstrate the effectiveness of our proposed model over five heuristics or pre-trained competitive methods and their variants on our collected dataset.

****

ISAAC Newton: Input-based Approximate Curvature for Newton's Method
Felix Petersen,Tobias Sutter,Christian Borgelt,Dongsung Huh,Hilde Kuehne,Yuekai Sun,Oliver Deussen

We present ISAAC (Input-baSed ApproximAte Curvature), a novel method that conditions the gradient using selected second-order information and has an asymptotically vanishing computational overhead, assuming a batch size smaller than the number of neurons. We show that it is possible to compute a good conditioner based on only the input to a respective layer without a substantial computational overhead. The proposed method allows effective training even in small-batch stochastic regimes, which makes it competitive to first-order as well as second-order methods.

****

Learning Human-Compatible Representations for Case-Based Decision Support
Han Liu,Yizhou Tian,Chacha Chen,Shi Feng,Yuxin Chen,Chenhao Tan

Algorithmic case-based decision support provides examples to help human make sense of predicted labels and aid human in decision-making tasks. Despite the promising performance of supervised learning, representations learned by supervised models may not align well with human intuitions: what models consider as similar examples can be perceived as distinct by humans. As a result, they have limited effectiveness in case-based decision support. In this work, we incorporate ideas from metric learning with supervised learning to examine the importance of alignment for effective decision support. In addition to instance-level labels, we use human-provided triplet judgments to learn human-compatible decision-focused representations. Using both synthetic data and human subject experiments in multiple classification tasks, we demonstrate that such representation is better aligned with human perception than representation solely optimized for classification. Human-compatible representations identify nearest neighbors that are perceived as more similar by humans and allow humans to make more accurate predictions, leading to substantial improvements in human decision accuracies (17.8% in butterfly vs. moth classification and 13.2% in pneumonia classification).

****

Long-Tailed Learning Requires Feature Learning
Thomas Laurent,James von Brecht,Xavier Bresson

We propose a simple data model inspired from natural data such as text or images, and use it to study the importance of learning features in order to achieve good generalization. Our data model follows a long-tailed distribution in the sense that some rare and uncommon subcategories have few representatives in the training set. In this context we provide evidence that a learner succeeds if and only if it identifies the correct features, and moreover derive non-asymptotic generalization error bounds that precisely quantify the penalty that one must pay for not learning features.

****

Understanding Hindsight Goal Relabeling Requires Rethinking Divergence Minimization
Lunjun Zhang,Bradly C. Stadie

Hindsight goal relabeling has become a foundational technique for multi-goal reinforcement learning (RL). The idea is quite simple: any arbitrary trajectory can be seen as an expert demonstration for reaching the trajectory's end state. Intuitively, this procedure trains a goal-conditioned policy to imitate a sub-optimal expert. However, this connection between imitation and hindsight relabeling is not well understood. Modern imitation learning algorithms are described in the language of divergence minimization, and yet it remains an open problem how to recast hindsight goal relabeling into that framework. In this work, we develop a unified objective for goal-reaching that explains such a connection, from which we can derive goal-conditioned supervised learning (GCSL) and the reward function in hindsight experience replay (HER) from first principles. Experimentally, we find that despite recent advances in goal-conditioned behaviour cloning (BC), multi-goal Q-learning can still outperform BC-like methods; moreover, a vanilla combination of both actually hurts model performance. Under our framework, we study when BC is expected to help, and empirically validate our findings. Our work further bridges goal-reaching and generative modeling, illustrating the nuances and new pathways of extending the success of generative models to RL.

****

DoE2Vec: Representation Learning for Exploratory Landscape Analysis
Bas Van Stein,Fu Xing Long,Moritz A. Frenzel,Peter Krause,Markus Gitterle,Thomas Bäck

We propose DoE2Vec, a variational autoencoder (VAE)-based methodology to learn o ptimization landscape characteristics for downstream meta-learning tasks, e.g., automated selection of optimization algorithms. Principally, using large training data sets generated with a random function generator, DoE2Vec self-learns an informative latent representation for any design of experiments (DoE).

Unlike the classical exploratory landscape analysis (ELA) method, our approach does not require any feature engineering and is easily applicable for high dimensional search spaces. For validation, we inspect the quality of latent reconstructions and analyze the latent representations using different experiments.

The latent representations not only show promising potentials in identifying similar (cheap-to-evaluate) surrogate functions, but also can boost performances when being used complementary to the ELA features in classification tasks.

How to Exploit Hyperspherical Embeddings for Out-of-Distribution Detection?

Yifei Ming,Yiyou Sun,Ousmane Dia,Yixuan Li

Out-of-distribution (OOD) detection is a critical task for reliable machine learning. Recent advances in representation learning give rise to distance-based OOD detection, where testing samples are detected as OOD if they are relatively far away from the centroids or prototypes of in-distribution (ID) classes. However, prior methods directly take off-the-shelf contrastive losses that suffice for classifying ID samples, but are not optimally designed when test inputs contain OOD samples. In this work, we propose CIDER, a novel representation learning framework that exploits hyperspherical embeddings for OOD detection. CIDER jointly optimizes two losses to promote strong ID-OOD separability: a dispersion loss that promotes large angular distances among different class prototypes, and a compactness loss that encourages samples to be close to their class prototypes. We analyze and establish the unexplored relationship between OOD detection performance and the embedding properties in the hyperspherical space, and demonstrate the importance of dispersion and compactness. CIDER establishes superior performance, outperforming the latest rival by 19.36% in FPR95. Code is available at https://github.com/deeplearning-wisc/cider.

AnyDA: Anytime Domain Adaptation

Omprakash Chakraborty,Aadarsh Sahoo,Rameswar Panda,Abir Das

Unsupervised domain adaptation is an open and challenging problem in computer vision. While existing research shows encouraging results in addressing cross-domain distribution shift on common benchmarks, they are often constrained to testing under a specific target setting, limiting their impact for many real-world applications. In this paper, we introduce a simple yet effective framework for anytime domain adaptation that is executable with dynamic resource constraints to achieve accuracy-efficiency trade-offs under domain-shifts. We achieve this by training a single shared network using both labeled source and unlabeled data, with switchable depth, width and input resolutions on the fly to enable testing under a wide range of computation budgets. Starting with a teacher network trained from a label-rich source domain, we utilize bootstrapped recursive knowledge distillation as a nexus between source and target domains to jointly train the student network with switchable subnetworks. Experiments on multiple datasets well demonstrate the superiority of our approach over state-of-the-art methods.

****

Improving Deep Regression with Ordinal Entropy

Shihao Zhang,Linlin Yang,Michael Bi Mi,Xiaoxu Zheng,Angela Yao

In computer vision, it is often observed that formulating regression problems as a classification task yields better performance. We investigate this curious phenomenon and provide a derivation to show that classification, with the cross-entropy loss, outperforms regression with a mean squared error loss in its ability to learn high-entropy feature representations. Based on the analysis, we propose an ordinal entropy loss to encourage higher-entropy feature spaces while maintaining ordinal relationships to improve the performance of regression tasks. Experiments on synthetic and real-world regression tasks demonstrate the importance and benefits of increasing entropy for regression.

Revisiting Pretraining Objectives for Tabular Deep Learning
Ivan Rubachev,Artem Alekberov,Yury Gorishniy,Artem Babenko
Recent deep learning models for tabular data currently compete with the traditional ML models based on decision trees (GBDT). Unlike GBDT, deep models can additionally benefit from pretraining, which is a workhorse of DL for vision and NLP.

For tabular problems, several pretraining methods were proposed, but it is not entirely clear if pretraining provides consistent noticeable improvements and what method should be used, since the methods are often not compared to each other or comparison is limited to the simplest MLP architectures.

In this work, we aim to identify the best practices to pretrain tabular DL models that can be universally applied to different datasets and architectures.
Among our findings, we show that using the object target labels during the pretraining stage is beneficial for the downstream performance and advocate several target-aware pretraining objectives.
Overall, our experiments demonstrate that properly performed pretraining significantly increases the performance of tabular DL models, which often leads to their superiority over GBDTs.

OoD-Control: Out-of-Distribution Generalization for Adaptive UAV Flight Control
Yuxiao Duan,Jundong Zhou,Zhaoyu Zeng,Haoqi Zeng,Nanyang Ye
Data-driven control methods have demonstrated precise and agile control of Unmanned Aerial Vehicles (UAVs) over turbulence environments. However, they are relatively weak at taming the out-of-distribution (OoD) data, i.e., encountering the generalization problem when faced with unknown environments with different data distributions from the training set. Many studies have designed algorithms to reduce the impact of the OoD problem, a common but tricky problem in machine learning. To tackle the OoD generalization problem in control, we propose a theoretically guaranteed approach: OoD-Control. We provide proof that for any perturbation within some range on the states, the control error can be upper bounded by a constant. In this paper, we present our OoD-Control generalization algorithm for online adaptive flight control and execute it on two instances. Experiments show that systems trained by the proposed OoD-Control algorithm perform better in quite different environments from training. And the control method is extensible and pervasively applicable and can be applied to different dynamical models. OoD-Control is validated on UAV dynamic models, and we find it performs state-of-the-art in positioning stability and trajectory tracking problems.

Unified Discrete Diffusion for Simultaneous Vision-Language Generation
Minghui Hu,Chuanxia Zheng,Zuopeng Yang,Tat-Jen Cham,Heliang Zheng,Chaoyue Wang,Dacheng Tao,Ponnuthurai N. Suganthan
The recently developed discrete diffusion model performs extraordinarily well in generation tasks, especially in the text-to-image task, showing great potential for modeling multimodal signals. In this paper, we leverage these properties and present a unified multimodal generation model, which can perform text-based, image-based, and even vision-language simultaneous generation using a single model. Specifically, we unify the discrete diffusion process for multimodal signals by proposing a unified Markov transition matrix and a unified objective. Moreover, we design a multimodal mutual attention module to highlight the inter-modal linkages, which is vital for multimodal generation. Extensive experiments indicate that our proposed method can perform comparably to the state-of-the-art solutions in various generation tasks.
****
Take 5: Interpretable Image Classification with a Handful of Features
Thomas Norrenbrock,Marco Rudolph,Bodo Rosenhahn
Deep Neural Networks use thousands of mostly incomprehensible features to identify a single class, a decision no human can follow. We propose an interpretable sparse and low dimensional final decision layer in a deep neural network with measurable aspects of interpretability and demonstrate it on fine-grained image cla

ssification. We argue that a human can only understand the decision of a machine learning model, if the input features are interpretable and only very few of them are used for a single decision. For that matter, the final layer has to be sparse and – to make interpreting the features feasible – low dimensional. We call a model with a Sparse Low-Dimensional Decision “SLDD-Model”. We show that a SLDD-Model is easier to interpret locally and globally than a dense high-dimensional decision layer while being able to maintain competitive accuracy. Additionally, we propose a loss function that improves a model’s feature diversity and accuracy. Our interpretable SLDD-Model only uses 5 out of just 50 features per class, while maintaining 97% to 100% of the accuracy on four common benchmark datasets compared to the baseline model with 2048 features.

****

On the Fast Convergence of Unstable Reinforcement Learning Problems
Wang Zhang,Lam M. Nguyen,Subhro Das,Alexandre Megretski,Luca Daniel,Tsui-Wei Weng

For many of the reinforcement learning applications, the system is assumed to be inherently stable and with bounded reward, state and action space. These are key requirements for the optimization convergence of classical reinforcement learning reward function with discount factors. Unfortunately, these assumptions do not hold true for many real world problems such as an unstable linear–quadratic regulator (LQR). In this work, we propose new methods to stabilize and speed up the convergence of unstable reinforcement learning problems with the policy gradient methods. We provide theoretical insights on the efficiency of our methods. In practice, our method achieve good experimental results over multiple examples where the vanilla methods mostly fail to converge due to system instability.

Iterative Patch Selection for High-Resolution Image Recognition
Benjamin Bergner,Christoph Lippert,Aravindh Mahendran

High-resolution images are prevalent in various applications, such as autonomous driving and computer-aided diagnosis. However, training neural networks on such images is computationally challenging and easily leads to out-of-memory errors even on modern GPUs. We propose a simple method, Iterative Patch Selection (IPS), which decouples the memory usage from the input size and thus enables the processing of arbitrarily large images under tight hardware constraints. IPS achieves this by selecting only the most salient patches, which are then aggregated into a global representation for image recognition. For both patch selection and aggregation, a cross-attention based transformer is introduced, which exhibits a close connection to Multiple Instance Learning. Our method demonstrates strong performance and has wide applicability across different domains, training regimes and image sizes while using minimal accelerator memory. For example, we are able to finetune our model on whole-slide images consisting of up to 250k patches (>16 gigapixels) with only 5 GB of GPU VRAM at a batch size of 16.

Conditional Antibody Design as 3D Equivariant Graph Translation
Xiangzhe Kong,Wenbing Huang,Yang Liu

Antibody design is valuable for therapeutic usage and biological research. Existing deep-learning-based methods encounter several key issues: 1) incomplete context for Complementarity-Determining Regions (CDRs) generation; 2) incapability of capturing the entire 3D geometry of the input structure; 3) inefficient prediction of the CDR sequences in an autoregressive manner. In this paper, we propose Multi-channel Equivariant Attention Network (MEAN) to co-design 1D sequences and 3D structures of CDRs. To be specific, MEAN formulates antibody design as a conditional graph translation problem by importing extra components including the target antigen and the light chain of the antibody. Then, MEAN resorts to E(3)-equivariant message passing along with a proposed attention mechanism to better capture the geometrical correlation between different components. Finally, it outputs both the 1D sequences and 3D structure via a multi-round progressive full-shot scheme, which enjoys more efficiency and precision against previous autoregressive approaches. Our method significantly surpasses state-of-the-art models in sequence and structure modeling, antigen-binding CDR design, and binding affini ty optimization. Specifically, the relative improvement to baselines is about 23\% in antigen-binding CDR design and 34\% for affinity optimization.

****

Robust Constrained Reinforcement Learning

Yue Wang,Fei Miao,Shaofeng Zou

Constrained reinforcement learning is to maximize the reward subject to constraints on utilities/costs. However, in practice it is often the case that the training environment is not the same as the test one, due to, e.g., modeling error, adversarial attack, non-stationarity, resulting in severe performance degradation and more importantly constraint violation in the test environment. To address this challenge, we formulate the framework of robust constrained reinforcement learning under model uncertainty, where the MDP is not fixed but lies in some uncertainty set. The goal is two fold: 1) to guarantee that constraints on utilities/costs are satisfied for all MDPs in the uncertainty set, and 2) to maximize the worst-case reward performance over the uncertainty set. We design a robust primal-dual approach, and further develop theoretical guarantee on its convergence, complexity and robust feasibility. We then investigate a concrete example of δ-contamination uncertainty set, design an online and model-free algorithm and theoretically characterize its sample complexity.

Fuzzy Alignments in Directed Acyclic Graph for Non-Autoregressive Machine Translation

Zhengrui Ma,Chenze Shao,Shangtong Gui,Min Zhang,Yang Feng

Non-autoregressive translation (NAT) reduces the decoding latency but suffers from performance degradation due to the multi-modality problem. Recently, the structure of directed acyclic graph has achieved great success in NAT, which tackles the multi-modality problem by introducing dependency between vertices. However, training it with negative log-likelihood loss implicitly requires a strict alignment between reference tokens and vertices, weakening its ability to handle multiple translation modalities. In this paper, we hold the view that all paths in the graph are fuzzily aligned with the reference sentence. We do not require the exact alignment but train the model to maximize a fuzzy alignment score between the graph and reference, which takes captured translations in all modalities into account. Extensive experiments on major WMT benchmarks show that our method substantially improves translation performance and increases prediction confidence, setting a new state of the art for NAT on the raw training data.

Efficient Federated Domain Translation

Zeyu Zhou,Sheikh Shams Azam,Christopher Brinton,David I. Inouye

A central theme in federated learning (FL) is the fact that client data distributions are often not independent and identically distributed (IID), which has strong implications on the training process. While most existing FL algorithms focus on the conventional non-IID setting of class imbalance or missing classes across clients, in practice, the distribution differences could be more complex, e.g., changes in class conditional (domain) distributions. In this paper, we consider this complex case in FL wherein each client has access to only one domain distribution. For tasks such as domain generalization, most existing learning algorithms require access to data from multiple clients (i.e., from multiple domains) during training, which is prohibitive in FL. To address this challenge, we propose a federated domain translation method that generates pseudodata for each client which could be useful for multiple downstream learning tasks. We empirically demonstrate that our translation model is more resource-efficient (in terms of both communication and computation) and easier to train in an FL setting than standard domain translation methods. Furthermore, we demonstrate that the learned translation model enables use of state-of-the-art domain generalization methods in a federated setting, which enhances accuracy and robustness to increases in the synchronization period compared to existing methodology.

Single-Stage Open-world Instance Segmentation with Cross-task Consistency Regularization

XIZHE XUE,Dongdong Yu,Lingqiao Liu,Yu Liu,Satoshi Tsutsui,Ying Li,Zehuan Yuan,Ping Song,Mike Zheng Shou

Open-World Instance Segmentation (OWIS) is an emerging research topic that aims to segment class-agnostic object instances from images. The mainstream approaches use a two-stage segmentation framework, which first locates the candidate object bounding boxes and then performs instance segmentation. In this work, we instead promote a single-stage framework for OWIS. We argue that the end-to-end training process in the single-stage framework can be more convenient for directly regularizing the localization of class-agnostic object pixels. Based on the single-stage instance segmentation framework, we propose a regularization model to predict foreground pixels and use its relation to instance segmentation to construct a cross-task consistency loss. We show that such a consistency loss could alleviate the problem of incomplete instance annotation -- a common problem in the existing OWIS datasets. We also show that the proposed loss lends itself to an effective solution to semi-supervised OWIS that could be considered an extreme case that all object annotations are absent for some images. Our extensive experiments demonstrate that the proposed method achieves impressive results in both fully-supervised and semi-supervised settings. Compared to SOTA methods, the proposed method significantly improves the AP_{100} score by 4.75\% in UVO$\rightarrow$UVO setting and 4.05\% in COCO$\rightarrow$UVO setting. In the case of semi-supervised learning, our model learned with only 30\% labeled data, even outperforms its fully-supervised counterpart with 50\% labeled data. The code will be released soon.

What can be learnt with wide convolutional neural networks?

Francesco Cagnetta,Alessandro Favero,Matthieu Wyart

Understanding how convolutional neural networks (CNNs) can efficiently learn high-dimensional functions remains a fundamental challenge. A popular belief is that these models harness the local and hierarchical structure of natural data such as images. Yet, we lack a quantitative understanding of how such structure affects performance, e.g. the rate of decay of the generalisation error with the number of training samples. In this paper, we study deep CNNs in the kernel regime. First, we show that the spectrum of the corresponding kernel inherits the hierarchical structure of the network, and we characterise its asymptotics. Then, we use this result together with generalisation bounds to prove that deep CNNs adapt to the spatial scale of the target function. In particular, we find that if the target function depends on low-dimensional subsets of adjacent input variables, then the rate of decay of the error is controlled by the effective dimensionality of these subsets. Conversely, if the teacher function depends on the full set of input variables, then the error rate is inversely proportional to the input dimension. We conclude by computing the rate when a deep CNN is trained on the output of another deep CNN with randomly-initialised parameters. Interestingly, we find that despite their hierarchical structure, the functions generated by deep CNNs are too rich to be efficiently learnable in high dimension.

3D Segmenter: 3D Transformer based Semantic Segmentation via 2D Panoramic Distillation

ZHENNAN WU,YANG LI,Yifei Huang,Lin Gu,Tatsuya Harada,Hiroyuki Sato

Recently, 2D semantic segmentation has witnessed a significant advancement thanks to the huge amount of 2D image datasets available. Therefore, in this work, we propose the first 2D-to-3D knowledge distillation strategy to enhance 3D semantic segmentation model with knowledge embedded in the latent space of powerful 2D models. Specifically, unlike standard knowledge distillation, where teacher and student models take the same data as input, we use 2D panoramas properly aligned with corresponding 3D rooms to train the teacher network and use the learned knowledge from 2D teacher to guide 3D student. To facilitate our research, we create a large-scale, fine-annotated 3D semantic segmentation benchmark, containing voxel-wise semantic labels and aligned panoramas of 5175 scenes. Based on this benchmark, we propose a 3D volumetric semantic segmentation network, which adapts Video Swin Transformer as backbone and introduces a skip connected linear deco der. Achieving a state-of-the-art performance, our 3D Segmenter is computationally efficient and only requires 3.8% of the parameters compared to the prior art. Our code and data will be released upon acceptance.

Towards Skilled Population Curriculum for MARL

Rundong Wang,Longtao Zheng,Wei Qiu,Bowei He,Bo An,Zinovi Rabinovich,Yujing Hu,Yingfeng Chen,Tangjie Lv,Changjie Fan

Recent advances in multi-agent reinforcement learning (MARL) allow agents to coordinate their behaviors in complex environments. However, common MARL algorithms still suffer from scalability and sparse reward issues. One promising approach to resolve them is automated curriculum learning (ACL), where a student (curriculum learner) train on tasks of increasing difficulty controlled by a teacher (curriculum generator). Unfortunately, in spite of its success, ACL’s applicability is restricted due to: (1) lack of a general student framework to deal with the varying number of agents across tasks and the sparse reward problem, and (2) the non-stationarity in the teacher’s task due to the ever-changing student strategies. As a remedy for ACL, we introduce a novel automatic curriculum learning framework, Skilled Population Curriculum (SPC), adapting curriculum learning to multi-agent coordination. To be specific, we endow the student with population-invariant communication and a hierarchical skill set. Thus, the student can learn cooperation and behavior skills from distinct tasks with a varying number of agents. In addition, we model the teacher as a contextual bandit conditioned by student policies. As a result, a team of agents can change its size while retaining previously acquired skills. We also analyze the inherent non-stationarity of this multi-agent automatic curriculum teaching problem, and provide a corresponding regret bound. Empirical results show that our method improves scalability, sample efficiency, and generalization in multiple MARL environments. The source code and the video can be found at https://sites.google.com/view/marl-spc/.

Clifford Neural Layers for PDE Modeling

Johannes Brandstetter,Rianne van den Berg,Max Welling,Jayesh K Gupta

Partial differential equations (PDEs) see widespread use in sciences and engineering to describe simulation of physical processes as scalar and vector fields interacting and coevolving over time. Due to the computationally expensive nature of their standard solution methods, neural PDE surrogates have become an active research topic to accelerate these simulations. However, current methods do not explicitly take into account the relationship between different fields and their internal components, which are often correlated. Viewing the time evolution of such correlated fields through the lens of multivector fields allows us to overcome these limitations. Multivector fields consist of scalar, vector, as well as higher-order components, such as bivectors and trivectors. Their algebraic properties, such as multiplication, addition and other arithmetic operations can be described by Clifford algebras. To our knowledge, this paper presents the first usage of such multivector representations together with Clifford convolutions and Clifford Fourier transforms in the context of deep learning. The resulting Clifford neural layers are universally applicable and will find direct use in the areas of fluid dynamics, weather forecasting, and the modeling of physical systems in general. We empirically evaluate the benefit of Clifford neural layers by replacing convolution and Fourier operations in common neural PDE surrogates by their Clifford counterparts on 2D Navier-Stokes and weather modeling tasks, as well as 3D Maxwell equations. For similar parameter count, Clifford neural layers consistently improve generalization capabilities of the tested neural PDE surrogates.

GOOD: Exploring geometric cues for detecting objects in an open world

Haiwen Huang,Andreas Geiger,Dan Zhang

We address the task of open-world class-agnostic object detection, i.e., detecting every object in an image by learning from a limited number of base object classes. State-of-the-art RGB-based models suffer from overfitting the training classes and often fail at detecting novel-looking objects. This is because RGB-base d models primarily rely on appearance similarity to detect novel objects and are also prone to overfitting short-cut cues such as textures and discriminative parts. To address these shortcomings of RGB-based object detectors, we propose incorporating geometric cues such as depth and normals, predicted by general-purpose monocular estimators. Specifically, we use the geometric cues to train an object proposal network for pseudo-labeling unannotated novel objects in the training set. Our resulting Geometry-guided Open-world Object Detector (GOOD) significantly improves detection recall for novel object categories and already performs well with only a few training classes. Using a single ``person'' class for training on the COCO dataset, GOOD surpasses SOTA methods by 5.0% AR@100, a relative improvement of 24%. The code has been made available at https://github.com/autonomousvision/good.

Bringing Saccades and Fixations into Self-supervised Video Representation Learning

Qiuxia LAI,Ailing Zeng,Ye Wang,Lihong Cao,Qiang Xu

In this paper, we propose a self-supervised video representation learning (video SSL) method by taking inspiration from cognitive science and neuroscience on human visual perception. Different from previous methods that mainly start from the inherent properties of videos, we argue that humans learn to perceive the world through the self-awareness of the semantic change or consistency in the input stimuli in the absence of labels, accompanied by representation reorganization during the post-learning rest periods. To this end, we first exploit the presence of saccades as an indicator of semantic change in a contrastive learning framework to mimic the self-awareness in human representation learning, where the saccades are generated without eye-tracking data. Second, we model the semantic consistency by minimizing the prediction error between the predicted and the true state of another time point during a fixation. Third, we later incorporate prototypical contrastive learning to reorganize the learned representations such that perceptually similar representations would be associated closer. Compared to previous counterparts, our method can capture finer-grained semantics from video instances, and the associations among similar ones are further strengthened. Experiments show that the proposed bio-inspired video SSL method significantly improves the Top-1 video retrieval accuracy on UCF101 and achieves superior performance on downstream tasks such as action recognition under comparable settings.

Improve learning combining crowdsourced labels by weighting Areas Under the Margin

Tanguy Lefort,Benjamin Charlier,Alexis Joly,Joseph Salmon

In supervised learning -- for instance in image classification -- modern massive datasets are commonly labelled by a crowd of workers. The obtained labels in this crowdsourcing setting are then aggregated for training. The aggregation step generally leverages a per worker trust score. Yet, such worker-centric approaches discard each task ambiguity. Some intrinsically ambiguous tasks might even fool expert workers, which could eventually be harmful for the learning step. In a standard supervised learning setting -- with one label per task and balanced classes -- the Area Under the Margin (AUM) statistic is tailored to identify mislabeled data. We adapt the AUM to identify ambiguous tasks in crowdsourced learning scenarios, introducing the Weighted AUM (WAUM). The WAUM is an average of AUMs weighted by worker and task dependent scores. We show that the WAUM can help discarding ambiguous tasks from the training set, leading to better generalization or calibration performance. We report improvements with respect to feature-blind aggregation strategies both for simulated settings and for the CIFAR-10H crowdsourced dataset.

Emergent World Representations: Exploring a Sequence Model Trained on a Synthetic Task

Kenneth Li,Aspen K Hopkins,David Bau,Fernanda Viégas,Hanspeter Pfister,Martin Wattenberg

Language models show a surprising range of capabilities, but the source of their apparent competence is unclear. Do these networks just memorize a collection of surface statistics, or do they rely on internal representations of the process that generates the sequences they see? We investigate this question by applying a variant of the GPT model to the task of predicting legal moves in a simple board game, Othello. Although the network has no a priori knowledge of the game or its rules, we uncover evidence of an emergent nonlinear internal representation of the board state. Interventional experiments indicate this representation can be used to control the output of the network and create "latent saliency maps" that can help explain predictions in human terms.

Programmatically Grounded, Compositionally Generalizable Robotic Manipulation

Renhao Wang,Jiayuan Mao,Joy Hsu,Hang Zhao,Jiajun Wu,Yang Gao

Robots operating in the real world require both rich manipulation skills as well as the ability to semantically reason about when to apply those skills. Towards this goal, recent works have integrated semantic representations from large-scale pretrained vision-language (VL) models into manipulation models, imparting them with more general reasoning capabilities. However, we show that the conventional {\it pretraining-finetuning} pipeline for integrating such representations entangles the learning of domain-specific action information and domain-general visual information, leading to less data-efficient training and poor generalization to unseen objects and tasks. To this end, we propose \ours, a {\it modular} approach to better leverage pretrained VL models by exploiting the syntactic and semantic structures of language instructions. Our framework uses a semantic parser to recover an executable program, composed of functional modules grounded on vision and action across different modalities. Each functional module is realized as a combination of deterministic computation and learnable neural networks. Program execution produces parameters to general manipulation primitives for a robotic end-effector. The entire modular network can be trained with end-to-end imitation learning objectives. Experiments show that our model successfully disentangles action and perception, translating to improved zero-shot and compositional generalization in a variety of manipulation behaviors. Project webpage at: \url{https://progport.github.io}.

ObPose: Leveraging Pose for Object-Centric Scene Inference and Generation in 3D

Yizhe Wu,Oiwi Parker Jones,Ingmar Posner

We present ObPose, an unsupervised object-centric inference and generation model which learns 3D-structured latent representations from RGB-D scenes. Inspired by prior art in 2D representation learning, ObPose considers a factorised latent space, separately encoding object location (where) and appearance (what). ObPose further leverages an object's pose (i.e. location and orientation), defined via a minimum volume principle, as a novel inductive bias for learning the where component. To achieve this, we propose an efficient, voxelised approximation approach to recover the object shape directly from a neural radiance field (NeRF). As a consequence, ObPose models each scene as a composition of NeRFs, richly representing individual objects. To evaluate the quality of the learned representations, ObPose is evaluated quantitatively on the YCB and CLEVR datatasets for unsupervised scene segmentation, outperforming the current state-of-the-art in 3D scene inference (ObSuRF) by a significant margin. Generative results provide qualitative demonstration that the same ObPose model can both generate novel scenes and flexibly edit the objects in them. These capacities again reflect the quality of the learned latents and the benefits of disentangling the where and what components of a scene. Key design choices made in the ObPose encoder are validated with ablations.

FedCL: Critical Learning Periods-aware Adaptive Client Selection in Federated Learning

Gang Yan,Hao Wang,Xu Yuan,Jian Li

Federated learning (FL) is a distributed optimization paradigm that learns from data samples distributed across a number of clients. Adaptive client selection that is cognizant of the training progress of clients has become a major trend t o improve FL efficiency but not yet well-understood. Most existing FL methods such as FedAvg and its state-of-the-art variants implicitly assume that all learning phases during the FL training process are equally important. Unfortunately, this assumption has been revealed to be invalid due to recent findings on critical learning (CL) periods, in which small gradient errors may lead to an irrecoverable deficiency on final test accuracy. In this paper, we develop FedCL, a CL periods-aware FL framework to reveal that adaptively augmenting exiting FL methods with CL periods, the resultant performance is significantly improved when the client selection is guided by the discovered CL periods. Experiments based on various machine learning models and datasets validate that the proposed FedCL framework consistently achieves an improved model accuracy while maintains comparable or even better communication efficiency as compared to state-of-the-art methods, demonstrating a promising and easily adopted method for tackling the heterogeneity of FL training.

TabCaps: A Capsule Neural Network for Tabular Data Classification with BoW Routing

Jintai Chen,KuanLun Liao,Yanwen Fang,Danny Chen,Jian Wu

Records in a table are represented by a collection of heterogeneous scalar features. Previous work often made predictions for records in a paradigm that processed each feature as an operating unit, which requires to well cope with the heterogeneity. In this paper, we propose to encapsulate all feature values of a record into vectorial features and process them collectively rather than have to deal with individual ones, which directly captures the representations at the data level and benefits robust performances. Specifically, we adopt the concept of "capsules" to organize features into vectorial features, and devise a novel capsule neural network called "TabCaps" to process the vectorial features for classification. In TabCaps, a record is encoded into several vectorial features by some optimizable multivariate Gaussian kernels in the primary capsule layer, where each vectorial feature represents a specific "profile" of the input record and is transformed into senior capsule layer under the guidance of a new straightforward routing algorithm. The design of routing algorithm is motivated by the Bag-of-Words (BoW) model, which performs capsule feature grouping straightforwardly and efficiently, in lieu of the computationally complex clustering of previous routing algorithms. Comprehensive experiments show that TabCaps achieves competitive and robust performances in tabular data classification tasks.

Learning Instance-Solution Operator For Optimal Control

Mingquan Feng,Zhijie Chen,Junchi Yan

Optimal control problems (OCPs) aim at finding a control function for a dynamical system such that a cost functional is optimized. These problems are central to physical system research in both academia and industry. In this paper, we propose a novel instance-solution operator learning perspective, which solves OCPs in a one-shot manner with no dependence on the explicit expression of dynamics or iterative optimization processes. The design is in principle endowed with substantial speedup in running time, and the model reusability is guaranteed by high-quality in- and out-of-distribution generalization. We theoretically validate the perspective by presenting the approximation bounds for the instance-solution operator learning. Extensive experiments on 6 physical systems verify the effectiveness and efficiency of our approach. The source code will be made publicly available.

Decentralized Online Bandit Optimization on Directed Graphs with Regret Bounds

Johan Östman,Ather Gattami,Daniel Gillblad

We consider a decentralized multiplayer game, played over T rounds, with a leader-follower hierarchy described by a directed acyclic graph. For each round, the graph structure dictates the order of the players and how players observe the actions of one another. By the end of each round, all players receive a joint bandit-reward based on their joint action that is used to update the player strate gies towards the goal of minimizing the joint pseudo-regret. We present a learning algorithm inspired by the single-player multi-armed bandit problem and show that it achieves sub-linear joint pseudo-regret in the number of rounds for both adversarial and stochastic bandit rewards. Furthermore, we quantify the cost incurred due to the decentralized nature of our problem compared to the centralized setting.

BAMBI: Vertical Federated Bilevel Optimization with Privacy-Preserving and Computation Efficiency

Qingsong Zhang,Fengxiang He,Jindong Gu,Bin Gu,Cheng Deng,Heng Huang,Dacheng Tao

Vertical federated learning (VFL) has shown promising in meeting the vast demands of multi-party privacy-preserving learning. However, existing VFL methods are not applicable to popular machine learning tasks falling under bilevel programming, such as hyper-representation learning and hyperparameter tuning. A desirable solution is adopting bilevel optimization (BO) into VFL, but on-shelf BO methods are shackled by the difficulty in computing the hypergradients with privacy-preserving and computation-efficient under the setting of VFL. To address this challenge, this paper proposes a stochastic Bilevel optimizAtion Method with a desirable JacoBian estImator (BAMBI), which constructs a novel zeroth-order (ZO) estimator to locally approximate the Jacobian matrix. This approximation enables BAMBI to compute the hypergradients in a privacy-preserving and computation-efficient manner. We prove that BAMBI convergences in the rate of $\mathcal{O}(1/\sqrt{K})$ (K is the total number of the upper-level iterations) under the nonconvex-strongly-convex setting which covers most practical scenarios. This convergence rate is comparable with the algorithms without ZO estimator, which justifies our advantage in privacy preservation without sacrifice in convergence rate. Moreover, we design a BAMBI-DP method for further mitigating the concerns on label privacy by leveraging the differential privacy (DP) technique. Extensive experiments fully support our algorithms. The code will be released publicly. To our best knowledge, this is the first work on the bilevel optimization under the setting of VFL.

Revitalize Region Feature for Democratizing Video-language Pre-training of Retrieval

Guanyu Cai,Yixiao Ge,Binjie Zhang,Jinpeng Wang,Rui Yan,Xudong Lin,Ying Shan,Lianghua He,Xiaohu Qie,Jianping Wu,Mike Zheng Shou

Recent dominant methods for video-language pre-training (VLP) learn transferable representations from the raw pixels in an end-to-end manner to achieve advanced performance on downstream video-language retrieval. Despite the impressive results, VLP research becomes extremely expensive with the need for massive data and a long training time, preventing further explorations. In this work, we revitalize region features of sparsely sampled video clips to significantly reduce both spatial and temporal visual redundancy towards democratizing VLP research at the same time achieving state-of-the-art results. Specifically, to fully explore the potential of region features, we introduce a novel bidirectional region-word alignment regularization that properly optimizes the fine-grained relations between regions and certain words in sentences, eliminating the domain/modality disconnections between pre-extracted region features and text. Extensive results of downstream video-language retrieval tasks on four datasets demonstrate the superiority of our method on both effectiveness and efficiency, e.g., our method achieves competing results with 80% fewer data and 85% less pre-training time compared to the most efficient VLP method so far.

****

MESSAGENET: MESSAGE CLASSIFICATION USING NATURAL LANGUAGE PROCESSING AND META-DATA

Adar Kahana,Oren Elisha

In this paper we propose a new Deep Learning (DL) approach for message classification. Our method
is based on the state-of-the-art Natural Language Processing (NLP) building blocks, combined

with a novel technique for infusing the meta-data input that is typically available in messages such as the sender information, timestamps, attached image, audio, affiliations, and more. As we demonstrate throughout the paper, going beyond the mere text by leveraging all available channels in the message, could yield an improved representation and higher classification accuracy. To achieve message representation, each type of input is processed in a dedicated block in the neural network architecture that is suitable for the data type. Such an implementation enables training all blocks together simultaneously, and forming cross channels features in the network. We show in the Experiments Section that in some cases, message’s meta-data holds an additional information that cannot be extracted just from the text, and when using this information we achieve better performance.
Furthermore, we demonstrate that our multi-modality block approach outperforms other approaches for injecting the meta data to the the text classifier.

Universal approximation and model compression for radial neural networks

Iordan Ganev,Twan van Laarhoven,Robin Walters

We introduce a class of fully-connected neural networks whose activation functions, rather than being pointwise, rescale feature vectors by a function depending only on their norm. We call such networks radial neural networks, extending previous work on rotation equivariant networks that considers rescaling activations in less generality. We prove universal approximation theorems for radial neural networks, including in the more difficult cases of bounded widths and unbounded domains. Our proof techniques are novel, distinct from those in the pointwise case. Additionally, radial neural networks exhibit a rich group of orthogonal change-of-basis symmetries on the vector space of trainable parameters. Factoring out these symmetries leads to a practical lossless model compression algorithm. Optimization of the compressed model by gradient descent is equivalent to projected gradient descent for the full model.
****

Momentum Diminishes the Effect of Spectral Bias in Physics-Informed Neural Networks

Ghazal Farhani,Alexander Kazachek,Boyu Wang

Physics-informed neural network (PINN) algorithms have shown promising results in solving a wide range of problems involving partial differential equations (PDEs). However, even the simplest PDEs, often fail to converge to desirable solutions when the target function contains high-frequency modes, due to a phenomenon known as spectral bias. In the present work, we exploit neural tangent kernels (NTKs) to investigate the training dynamics of PINNs evolving under stochastic gradient descent with momentum (SGDM). This demonstrates SGDM significantly reduces the effect of spectral bias. We have also examined why training a model via the Adam optimizer can accelerate the convergence while reducing the spectral bias. Moreover, our numerical experiments have confirmed that wide-enough networks using SGDM or Adam still converge to desirable solutions, even in the presence of high-frequency features.
****

MULTILEVEL XAI: VISUAL AND LINGUISTIC BONDED EXPLANATIONS

Halil Ibrahim Aysel,Xiaohao Cai,Adam Prugel-Bennett

Applications of deep neural networks are booming in more and more fields but lack transparency due to their black-box nature. Explainable Artificial Intelligence (XAI) is therefore of paramount importance, where strategies are proposed to understand how these black-box models function. The research so far mainly focuses on producing, for example, class-wise saliency maps, highlighting parts of a g

iven image that affect the prediction the most. However, this way does not fully represent the way humans explain their reasoning and, awkwardly, validating these maps is quite complex and generally requires subjective interpretation. In this article, we conduct XAI differently by proposing a new XAI methodology in a multilevel (i.e., visual and linguistic) manner. By leveraging the interplay between the learned representations, i.e., image features and linguistic attributes, the proposed approach can provide salient attributes and attribute-wise saliency maps, which are far more intuitive than the class-wise maps, without requiring per-image ground-truth human explanations. It introduces self-interpretable attributes to overcome the current limitations in XAI and bring the XAI towards human-like level. The proposed architecture is simple in use and can reach surprisingly good performance in both prediction and explainability for deep neural networks thanks to the low-cost per-class attributes.

An Exact Poly-Time Membership-Queries Algorithm for Extracting a Three-Layer ReLU Network

Amit Daniely,Elad Granot

We consider the natural problem of learning a ReLU network from queries, which was recently remotivated by model extraction attacks. In this work, we present a polynomial-time algorithm that can learn a depth-two ReLU network from queries under mild general position assumptions. We also present a polynomial-time algorithm that, under mild general position assumptions, can learn a rich class of depth-three ReLU networks from queries. For instance, it can learn most networks where the number of first layer neurons is smaller than the dimension and the number of second layer neurons.

These two results substantially improve state-of-the-art: Until our work, polynomial-time algorithms were only shown to learn from queries depth-two networks under the assumption that either the underlying distribution is Gaussian (Chen et al. (2021)) or that the weights matrix rows are linearly independent (Milli et al. (2019)). For depth three or more, there were no known poly-time results.

Neural Discrete Reinforcement Learning

Yazhe Niu,Yuan Pu,Chuming Li,Zhenjie Yang,Hongsheng Li,Yu Liu

Designing effective action spaces for complex environments is a fundamental and challenging problem in reinforcement learning (RL).

Some recent works have revealed that naive RL algorithms utilizing well-designed handcrafted discrete action spaces can achieve promising results even when dealing with high-dimensional continuous or hybrid decision-making problems. However, elaborately designing such action spaces requires comprehensive domain knowledge.

In this paper, we systemically analyze the advantages of discretization for different action spaces and then propose a unified framework, Neural Discrete Reinforcement Learning (NDRL), to automatically learn how to effectively discretize almost arbitrary action spaces.

Specifically, we propose the Action Discretization Variational AutoEncoder (AD-VAE), an action representation learning method that can learn compact latent action spaces while maintain the essential properties of original environments, such as boundary actions and the relationship between different action dimensions. Moreover, we uncover a key issue that parallel optimization of the AD-VAE and online RL agents is often unstable. To address it, we further design several techniques to adapt RL agents to learned action representations, including latent action remapping and ensemble Q-learning. Quantitative experiments and visualization results demonstrate the efficiency and stability of our proposed framework for complex action spaces in various environments.
****

CAB: Comprehensive Attention Benchmarking on Long Sequence Modeling

Jun Zhang,Shuyang Jiang,Jiangtao Feng,Lin Zheng,Lingpeng Kong

Transformer has achieved remarkable success in language, image, and speech processing. Recently, various efficient attention architectures have been proposed to improve transformer's efficiency while largely preserving its efficacy, especially in modeling long sequences. A widely-used benchmark to test these efficient methods' capability on long-range modeling is Long Range Arena (LRA). However, LRA only focuses on the standard bidirectional (or noncausal) self attention, and completely ignores cross attentions and unidirectional (or causal) attentions, which are equally important to downstream applications. Although designing cross and causal variants of an attention method is straightforward for vanilla attention, it is often challenging for efficient attentions with subquadratic time and memory complexity. In this paper, we propose Comprehensive Attention Benchmark (CAB) under a fine-grained attention taxonomy with four distinguishable attention patterns, namely, noncausal self, causal self, noncausal cross, and causal cross attentions. CAB collects seven real-world tasks from different research areas to evaluate efficient attentions under the four attention patterns. Among these tasks, CAB validates efficient attentions in eight backbone networks to show their generalization across neural architectures. We conduct exhaustive experiments to benchmark the performances of nine widely-used efficient attention architectures designed with different philosophies on CAB. Extensive experimental results also shed light on the fundamental problems of efficient attentions, such as efficiency length against vanilla attention, performance consistency across attention patterns, the benefit of attention mechanisms, and interpolation/extrapolation on long-context language modeling.

Formal Conceptual Views in Neural Networks

Johannes Hirth,Tom Hanika

Explaining neural network models is a challenging task that remains unsolved in its entirety to this day. This is especially true for high dimensional and complex data. With the present work, we introduce two notions for conceptual views of a neural network, specifically a many-valued and a symbolic view. Both provide novel analysis methods to enable a human AI analyst to grasp deeper insights into the knowledge that is captured by the neurons of a network. We test the conceptual expressivity of our novel views through different experiments on the ImageNet and Fruit-360 data sets. Furthermore, we show to which extent the views allow to quantify the conceptual similarity of different learning architectures. Finally, we demonstrate how conceptual views can be applied for abductive learning of human comprehensible rules from neurons. In summary, with our work, we contribute to the most relevant task of globally explaining neural networks models.

Towards Understanding and Mitigating Dimensional Collapse in Heterogeneous Federated Learning

Yujun Shi,Jian Liang,Wenqing Zhang,Vincent Tan,Song Bai

Federated learning aims to train models collaboratively across different clients without sharing data for privacy considerations. However, one major challenge for this learning paradigm is the data heterogeneity problem, which refers to the discrepancies between the local data distributions among various clients. To tackle this problem, we first study how data heterogeneity affects the representations of the globally aggregated models. Interestingly, we find that heterogeneous data results in the global model suffering from severe dimensional collapse, in which representations tend to reside in a lower-dimensional space instead of the ambient space. Moreover, we observe a similar phenomenon on models locally trained on each client and deduce that the dimensional collapse on the global model is inherited from local models. In addition, we theoretically analyze the gradient flow dynamics to shed light on how data heterogeneity result in dimensional collapse for local models. To remedy this problem caused by the data heterogeneity, we propose FedDecorr, a novel method that can effectively mitigate dimensional collapse in federated learning. Specifically, FedDecorr applies a regularization term during local training that encourages different dimensions of representations to be uncorrelated. FedDecorr, which is implementation-friendly and computationally-efficient, yields consistent improvements over baselines on standard benchmark datasets. Code: https://github.com/bytedance/FedDecorr.

A New Paradigm for Federated Structure Non-IID Subgraph Learning

Xunkai Li,Wentao Zhang,Rong-Hua Li,Yulin Zhao,Yinlin Zhu,Guoren Wang

Federated graph learning (FGL), a distributed training framework for graph neural networks (GNNs) has attracted much attention for breaking the centralized machine learning assumptions. Despite its effectiveness, the differences in data collection perspectives and quality lead to the challenges of heterogeneity, especially the domain-specific graph is partitioned into subgraphs in different institutions. However, existing FGL methods implement graph data augmentation or personalization with community split which follows the cluster homogeneity assumptions. Hence we investigate the above issues and suggest that subgraph heterogeneity is essentially the structure variations. From the observations on FGL, we first define the structure non-independent identical distribution (Non-IID) problem, which presents covariant shift challenges among client-wise subgraphs. Meanwhile, we propose a new paradigm for general federated data settings called Adaptive Federated Graph Learning (AdaFGL). The motivation behind it is to implement adaptive propagation mechanisms based on federated global knowledge and non-params label propagation. We conduct extensive experiments with community split and structure Non-IID settings, our approach achieves state-of-the-art performance on five benchmark datasets.

SketchKnitter: Vectorized Sketch Generation with Diffusion Models

Qiang Wang,Haoge Deng,Yonggang Qi,Da Li,Yi-Zhe Song

We show vectorized sketch generation can be identified as a reversal of the stroke deformation process. This relationship was established by means of a diffusion model that learns data distributions over the stroke-point locations and pen states of real human sketches. Given randomly scattered stroke-points, sketch generation becomes a process of deformation-based denoising, where the generator rectifies positions of stroke points at each timestep to converge at a recognizable sketch. A key innovation was to embed recognizability into the reverse time diffusion process. It was observed that the estimated noise during the reversal process is strongly correlated with sketch classification accuracy. An auxiliary recurrent neural network (RNN) was consequently used to quantify recognizability during data sampling. It follows that, based on the recognizability scores, a sampling shortcut function can also be devised that renders better quality sketches with fewer sampling steps. Finally it is shown that the model can be easily extended to a conditional generation framework, where given incomplete and unfaithful sketches, it yields one that is more visually appealing and with higher recognizability.

Evidential Uncertainty and Diversity Guided Active Learning for Scene Graph Generation

Shuzhou Sun,Shuaifeng Zhi,Janne Heikkilä,Li Liu

Scene Graph Generation (SGG) has already shown its great potential in various downstream tasks, but it comes at the price of a prohibitively expensive annotation process. To reduce the annotation cost, we propose using Active Learning (AL) for sampling the most informative data. However, directly porting current AL methods to the SGG task poses the following challenges: 1) unreliable uncertainty estimates, and 2) data bias problems. To deal with these challenges, we propose EDAL (\textbf{E}vidential Uncertainty and \textbf{D}iversity Guided Deep \textbf{A}ctive \textbf{L}earning), a novel AL framework tailored for the SGG task. For challenge 1), we start with Evidential Deep Learning (EDL) coupled with a global relationship mining approach to estimate uncertainty, which can effectively overcome the perturbations of open-set relationships and background-relationships to obtain reliable uncertainty estimates. To address challenge 2), we seek the diversity-based method and design the Context Blocking Module (CBM) and Image Blocking Module (IBM) to alleviate context-level bias and image-level bias, respectively. Experiments show that our AL framework can approach the performance of a fully supervised SGG model with only about 10% annotation cost. Furthermore, our ablation studies indicate that introducing AL into the SGG will face many challenges not observed in other vision tasks that are successfully overcome by our

new modules.

Test-time recalibration of conformal predictors under distribution shift based on unlabeled examples

Fatih Furkan Yilmaz,Reinhard Heckel

Modern image classifiers achieve high predictive accuracy, but the predictions typically come without reliable uncertainty estimates. Conformal prediction algorithms provide uncertainty estimates by predicting a set of classes based on the probability estimates of the classifier (for example, the softmax scores). To provide such sets, conformal prediction algorithms often rely on estimating a cutoff threshold for the probability estimates, and this threshold is chosen based on a calibration set. Conformal prediction methods guarantee reliability only when the calibration set is from the same distribution as the test set. Therefore, the methods need to be recalibrated for new distributions. However, in practice, labeled data from new distributions is rarely available, making calibration infeasible. In this work, we consider the problem of predicting the cutoff threshold for a new distribution only based on unlabeled examples. While it is impossible in general to guarantee reliability when calibrating based on unlabeled examples, we show that our method provides excellent uncertainty estimates under natural distribution shifts.

TabDDPM: Modelling Tabular Data with Diffusion Models

Akim Kotelnikov,Dmitry Baranchuk,Ivan Rubachev,Artem Babenko

Denoising diffusion probabilistic models are currently becoming the leading paradigm of generative modeling for many important data modalities. Being the most prevalent in the computer vision community, diffusion models have also recently gained some attention for other domains, including speech, NLP, and graph-like data. In this work, we investigate if the framework of diffusion models can be advantageous for general tabular problems, where datapoints are typically represented by vectors of heterogeneous features. The inherent heterogeneity of tabular data makes it quite challenging for accurate modeling, since the individual features can be of completely different nature, i.e., some of them can be continuous and some of them can be discrete. To address such data types, we introduce TabDDPM --- a diffusion model that can be universally applied to any tabular dataset and handles any types of features. We extensively evaluate TabDDPM on a wide set of benchmarks and demonstrate its superiority over existing GAN/VAE alternatives, which is consistent with the advantage of diffusion models in other fields. Additionally, we show that TabDDPM can be successfully used in privacy-oriented setups, where the original datapoints cannot be shared.

BED: Boundary-Enhanced Decoder for Chinese Word Segmentation

Shiting Xu,Dongge Tang,Weiwei Jiang,Qing Yang

Chinese Word Segmentation (CWS) is an essential fundamental step in the Chinese NLP processing pipeline. In recent years, with the development of deep learning and pre-training language models, many CWS models based on pre-training models, e.g., BERT and Roberta, have been proposed, and the performance of CWS models has been dramatically improved. However, CWS remains an open problem that deserves further study, such as the poor effect on OOV words. To our knowledge, the current proposed CWS approaches mainly focus on optimizing the encoder part of the model, such as incorporating more word information into the encoder or doing pre-training related to the CWS task, etc. And there is no attempt to improve the decoder's performance in the CWS model. This paper proposes an optimized decoder for the CWS model called Boundary-Enhanced Decoder (BED). It could bring 0.05% and 0.69% improvement on Average-F1 and OOV Average-F1 on four benchmark datasets when using a model with a BERT encoder and softmax standard decoder. We also publish our implementation of BED.

Tailoring Language Generation Models under Total Variation Distance

Haozhe Ji,Pei Ke,Zhipeng Hu,Rongsheng Zhang,Minlie Huang

The standard paradigm of neural language generation adopts maximum likelihood es

timation (MLE) as the optimizing method. From a distributional view, MLE in fact minimizes the Kullback-Leibler divergence (KLD) between the distribution of the real data and that of the model. However, this approach forces the model to distribute non-zero (sometimes large) probability mass to all training samples regardless of their quality. Moreover, in the attempt to cover the low-probability regions in the data distribution, the model systematically overestimates the probability of corrupted text sequences, which we conjecture is one of the main reasons for text degeneration during autoregressive decoding. To remedy this problem, we leverage the total variation distance (TVD) with its robustness to outliers, and develop practical bounds to apply it to language generation. Then, we introduce the TaiLr objective that balances the tradeoff of estimating TVD. Intuitively, TaiLr downweights real data samples that have low model probabilities with tunable penalization intensity. Experimental results show that our method alleviates the overestimation of degenerated sequences without sacrificing diversity and improves generation quality on a wide range of text generation tasks.

SeqSHAP: Subsequence Level Shapley Value Explanations for Sequential Predictions
Guanyu Jiang,Fuzhen Zhuang,Bowen Song,Jiani Li,Ying Sun,Yongchun Zhu,Tianyi Zhang,Weiqiang Wang,deqing wang
With the increasing demands of interpretability in real-world applications, various methods for explainable artificial intelligence (XAI) have been proposed. However, most of them overlook the interpretability in sequential scenarios, which have a wide range of applications, e.g., online transactions and sequential recommendations. In this paper, we propose a Shapley value based explainer named SeqSHAP to explain the model predictions in sequential scenarios. Compared to existing methods, SeqSHAP provides more intuitive explanations at a subsequence level, which explicitly models the effect of contextual information among the related elements in a sequence. We propose to calculate subsequence-level feature attributions instead of element-wise attributions to utilize the information embedded in sequence structure, and provide a distribution-based segmentation method to obtain reasonable subsequences. Extensive experiments on two online transaction datasets from a real-world e-commerce platform show that the proposed method could provide valid and reliable explanations for sequential predictions.
****
Newton Losses: Efficiently Including Second-Order Information into Gradient Descent
Felix Petersen,Christian Borgelt,Tobias Sutter,Hilde Kuehne,Oliver Deussen
We present Newton losses, a method for incorporating second-order information of losses by approximating them with quadratic functions. The presented method is applied only to the loss function and allows training the neural network with gradient descent. As loss functions are usually substantially cheaper to compute than the neural network, Newton losses can be used at a relatively small additional cost. We find that they yield superior performance, especially when applied to non-convex and hard-to-optimize loss functions such as algorithmic losses, which have been popularized in recent research.
****
Anisotropic Message Passing: Graph Neural Networks with Directional and Long-Range Interactions
Moritz Thürlemann,Sereina Riniker
Graph neural networks have shown great potential for the description of a variety of chemical systems.
However, standard message passing does not explicitly account for long-range and directional interactions, for instance due to electrostatics.
In this work, an anisotropic state based on Cartesian multipoles is proposed as an addition to the existing hidden features.
With the anisotropic state, message passing can be modified to explicitly account for directional interactions.
Compared to existing models, this modification results in relatively little additional computational cost.
Most importantly, the proposed formalism offers as a distinct advantage the seam

less integration of (1) anisotropic long-range interactions, (2) interactions with surrounding fields and particles that are not part of the graph, and (3) the fast multipole method.
As an exemplary use case, the application to quantum mechanics/molecular mechanics (QM/MM) systems is demonstrated.

Learn Low-dimensional Shortest-path Representation of Large-scale and Complex Graphs
Haoyu Wang,Chun Yuan,Lei Li,Jiahui Jin
Estimation of shortest-path (SP) distance lies at the heart of network analysis tasks. Along with the rapid emergence of large-scale and complex graphs, approximate SP-representing algorithms that transform a graph into compact and low-dimensional representations are critical for fast and scalable online analysis. Among different approaches, learning-based representation methods have made a breakthrough both in response time and accuracy. Several competitive works in learning-based methods heuristically leverage truncated random walk and optimization on the arbitrary linkage for SP representation learning. However, they have limitations on both exploration range and distance preservation. We propose in this paper an efficient and interpretable SP representation method called Betweenness Centrality-based Distance Resampling (BCDR). First, we prove that betweenness centrality-based random walk can occupy a wider exploration range of distance due to its awareness of high-order path structures. Second, we leverage distance resampling to simulate random shortest paths from original paths and prove that the optimization on such shortest paths preserves distance relations via implicitly decomposing SP distance-based similarity matrix. BCDR yields an average improvement of 25% accuracy and 25-30% query speed, compared to all existing approximate methods when evaluated on a broad class of real-world and synthetic graphs with diverse sizes and structures.

SYNC: SAFETY-AWARE NEURAL CONTROL FOR STABILIZING STOCHASTIC DELAY-DIFFERENTIAL EQUATIONS
Jingdong Zhang,Qunxi Zhu,Wei Yang,Wei Lin
Stabilization of the systems described by \textit{stochastic delay}-differential equations (SDDEs) under preset conditions is a challenging task in the control community. Here, to achieve this task, we leverage neural networks to learn control policies using the information of the controlled systems in some prescribed regions. Specifically, two learned control policies, i.e., the neural deterministic controller (NDC) and the neural stochastic controller (NSC), work effectively in the learning procedures that rely on, respectively, the well-known LaSalle-type theorem and the newly-established theorem for guaranteeing the stochastic stability in SDDEs. We theoretically investigate the performance of the proposed controllers in terms of convergence time and energy cost. More practically and significantly, we improve our learned control policies through considering the situation where the controlled trajectories only evolve in some specific safety set. {\color{black} The practical validity of such control policies restricted in safety set is attributed to the theory that we further develop for safety and stability guarantees in SDDEs using the stochastic control barrier function and the spatial discretization}. We call this control as SYNC (\textbf{S}afet\textbf{Y}-aware \textbf{N}eural \textbf{C}ontrol). The efficacy of all the articulated control policies, including the SYNC, is demonstrated systematically by using representative control problems.

Byzantine-robust Decentralized Learning via ClippedGossip
Lie He,Sai Praneeth Karimireddy,Martin Jaggi
In this paper, we study the challenging task of Byzantine-robust decentralized training on arbitrary communication graphs. Unlike federated learning where workers communicate through a server, workers in the decentralized environment can only talk to their neighbors, making it harder to reach consensus and benefit from collaborative training. To address these issues, we propose an algorithm, termed ClippedGossip, for Byzantine-robust consensus and optimization, which is the f

irst to provably converge to a $O(\delta_{\max}\zeta^2/\gamma^2)$ neighborhood of the stationary point for non-convex objectives under standard assumptions. Finally, we demonstrate the encouraging empirical performance of ClippedGossip under a large number of attacks.

A Model or 603 Exemplars: Towards Memory-Efficient Class-Incremental Learning

Da-Wei Zhou,Qi-Wei Wang,Han-Jia Ye,De-Chuan Zhan

Real-world applications require the classification model to adapt to new classes without forgetting old ones. Correspondingly, Class-Incremental Learning (CIL) aims to train a model with limited memory size to meet this requirement. Typical CIL methods tend to save representative exemplars from former classes to resist forgetting, while recent works find that storing models from history can substantially boost the performance. However, the stored models are not counted into the memory budget, which implicitly results in unfair comparisons. We find that when counting the model size into the total budget and comparing methods with aligned memory size, saving models do not consistently work, especially for the case with limited memory budgets. As a result, we need to holistically evaluate different CIL methods at different memory scales and simultaneously consider accuracy and memory size for measurement. On the other hand, we dive deeply into the construction of the memory buffer for memory efficiency. By analyzing the effect of different layers in the network, we find that shallow and deep layers have different characteristics in CIL. Motivated by this, we propose a simple yet effective baseline, denoted as MEMO for Memory-efficient Expandable MOdel. MEMO extends specialized layers based on the shared generalized representations, efficiently extracting diverse representations with modest cost and maintaining representative exemplars. Extensive experiments on benchmark datasets validate MEMO's competitive performance. Code is available at: https://github.com/wangkiw/ICLR23-MEMO

Reinforcement learning for instance segmentation with high-level priors

Paul Hilt,Edgar Kaziakhmedov,Maedeh Zarvandi,Sourabh Bhide,Maria Leptin,Constantin Pape,Anna Kreshuk

Instance segmentation is a fundamental computer vision problem which remains challenging despite impressive recent advances due to deep learning-based methods. Given sufficient training data, fully supervised methods can yield excellent performance, but annotation of groundtruth data remains a major bottleneck, especially for biomedical applications where it has to be performed by domain experts. The amount of labels required can be drastically reduced by using rules derived from prior knowledge to guide the segmentation. However, these rules are in general not differentiable and thus cannot be used with existing methods. Here, we revoke this requirement by using stateless actor critic reinforcement learning, which enables non-differentiable rewards. We formulate the instance segmentation problem as graph partitioning and the actor critic predicts the edge weights driven by the rewards, which are based on the conformity of segmented instances to high-level priors on object shape, position or size. The experiments on toy and real data demonstrate that a good set of priors is sufficient to reach excellent performance without any direct object-level supervision.

Differentiable Mathematical Programming for Object-Centric Representation Learning

Adeel Pervez,Phillip Lippe,Efstratios Gavves

We propose topology-aware feature partitioning into k disjoint partitions for given scene features as a method for object-centric representation learning. To this end, we propose to use minimum s-t graph cuts as a partitioning method which is represented as a linear program. The method is topologically aware since it explicitly encodes neighborhood relationships in the image graph. To solve the graph cuts our solution relies on an efficient, scalable, and differentiable quadratic programming approximation. Optimizations specific to cut problems allow us to solve the quadratic programs and compute their gradients significantly more efficiently compared with the general quadratic programming approach. Our r

esults show that our approach is scalable and outperforms existing methods on object discovery tasks with textured scenes and objects.

Transformers are Sample-Efficient World Models
Vincent Micheli,Eloi Alonso,François Fleuret
Deep reinforcement learning agents are notoriously sample inefficient, which considerably limits their application to real-world problems. Recently, many model-based methods have been designed to address this issue, with learning in the imagination of a world model being one of the most prominent approaches. However, while virtually unlimited interaction with a simulated environment sounds appealing, the world model has to be accurate over extended periods of time. Motivated by the success of Transformers in sequence modeling tasks, we introduce IRIS, a data-efficient agent that learns in a world model composed of a discrete autoencoder and an autoregressive Transformer. With the equivalent of only two hours of gameplay in the Atari 100k benchmark, IRIS achieves a mean human normalized score of 1.046, and outperforms humans on 10 out of 26 games, setting a new state of the art for methods without lookahead search. To foster future research on Transformers and world models for sample-efficient reinforcement learning, we release our code and models at https://github.com/eloialonso/iris.
****
Considering Layerwise Importance in the Lottery Ticket Hypothesis
Benjamin Vandersmissen,Jose Oramas
The recently-introduced Lottery Ticket Hypothesis (LTH) posits that it is possible to extract a sparse trainable subnetwork from a dense network using iterative magnitude pruning.
By iteratively training the model, removing the connections with the lowest global weight magnitude and rewinding the remaining connections, sparse networks can be extracted that, when fully trained, reach a similar or better performance than their dense counterpart.

Intuitively, this approach of comparing connection weights globally removes a lot of context about the connection weights and their relations to other connections in their layer as the weight distributions in layers throughout the network often differ significantly.

In this paper we study a number of different approaches that try to recover some of this layer distributional context by computing an importance value for each connection that is dependent on the weights of the other connections in the same layer. We then generalise the LTH to use weight importances rather than weight magnitudes.

Experiments using these importance metrics on several architectures and datasets, reveal interesting aspects on the structure and emergence of Lottery tickets.

We find that given a repeatable training procedure, applying different importance metrics lead to distinct performant lottery tickets with little overlapping connections.
****
Generalized Sum Pooling for Metric Learning
Yeti Z. Gürbüz,Ozan Sener,A. Ayd■n Alatan
A common architectural choice for deep metric learning is a convolutional neural network followed by global average pooling (GAP). Albeit simple, GAP is a highly effective way to aggregate information. One possible explanation for the effectiveness of GAP is considering each feature vector as representing a different semantic entity and GAP as a convex combination of them. Following this perspective, we generalize GAP and propose a learnable generalized sum pooling method (GSP). GSP improves GAP with two distinct abilities: i) the ability to choose a subset of semantic entities, effectively learning to ignore nuisance information, and ii) learning the weights corresponding to the importance of each entity. Form

ally, we propose an entropy-smoothed optimal transport problem and show that it is a strict generalization of GAP, \ie a specific realization of the problem gives back GAP. We show that this optimization problem enjoys analytical gradients enabling us to use it as a direct learnable replacement for GAP. We further propose a zero-shot loss to ease the learning of GSP. We show the effectiveness of our method with extensive evaluations on 4 popular metric learning benchmarks. Code is available at: GSP-DML Framework

SAAL: Sharpness-Aware Active Learning

Yoon-Yeong Kim,JoonHo Jang,Byeonghu Na,Yeongmin Kim,Kyungwoo Song,Wanmo Kang,Il-chul Moon

While modern deep neural networks play significant roles in many research areas, they are also prone to overfitting problems under limited data instances. Particularly, this overfitting, or generalization issue, could be a problem in the framework of active learning because it selects a few data instances for learning over time. To consider the generalization, this paper introduces the first active learning method to incorporate the sharpness of loss space in the design of the acquisition function, inspired by sharpness-aware minimization (SAM). SAM intends to maximally perturb the training dataset, so the optimization can be led to a flat minima, which is known to have better generalization ability. Specifically, our active learning, Sharpness-Aware Active Learning (SAAL), constructs its acquisition function by selecting unlabeled instances whose perturbed loss becomes maximum. Over the adaptation of SAM into SAAL, we design a pseudo labeling mechanism to look forward to the perturbed loss w.r.t. the ground-truth label. Furthermore, we present a theoretic analysis between SAAL and recent active learning methods, so the recent works could be reduced to SAAL under a specific condition. We conduct experiments on various benchmark datasets for vision-based tasks in image classification and object detection. The experimental results confirm that SAAL outperforms the baselines by selecting instances that have the potentially maximal perturbation on the loss.

Scalable Subset Sampling with Neural Conditional Poisson Networks

Adeel Pervez,Phillip Lippe,Efstratios Gavves

A number of problems in learning can be formulated in terms of the basic primitive of sampling k elements out of a universe of n elements. This subset sampling operation cannot directly be included in differentiable models and approximations are essential. Current approaches take an \emph{order sampling} approach to sampling subsets and depend on differentiable approximations of the Top-k operator for selecting the largest k elements from a set. We present a simple alternative method for sampling subsets based on \emph{conditional Poisson sampling}. Unlike order sampling approaches, the parallel complexity of the proposed method is independent of the subset size which makes the method scalable to large subset sizes. We adapt the procedure to make it efficient and amenable to discrete gradient approximations for use in differentiable models. Furthermore, the method also allows the subset size parameter k to be differentiable. We demonstrate our approach on model explanation, image sub-sampling and stochastic k-nearest neighbor tasks outperforming existing methods in accuracy, efficiency and scalability.

Improved Convergence of Differential Private SGD with Gradient Clipping

Huang Fang,Xiaoyun Li,Chenglin Fan,Ping Li

Differential private stochastic gradient descent (DP-SGD) with gradient clipping (DP-SGD-GC) is an effective optimization algorithm that can train machine learning models with a privacy guarantee. Despite the popularity of DP-SGD-GC, its convergence in unbounded domain without the Lipschitz continuous assumption is less-understood; existing analysis of DP-SGD-GC either impose additional assumptions or end up with an utility bound that involves an non-vanishing bias term. In this work, for smooth and unconstrained problems, we improve the current analysis and show that DP-SGD-GC can achieve a vanishing utility bound without any bias term. Furthermore, when the noise generated from subsampled gradients is light-t ailed, we prove that DP-SGD-GC can achieve nearly the same utility bound as DP-SGD applies to the Lipschitz continuous objectives. As a by-product, we propose a new clipping technique, called value clipping, to mitigate the computational overhead caused by the classic gradient clipping. Experiments on standard benchmark datasets are conducted to support our analysis.

Group-level Brain Decoding with Deep Learning

Richard Csaky,Mats W.J. Van Es,Oiwi Parker Jones,Mark Woolrich

Decoding experimental variables from brain imaging data is gaining popularity, with applications in brain-computer interfaces and the study of neural representations. Decoding is typically subject-specific and does not generalise well over subjects. Here, we propose a method that uses subject embedding, analogous to word embedding in Natural Language Processing, to learn and exploit the structure in between subject variability as part of a decoding model, our adaptation of the WaveNet architecture for classification. We apply this to magnetoencephalography data, where 15 subjects viewed 118 different images, with 30 examples per image; to classify images using the entire 1s window following image presentation. We show that the combination of deep learning and subject embedding is crucial to closing the performance gap between subject- and group-level decoding models. Importantly, group models outperform subject models on low-accuracy subjects (but impair high-accuracy subjects) and can be helpful for initialising subject models. The potential of such group modelling is even higher with bigger datasets. To better enable physiological interpretation at the group level we demonstrate the use of permutation feature importance developing insights into the spatio-temporal and spectral information encoded in the models. All code is available on GitHub.

QUANTILE-LSTM: A ROBUST LSTM FOR ANOMALY DETECTION

Snehanshu Saha,Soma Dhavala,Jyotirmoy Sarkar,Preyank Bhavesh Mota,Santonu Sarkar

Anomalies refer to departure of systems and devices from their normal behaviour in standard operating conditions. An anomaly in an industrial device can indicate an upcoming failure, often in the temporal direction. In this paper, we make two contributions: 1) we estimate conditional quantiles, and consider three different ways to define anomalies based on the estimated quantiles and 2) use a new learnable activation function in the popular Long Short Term Memory (LSTM) architecture to model temporal long-range dependency. In particular, we propose Parametrized Elliot Function (Parametric Elliot Function (PEF)) as an activation function inside LSTM, which saturates lately compared to sigmoid and tanh. The proposed algorithms are compared with other well known anomaly detection algorithms, such as Isolation Forest (iForest), Elliptic Envelope, Autoencoder,and modern Deep Learning models such as Deep Autoencoding Gaussian Mixture Model (DAGMM), Generative Adversarial Networks (GAN) etc. The algorithms are evaluated in terms of various performance metrics, such as precision and recall. The algorithms are experimented on multiple industrial timeseries datasets such as Yahoo, AWS, GE, and machine sensor. We have found the LSTM based quantile algorithms are very effective and outperformed the existing algorithms in identifying the anomalies.

Neural Field Discovery Disentangles Equivariance in Interacting Dynamical Systems

Miltiadis Kofinas,Erik J Bekkers,Naveen Shankar Nagaraja,Efstratios Gavves

Systems of interacting objects often evolve under the influence of underlying field effects that govern their dynamics, \emph{e.g.} electromagnetic fields in physics, or map topologies and traffic rules in traffic scenes. While the interactions between objects depend on local information, the underlying fields depend on global states. Pedestrians and vehicles in traffic scenes, for example, follow different traffic rules and social norms depending on their absolute geolocation. The entanglement of global and local effects makes recently popularized equivariant networks inapplicable, since they fail to capture global information. To address this, in this work, we propose to \emph{disentangle} local object intera ctions --which are equivariant to global roto-translations and depend on relative positions and orientations-- from external global field effects --which depend on absolute positions and orientations. We theorize the presence of latent fields, which we aim to discover \emph{without} directly observing them, but infer them instead from the dynamics alone. We propose neural fields to learn the latent fields, and model the interactions with equivariant graph networks operating in local coordinate frames. We combine the two components in a graph network that transforms field effects in local frames and operates solely there. Our experiments show that we can accurately discover the underlying fields in charged particles settings, traffic scenes, and gravitational n-body problems, and effectively use them to learn the system and forecast future trajectories.

DIMENSION-REDUCED ADAPTIVE GRADIENT METHOD

Jingyang Li,Pan Zhou,Kuangyu Ding,Kim-Chuan Toh,Yinyu Ye

Adaptive gradient methods, such as Adam, have shown faster convergence speed than SGD across various kinds of network models. However, adaptive algorithms often suffer from inferior generalization performance than SGD. Though much effort via combining Adam and SGD have been invested to solve this issue, adaptive methods still fail to attain as good generalization as SGD. In this work, we proposed a Dimension-Reduced Adaptive Gradient Method (DRAG) to eliminate the generalization gap. DRAG makes an elegant combination of SGD and Adam by adopting a trust-region like framework. We observe that 1) Adam adjusts stepsizes for each gradient coordinate according to some loss curvature, and indeed decomposes the n-dimensional gradient into n independent directions to search, in which each direction inherits one coordinate element from the gradient and sets the remaining coordinate positions as zeros; 2) SGD uniformly scales gradient for all gradient coordinates and actually has only one descent direction to minimize. Accordingly, DRAG reduces the high degree of freedom of Adam and also improves the flexibility of SGD via optimizing the loss along $k\ (\ll \! n)$ descent directions, e.g. the gradient direction and momentum direction used in this work. Then per iteration, DRAG finds the best stepsizes for k descent directions by solving a trust-region subproblem whose computational overhead is negligible since the trust-region subproblem is low-dimensional, e.g. $k=2$ in this work. DRAG is compatible with the common deep learning training pipeline without introducing extra hyper-parameters and with negligible extra computation. Moreover, we prove the convergence property of DRAG for non-convex stochastic problems that often occur in deep learning training. Experimental results on representative benchmarks testify the fast convergence speed and also superior generalization of DRAG.

Learning to Estimate Single-View Volumetric Flow Motions without 3D Supervision

Erik Franz,Barbara Solenthaler,Nils Thuerey

We address the challenging problem of jointly inferring the 3D flow and volumetric densities moving in a fluid from a monocular input video with a deep neural network. Despite the complexity of this task, we show that it is possible to train the corresponding networks without requiring any 3D ground truth for training. In the absence of ground truth data we can train our model with observations from real-world capture setups instead of relying on synthetic reconstructions. We make this unsupervised training approach possible by first generating an initial prototype volume which is then moved and transported over time without the need for volumetric supervision. Our approach relies purely on image-based losses, an adversarial discriminator network, and regularization. Our method can estimate long-term sequences in a stable manner, while achieving closely matching targets for inputs such as rising smoke plumes.

ArCL: Enhancing Contrastive Learning with Augmentation-Robust Representations

Xuyang Zhao,Tianqi Du,Yisen Wang,Jun Yao,Weiran Huang

Self-Supervised Learning (SSL) is a paradigm that leverages unlabeled data for model training. Empirical studies show that SSL can achieve promising performance in distribution shift scenarios, where the downstream and training distributions differ. However, the theoretical understanding of its transferability remains limited. In this paper, we develop a theoretical framework to analyze the transferability of self-supervised contrastive learning, by investigating the impact of data augmentation on it. Our results reveal that the downstream performance of contrastive learning depends largely on the choice of data augmentation. Moreover, we show that contrastive learning fails to learn domain-invariant features, which limits its transferability. Based on these theoretical insights, we propose a novel method called Augmentation-robust Contrastive Learning (ArCL), which guarantees to learn domain-invariant features and can be easily integrated with existing contrastive learning algorithms. We conduct experiments on several datasets and show that ArCL significantly improves the transferability of contrastive learning.

Online Policy Optimization for Robust MDP

Jing Dong,Jingwei Li,Baoxiang Wang,Jingzhao Zhang

Reinforcement learning (RL) has exceeded human performance in many synthetic settings such as video games and Go. However, real-world deployment of end-to-end RL models is rare, as RL models can be very sensitive to slight perturbation of the environment. The robust Markov decision process (MDP) framework---in which the transition probabilities belong to an uncertainty set around a nominal model---provides one way to develop robust models. While previous analysis shows RL algorithms are effective assuming access to a generative model, it remains unclear whether RL can be efficient under a more realistic online setting, which requires carefully balancing exploration and exploitation. In this work, we consider online robust MDP by interacting with an unknown nominal system. We propose a robust optimistic policy optimization algorithm that is provably efficient. To address the additional uncertainty caused by an adversarial environment, our model features a new optimistic update rule derived via Fenchel conjugates. Our analysis establishes the first regret upper bound for online robust MDPs.

Toeplitz Neural Network for Sequence Modeling

Zhen Qin,Xiaodong Han,Weixuan Sun,Bowen He,Dong Li,Dongxu Li,Yuchao Dai,Lingpeng Kong,Yiran Zhong

Sequence modeling has important applications in natural language processing and computer vision. Recently, the transformer-based models have shown strong performance on various sequence modeling tasks, which rely on attention to capture pairwise token relations, and position embedding to inject positional information. While showing good performance, the transformer models are inefficient to scale to long input sequences, mainly due to the quadratic space-time complexity of attention. To overcome this inefficiency, we propose to model sequences with a relative position encoded Toeplitz matrix and use a Toeplitz matrix-vector production trick to reduce the space-time complexity of the sequence modeling to log linear. A lightweight sub-network called relative position encoder is proposed to generate relative position coefficients with a fixed budget of parameters, enabling the proposed Toeplitz neural network to deal with varying sequence lengths. In addition, despite being trained on 512-token sequences, our model can extrapolate input sequence length up to 14K tokens in inference with consistent performance. Extensive experiments on autoregressive and bidirectional language modeling, image modeling, and the challenging Long-range Arena Benchmark show that our method achieves better performance than its competitors in most downstream tasks while being significantly faster.

An Adaptive Entropy-Regularization Framework for Multi-Agent Reinforcement Learning

Woojun Kim,Youngchul Sung

In this paper, we propose an adaptive entropy-regularization framework (ADER) for multi-agent reinforcement learning (RL) to learn the adequate amount of exploration for each agent based on the degree of required exploration. In order to handle instability arising from updating multiple entropy temperature parameters for multiple agents, we disentangle the soft value function into two types: one for pure reward and the other for entropy. By applying multi-agent value factoriz ation to the disentangled value function of pure reward, we obtain a relevant metric to assess the necessary degree of exploration for each agent. Based on this metric, we propose the ADER algorithm based on maximum entropy RL, which controls the necessary level of exploration across agents over time by learning the proper target entropy for each agent. Experimental results show that the proposed scheme significantly outperforms current state-of-the-art multi-agent RL algorithms.

Relative Positional Encoding Family via Unitary Transformation

Zhen Qin,Weixuan Sun,Kaiyue Lu,Hui Deng,Dongxu Li,XiaoDong Han,Yuchao Dai,Lingpeng Kong,Yiran Zhong

Relative position encoding is widely used in vanilla and linear transformers to represent positional information. However, the existing encoding methods of a vanilla transformer are not always directly applicable to a linear transformer, because the latter requires a decomposition of the query and key representations into separate kernel functions. Nevertheless, principles to design encoding methods suitable for linear transformers remain under-studied. In this work, we put together a variety of existing encoding methods under a canonical form and further propose a family of relative positional encodings via unitary transformation. Our formulation leads to a principled framework that can be used to develop new relative positional encoding methods that preserve linear space-time complexity. Equipping with different parameters, the proposed unitary relative positional encoding family (URPE) derives effective encoding for various applications. Experiments show that compared with existing encoding methods, unitary encoding achieves competitive performance on language modeling and various challenging downstream tasks, such as machine translation and text classification. In the meantime, it highlights a general paradigm to design broadly more relative positional encoding methods, applicable inclusively to linear and vanilla transformers.

ColoristaNet for Photorealistic Video Style Transfer

Xiaowen Qiu,Ruize Xu,Boan He,Weifeng Ge

Photorealistic style transfer aims to transfer the artistic style of an image onto an input image or video while keeping photorealism. In this paper, we think it's the summary statistics matching scheme in existing algorithms that leads to unrealistic stylization. To avoid employing the popular Gram loss, we propose a self-supervised style transfer framework, which contains a style removal part and a style restoration part. The style removal network removes the original image styles, and the style restoration network recovers image styles in a supervised manner. Meanwhile, to address the problems in current feature transformation methods, we propose decoupled instance normalization to decompose feature transformation into style whitening and restylization. It works quite well in ColoristaNet and can transfer image styles efficiently while keeping photorealism. To ensure temporal coherency, we also incorporate optical flow methods and ConvLSTM to embed contextual information. Experiments demonstrates that ColoristaNet can achieve better stylization effects when compared with state-of-the-art algorithms.

Auto-Encoding Adversarial Imitation Learning

Kaifeng Zhang,Rui Zhao,Ziming Zhang,Yang Gao

Reinforcement learning (RL) provides a powerful framework for decision-making, but its application in practice often requires a carefully designed reward function. Adversarial Imitation Learning (AIL) sheds light on automatic policy acquisition without access to the reward signal from the environment. In this work, we propose Auto-Encoding Adversarial Imitation Learning (AEAIL), a robust and scalable AIL framework. To induce expert policies from demonstrations, AEAIL utilizes the reconstruction error of an auto-encoder as a reward signal, which provides more information for optimizing policies than the prior discriminator-based ones. Subsequently, we use the derived objective functions to train the auto-encoder and the agent policy. Experiments show that our AEAIL performs superior compared to state-of-the-art methods in the MuJoCo environments. More importantly, AEAIL shows much better robustness when the expert demonstrations are noisy. Specifi

cally, our method achieves 11% and 50.7% relative improvement overall compared to the best baseline GAIL and PWIL on clean and noisy expert data, respectively. Video results, open-source code and dataset are available in supplementary materials.

Δ-PINNs: physics-informed neural networks on complex geometries
Francisco Sahli Costabal,Simone Pezzuto,Paris Perdikaris
Physics-informed neural networks (PINNs) have demonstrated promise in solving forward and inverse problems involving partial differential equations. Despite recent progress on expanding the class of problems that can be tackled by PINNs, most of existing use-cases involve simple geometric domains. To date, there is no clear way to inform PINNs about the topology of the domain where the problem is being solved. In this work, we propose a novel positional encoding mechanism for PINNs based on the eigenfunctions of the Laplace-Beltrami operator. This technique allows to create an input space for the neural network that represents the geometry of a given object. We approximate the eigenfunctions as well as the operators involved in the partial differential equations with finite elements. We extensively test and compare the proposed methodology against traditional PINNs in complex shapes, such as a coil, a heat sink and a bunny, with different physics, such as the Eikonal equation and heat transfer. We also study the sensitivity of our method to the number of eigenfunctions used, as well as the discretization used for the eigenfunctions and the underlying operators. Our results show excellent agreement with the ground truth data in cases where traditional PINNs fail to produce a meaningful solution. We envision this new technique will expand the effectiveness of PINNs to more realistic applications.

BiTAT: Neural Network Binarization with Task-Dependent Aggregated Transformation
Geon Park,Jaehong Yoon,Haiyang Zhang,Xing Zhang,Sung Ju Hwang,Yonina C. Eldar
Neural network quantization aims to transform high-precision weights and activations of a given neural network into low-precision weights/activations for reduced memory usage and computation, while preserving the performance of the original model. However, extreme quantization (1-bit weight/1-bit activations) of compactly-designed backbone architectures (e.g., MobileNets) often used for edge-device deployments results in severe performance degeneration. This paper proposes a novel Quantization-Aware Training (QAT) method that can effectively alleviate performance degeneration even with extreme quantization by focusing on the inter-weight dependencies, between the weights within each layer and across consecutive layers. To minimize the quantization impact of each weight on others, we perform an orthonormal transformation of the weights at each layer by training an input-dependent correlation matrix and importance vector, such that each weight is disentangled from the others. Then, we quantize the weights based on their importance to minimize the loss of the information from the original weights/activations. We further perform progressive layer-wise quantization from the bottom layer to the top, so that quantization at each layer reflects the quantized distributions of weights and activations at previous layers. We validate the effectiveness of our method on various benchmark datasets against strong neural quantization baselines, demonstrating that it alleviates the performance degeneration on ImageNet and successfully preserves the full-precision model performance on CIFAR-100 with compact backbone networks.

Memory of Unimaginable Outcomes in Experience Replay
Adrian Remonda,Cole Corbitt Terrell,Eduardo E. Veas
Model-based reinforcement learning (MBRL) applies a single-shot dynamics model to imagined actions to select those with best expected outcome. The dynamics model is an unfaithful representation of the environment physics, and its capacity to predict the outcome of a future action varies as it is trained iteratively. An experience replay buffer collects the outcomes of all actions executed in the environment and is used to iteratively train the dynamics model. With growing experience, it is expected that the model becomes more accurate at predicting the outcome and expected reward of imagined actions. However, training times and memo

ry requirements drastically increase with the growing collection of experiences.

Indeed, it would be preferable to retain only those experiences that could not be anticipated by the model while interacting with the environment.
We argue that doing so results in a lean replay buffer with diverse experiences that correspond directly to the model's predictive weaknesses at a given point in time.
We propose strategies for: i) determining reliable predictions of the dynamics model with respect to the imagined actions, ii) retaining only the unimaginable experiences in the replay buffer, and iii) training further only when sufficient novel experience has been acquired.
We show that these contributions lead to lower training times, drastic reduction of the replay buffer size, fewer updates to the dynamics model and reduction of catastrophic forgetting. All of which enable the effective implementation of continual-learning agents using MBRL.

Temperature Schedules for self-supervised contrastive methods on long-tail data
Anna Kukleva,Moritz Böhle,Bernt Schiele,Hilde Kuehne,Christian Rupprecht
Most approaches for self-supervised learning (SSL) are optimised on curated balanced datasets, e.g. ImageNet, despite the fact that natural data usually exhibits long-tail distributions. In this paper, we analyse the behaviour of one of the most popular variants of SSL, i.e. contrastive methods, on imbalanced data. In particular, we investigate the role of the temperature parameter τ in the contrastive loss, by analysing the loss through the lens of average distance maximisation, and find that a large τ emphasises group-wise discrimination, whereas a small τ leads to a higher degree of instance discrimination. While τ has thus far been treated exclusively as a constant hyperparameter, in this work, we propose to employ a dynamic τ and show that a simple cosine schedule can yield significant improvements in the learnt representations. Such a schedule results in a constant `task switching' between an emphasis on instance discrimination and group-wise discrimination and thereby ensures that the model learns both group-wise features, as well as instance-specific details. Since frequent classes benefit from the former, while infrequent classes require the latter, we find this method to consistently improve separation between the classes in long-tail data without any additional computational cost.
****

Deep Learning on Implicit Neural Representations of Shapes
Luca De Luigi,Adriano Cardace,Riccardo Spezialetti,Pierluigi Zama Ramirez,Samuele Salti,Luigi di Stefano
Implicit Neural Representations (INRs) have emerged in the last few years as a powerful tool to encode continuously a variety of different signals like images, videos, audio and 3D shapes. When applied to 3D shapes, INRs allow to overcome the fragmentation and shortcomings of the popular discrete representations used so far. Yet, considering that INRs consist in neural networks, it is not clear whether and how it may be possible to feed them into deep learning pipelines aimed at solving a downstream task. In this paper, we put forward this research problem and propose inr2vec, a framework that can compute a compact latent representation for an input INR in a single inference pass. We verify that inr2vec can embed effectively the 3D shapes represented by the input INRs and show how the produced embeddings can be fed into deep learning pipelines to solve several tasks by processing exclusively INRs.

Continual Vision-Language Representaion Learning with Off-Diagonal Information
Zixuan Ni,Longhui Wei,Siliang Tang,Yueting Zhuang,Qi Tian
Multimodal pre-trained methods with a contrastive learning framework (like CLIP) have recently achieved consistent advantages on various cross-model downstream tasks. However, they usually require a large amount of image-text samples and a vast computing budget for training, which makes the re-training process expensive while the training data is collected continuously (the phenomenon is widespread in real scenarios). In this paper, we discuss the feasibility of continuously

training CLIP models based on discrete streaming data. We find that the multimodal retrieval performance of the CLIP in a continual training setting is significantly lower than that in a joint training setting. We name this phenomenon Cognitive Disorder(CD). By tracking the directional changes of the representation vectors in the continuously updated CLIP model, we explore and summarize the spatial variation of the modal encoders within the CLIP: Intra-modal Rotation and Inter-modal Deviation. Intra-modal Rotation means that the vision and language representation space in the CLIP is rotating greatly around the center of a high-dimensional unit sphere during continual training, accompanied by a relatively small change in the topology of the representation space. Inter-modal deviation happens when the vision and language's intra-modal rotation is unsynchronized. Moreover, we empirically and theoretically demonstrate how intra-modal rotation and inter-modal deviation lead to CD. In order to alleviate CD in continual CLIP training, we propose a new continual training framework Mod-X: Maintain off-diagonal information-matrix. By selectively aligning the off-diagonal information distribution of contrastive matrixes, the Mod-X helps the model not only better fits the newly trained data domain but also maintains the multimodal cognitive ability on the old data domain during the continual large-scale training (Section \ref{experiments}).

Learning Counterfactually Invariant Predictors

Francesco Quinzan,Cecilia Casolo,Krikamol Muandet,Niki Kilbertus,Yucen Luo

We propose a method to learn predictors that are invariant under counterfactual changes of certain covariates. This method is useful when the prediction target is causally influenced by covariates that should not affect the predictor output. For instance, this could prevent an object recognition model from being influenced by position, orientation, or scale of the object itself. We propose a model-agnostic regularization term based on conditional kernel mean embeddings to enforce counterfactual invariance during training. We prove the soundness of our method, which can handle mixed categorical and continuous multivariate attributes. Empirical results on synthetic and real-world data demonstrate the efficacy of our method in a variety of settings.

ImaginaryNet: Learning Object Detectors without Real Images and Annotations

Minheng Ni,Zitong Huang,Kailai Feng,Wangmeng Zuo

Without the demand of training in reality, humans are able of detecting a new category of object simply based on the language description on its visual characteristics. Empowering deep learning with this ability undoubtedly enables the neural network to handle complex vision tasks, e.g., object detection, without collecting and annotating real images. To this end, this paper introduces a novel challenging learning paradigm Imaginary-Supervised Object Detection (ISOD), where neither real images nor manual annotations are allowed for training object detectors. To resolve this challenge, we propose ImaginaryNet, a framework to synthesize images by combining pretrained language model and text-to-image synthesis model. Given a class label, the language model is used to generate a full description of a scene with a target object, and the text-to-image model is deployed to generate a photo-realistic image. With the synthesized images and class labels, weakly supervised object detection can then be leveraged to accomplish ISOD. By gradually introducing real images and manual annotations, ImaginaryNet can collaborate with other supervision settings to further boost detection performance. Experiments show that ImaginaryNet can (i) obtain about 75% performance in ISOD compared with the weakly supervised counterpart of the same backbone trained on real data, (ii) significantly improve the baseline while achieving state-of-the-art or comparable performance by incorporating ImaginaryNet with other supervision settings. Our code will be publicly available at https://github.com/kodenii/ImaginaryNet.

Don't Throw Your Old Policies Away: Knowledge-based Policy Recycling Protects Against Adversarial Attacks

Yaqi Xie,Chen Yu,Harold Soh

Recent work has shown that Deep Reinforcement Learning (DRL) is vulnerable to adversarial attacks, in which minor perturbations of input signals cause agents to behave inappropriately and unexpectedly. Humans, on the other hand, appear robust to these particular sorts of input variations. We posit that this part of robustness stems from accumulated knowledge about the world.
In this work, we propose to leverage prior knowledge to defend against adversarial attacks in RL settings using a framework we call Knowledge-based Policy Recycling (KPR). Different from previous defense methods such as adversarial training and robust learning, KPR incorporates domain knowledge over a set of auxiliary tasks policies and learns relations among them from interactions with the environment via a Graph Neural Network (GNN). KPR can use any relevant policy as an auxiliary policy and, importantly, does not assume access or information regarding the adversarial attack. Empirically, KPR results in policies that are more robust to various adversarial attacks in Atari games and a simulated Robot Foodcourt environment.

Contextual bandits with concave rewards, and an application to fair ranking
Virginie Do,Elvis Dohmatob,Matteo Pirotta,Alessandro Lazaric,Nicolas Usunier
We consider Contextual Bandits with Concave Rewards (CBCR), a multi-objective bandit problem where the desired trade-off between the rewards is defined by a known concave objective function, and the reward vector depends on an observed stochastic context. We present the first algorithm with provably vanishing regret for CBCR without restrictions on the policy space, whereas prior works were restricted to finite policy spaces or tabular representations. Our solution is based on a geometric interpretation of CBCR algorithms as optimization algorithms over the convex set of expected rewards spanned by all stochastic policies. Building on Frank-Wolfe analyses in constrained convex optimization, we derive a novel reduction from the CBCR regret to the regret of a \emph{scalar-reward} bandit problem. We illustrate how to apply the reduction off-the-shelf to obtain algorithms for CBCR with both linear and general reward functions, in the case of non-combinatorial actions. Motivated by fairness in recommendation, we describe a special case of CBCR with rankings and fairness-aware objectives, leading to the first algorithm with regret guarantees for contextual combinatorial bandits with fairness of exposure.

Gradient Boosting Performs Gaussian Process Inference
Aleksei Ustimenko,Artem Beliakov,Liudmila Prokhorenkova
This paper shows that gradient boosting based on symmetric decision trees can be equivalently reformulated as a kernel method that converges to the solution of a certain Kernel Ridge Regression problem. Thus, we obtain the convergence to a Gaussian Process' posterior mean, which, in turn, allows us to easily transform gradient boosting into a sampler from the posterior to provide better knowledge uncertainty estimates through Monte-Carlo estimation of the posterior variance. We show that the proposed sampler allows for better knowledge uncertainty estimates leading to improved out-of-domain detection.
****

Constrained Reinforcement Learning for Safety-Critical Tasks via Scenario-Based Programming
Davide Corsi,Raz Yerushalmi,Guy Amir,Alessandro Farinelli,David Harel,Guy Katz
Deep reinforcement learning (DRL) has achieved groundbreaking successes in various applications, including robotics. A natural consequence is the adoption of this paradigm for safety-critical tasks, where human safety and expensive hardware can be involved. In this context, it is crucial to optimize the performance of DRL-based agents while providing guarantees about their behavior. This paper presents a novel technique for incorporating domain-expert knowledge into a constrained DRL training loop. Our technique exploits the scenario-based programming paradigm, designed to specify such knowledge in a simple and intuitive way. While our approach can be considered general purpose, we validated our method by performing experiments on a synthetic set of benchmark environments, and the popular robotic mapless navigation problem, in simulation and on the actual platform. Ou

r results demonstrate that using our approach to leverage expert knowledge dramatically improves the safety and performance of the agent.

When is Adversarial Robustness Transferable?

Anna-Kathrin Kopetzki,Aleksandar Bojchevski,Stephan Günnemann

Knowledge transfer is an effective tool for learning, especially when labeled data is scarce or when training from scratch is prohibitively costly. The overwhelming majority of transfer learning literature is focused on obtaining accurate models, neglecting the issue of adversarial robustness. Yet, robustness is essential, particularly when transferring to safety-critical domains.

We analyze and compare how different training procedures on the source domain and different fine-tuning strategies on the target domain affect robustness. More precisely, we study 10 training schemes for source models and 3 for target models, including normal, adversarial, contrastive and Lipschitz constrained variants. We quantify model robustness via randomized smoothing and adversarial attacks. Our results show that improving model robustness on the source domain increases robustness on the target domain. Target retraining has a minor influence on target model robustness. These results indicate that model robustness is preserved during target retraining and transfered from the source domain to the target domain.

COFS: COntrollable Furniture layout Synthesis

Wamiq Reyaz Para,Paul Guerrero,Niloy Mitra,Peter Wonka

Realistic, scalable, and controllable generation of furniture layouts is essential for many applications in virtual reality, augmented reality, game development and synthetic data generation. The most successful current methods tackle this problem as a sequence generation problem which imposes a specific ordering on the elements of the layout, making it hard to exert fine-grained control over the attributes of a generated scene. Existing methods provide control through object-level conditioning, or scene completion, where generation can be conditioned on an arbitrary subset of furniture objects. However, attribute-level conditioning, where generation can be conditioned on an arbitrary subset of object attributes, is not supported. We propose COFS, a method to generate furniture layouts that enables fine-grained control through attribute-level conditioning. For example, COFS allows specifying only the scale and type of objects that should be placed in the scene and the generator chooses their positions and orientations; or the position that should be occupied by objects can be specified and the generator chooses their type, scale, orientation, etc. Our results show both qualitatively and quantitatively that we significantly outperform existing methods on attribute-level conditioning.

Distribution Shift Detection for Deep Neural Networks

Guy Bar-Shalom,Yonatan Geifman,Ran El-Yaniv

To deploy and operate deep neural models in production, the quality of their predictions, which might be contaminated benignly or manipulated maliciously by input distributional deviations, must be monitored and assessed. Specifically, we study the case of monitoring the healthy operation of a deep neural network (DNN) receiving a stream of data, with the aim of detecting input distributional deviations over which the quality of the network's predictions is potentially damaged. Using selective prediction principles, we propose a distribution deviation detection method for DNNs. The proposed method is derived from a tight coverage generalization bound computed over a sample of instances drawn from the true underlying distribution. Based on this bound, our detector continuously monitors the operation of the network over a test window and fires off an alarm whenever a deviation is detected. This novel detection method consistently and significantly outperforms the state of the art with respect to the CIFAR-10 and ImageNet datasets, thus establishing a new performance bar for this task, while being substantially more efficient in time and space complexities.

Learning Zero-Shot Cooperation with Humans, Assuming Humans Are Biased

Chao Yu,Jiaxuan Gao,Weilin Liu,Botian Xu,Hao Tang,Jiaqi Yang,Yu Wang,Yi Wu

There is a recent trend of applying multi-agent reinforcement learning (MARL) to train an agent that can cooperate with humans in a zero-shot fashion without using any human data. The typical workflow is to first repeatedly run self-play (SP) to build a policy pool and then train the final adaptive policy against this pool. A crucial limitation of this framework is that every policy in the pool is optimized w.r.t. the environment reward function, which implicitly assumes that the testing partners of the adaptive policy will be precisely optimizing the same reward function as well. However, human objectives are often substantially biased according to their own preferences, which can differ greatly from the environment reward. We propose a more general framework, Hidden-Utility Self-Play (HSP), which explicitly models human biases as hidden reward functions in the self-play objective. By approximating the reward space as linear functions, HSP adopts an effective technique to generate an augmented policy pool with biased policies. We evaluate HSP on the Overcooked benchmark. Empirical results show that our HSP method produces higher rewards than baselines when cooperating with learned human models, manually scripted policies, and real humans. The HSP policy is also rated as the most assistive policy based on human feedback.

SUG: Single-dataset Unified Generalization for 3D Point Cloud Classification

Siyuan Huang,Bo Zhang,Botian Shi,Peng Gao,Tao Chen,Hongsheng Li,Yikang LI

In recent years, research on zero-shot domain adaptation, namely Domain Generalization (DG), which aims to adapt a well-trained source domain model to unseen target domains without accessing any target sample, has been fast-growing in the 2D image tasks such as classification and object detection. However, its exploration on 3D point cloud data is still insufficient and challenged by more complex and uncertain cross-domain variances with irregular point data structures and uneven inter-class modality distribution. In this paper, different from previous 2D DG works, we focus on the 3D DG problem, and propose a Single-dataset Unified Generalization (SUG) framework that only leverages the source domain data to alleviate the unforeseen domain differences faced by the well-pretrained source model. Specifically, we first design a Multi-grained Sub-domain Alignment (MSA) method that can constrain the learned representations to be domain-agnostic and discriminative, by performing a multi-grained feature alignment process between the splitted sub-domains from the single source dataset. Then, a Sample-level Domain-aware Attention (SDA) strategy is presented, which can selectively enhance easy-to-adapt samples from different sub-domains according to the sample-level inter-domain distance, to avoid the negative transfer. Extensive experiments are conducted on three common 3D point cloud benchmarks. The experimental results demonstrate that SUG framework is effective to boost the model generalization ability for unseen target domains, even outperforming the existing unsupervised domain adaptation methods that have to access extensive target domain data, where we significantly improve classification accuracy by 7.7% on ModelNet-to-ScanNet setting and 2.3% on ShapeNet-to-ScanNet setting. Our code will be available.

An Optimal Transport Perspective on Unpaired Image Super-Resolution

Milena Gazdieva,Litu Rout,Alexander Korotin,Andrey Kravchenko,Alexander Filippov,Evgeny Burnaev

Real-world image super-resolution (SR) tasks often do not have paired
datasets, which limits the application of supervised techniques. As a result, the tasks are usually approached by unpaired techniques based on Generative Adversarial Networks (GANs), which yield complex training losses with several regularization terms, e.g., content or identity losses. We theoretically investigate optimization problems which arise in such models and find two surprizing observations. First, the learned SR map is always an optimal transport (OT) map. Second, we theoretically prove and empirically show that the learned map is biased, i.e., it does not actually transform the distribution of low-resolution images to high-resolution ones. Inspired by these findings, we propose an algorithm for unpaired SR which learns an unbiased OT map for the perceptual transport cost. Unlike the existing GAN-based alternatives, our algorithm has a simple optimization ob

jective reducing the need for complex hyperparameter selection and an application of additional regularizations. At the same time, it provides a nearly state-of-the-art performance on the large-scale unpaired AIM19 dataset.

A Functional Perspective on Multi-Layer Out-of-Distribution Detection
Eduardo Dadalto Câmara Gomes,Pierre Colombo,Guillaume Staerman,Nathan Noiry,Pablo Piantanida
A crucial component for implementing reliable classifiers is detecting examples far from the reference (training) distribution, referred to as out-of-distribution (OOD) samples. A key feature of OOD detection is to exploit the network by extracting statistical patterns and relationships through the pre-trained multi-layer classifier. Despite achieving solid results, state-of-the-art methods require either additional OOD examples, expensive computation of gradients, or are tightened to a particular architecture, limiting their applications. This work adopts an original approach based on a functional view of the network that exploits the sample's trajectories through the various layers and their statistical dependencies. In this new framework, OOD detection translates into detecting samples whose trajectories differ from the typical behavior characterized by the training set. Our method significantly decreases the OOD detection error of classifiers trained on ImageNet and outperforms the state-of-the-art methods on average AUROC and TNR at 95% TPR. We demonstrate that the functional signature left by a sample in a network carries relevant information for OOD detection.

Modelling Long Range Dependencies in ND: From Task-Specific to a General Purpose CNN
David M Knigge,David W. Romero,Albert Gu,Efstratios Gavves,Erik J Bekkers,Jakub Mikolaj Tomczak,Mark Hoogendoorn,Jan-jakob Sonke
Performant Convolutional Neural Network (CNN) architectures must be tailored to specific tasks in order to consider the length, resolution, and dimensionality of the input data. In this work, we tackle the need for problem-specific CNN architectures. We present the Continuous Convolutional Neural Network (CCNN): a single CNN able to process data of arbitrary resolution, dimensionality and length without any structural changes. Its key component are its continuous convolutional kernels which model long-range dependencies at every layer, and thus remove the need of current CNN architectures for task-dependent downsampling and depths. We showcase the generality of our method by using the same architecture for tasks on sequential ($1{\rm D}$), visual ($2{\rm D}$) and point-cloud ($3{\rm D}$) data. Our CCNN matches and often outperforms the current state-of-the-art across all tasks considered.
****

Ahead-of-Time P-Tuning
Daniil Gavrilov
This paper proposes a new parameter-efficient method for fine-tuning, AoT P-Tuning. This method adds input-dependent biases before evaluating the Transformer layer, reducing the required evaluation time when compared to P-Tuning. Same as P-Tuning, AoT P-Tuning allows multi-task inference with a single backbone model for evaluating different tasks in a single batch.
We experimented with the proposed method on the GLUE and SuperGLUE benchmarking datasets using RoBERTa-Base, RoBERTa-Large, and DeBERTa-XL backbone models. Our observations show that AoT P-tuning performed on par with or better than P-Tuning v2 while being up to $1.3\times$ times faster during inference.

Planckian Jitter: countering the color-crippling effects of color jitter on self-supervised training
Simone Zini,Alex Gomez-Villa,Marco Buzzelli,Bart■omiej Twardowski,Andrew D. Bagdanov,Joost van de weijer
Several recent works on self-supervised learning are trained by mapping different augmentations of the same image to the same feature representation. The data augmentations used are of crucial importance to the quality of learned feature representations. In this paper, we analyze how the color jitter traditionally used

in data augmentation negatively impacts the quality of the color features in learned feature representations. To address this problem, we propose a more realistic, physics-based color data augmentation - which we call Planckian Jitter - that creates realistic variations in chromaticity and produces a model robust to illumination changes that can be commonly observed in real life, while maintaining the ability to discriminate image content based on color information.

Experiments confirm that such a representation is complementary to the representations learned with the currently-used color jitter augmentation and that a simple concatenation leads to significant performance gains on a wide range of downstream datasets.

In addition, we present a color sensitivity analysis that documents the impact of different training methods on model neurons and shows that the performance of the learned features is robust with respect to illuminant variations.

Official code available at: https://github.com/TheZino/PlanckianJitter

Efficient and Stealthy Backdoor Attack Triggers are Close at Hand

Minlong Peng,Xu Li,Mingming Sun

A backdoor attack aims to inject a backdoor into a deep model so that the model performs normally on benign samples while maliciously predicting the input as the attacker-defined target class when the backdoor is activated by a predefined trigger pattern. Most existing backdoor attacks use a pattern that rarely occurs in benign data as the trigger pattern. In this way, the impact of the attack on the label prediction of benign data can be mitigated. However, this practice also results in the attack being defended against with little performance degradation on benign data by preventing the trigger pattern from being activated. In this work, we present a new attack strategy to solve this dilemma. Unlike the conventional strategy, our strategy extracts the trigger pattern from benign training data, which frequently occurs in samples of the target class but rarely occurs in samples of the other classes. Compared with the prevailing strategy, our proposed strategy has two advantages. First, it can improve the efficiency of the attack because learning on benign samples of the target class can facilitate the fitting of the trigger pattern. Second, it increases the difficulty or cost of identifying the trigger pattern and preventing its activation, since many benign samples of the target class contain the trigger pattern. We empirically evaluate our strategy on four benchmark datasets. The experimental studies show that attacks performed with our strategy can achieve much better performance when poisoning only 0.1\% or more of the training data, and can achieve better performance against several benchmark defense algorithms.

Property Inference Attacks Against t-SNE Plots

Jingcan Chen,Xinlei He,Boyang Zhang,Yang Chen,Yang Zhang

With the prevailing of machine learning (ML), researchers have shown that ML models are also vulnerable to various privacy and security attacks. As one of the representative attacks, the property inference attack aims to infer the private/sensitive properties of the training data (e.g., race distribution) given the output of ML models. In this paper, we present a new side channel for property inference attacks, i.e., t-SNE plots, which are widely used to show feature distribution or demonstrate model performance. We show for the first time that the private/sensitive properties of the data that are used to generate the plot can be successfully predicted. Briefly, we leverage the publicly available model as the shadow model to generate t-SNE plots with different properties. We use those plots to train an attack model, which is a simple image classifier, to infer the specific property of a given t-SNE plot. Extensive evaluation on four datasets shows that our proposed attack can effectively infer the undisclosed property of the data presented in the t-SNE plots, even when the shadow model is different from the target model used to generate the t-SNE plots. We also reveal that the attacks are robust in various scenarios, such as constructing the attack with fewer t-SNE plots/different density settings and attacking t-SNE plots generated by fine-tuned target models. The simplicity of our attack method indicates that the potential risk of leaking sensitive properties in t-SNE plots is largely underest

imated. As possible defenses, we observe that adding noise to the image embeddings or t-SNE coordinates effectively mitigates attacks but can be bypassed by adaptive attacks, which prompts the need for more effective defenses.

GAMR: A Guided Attention Model for (visual) Reasoning
Mohit Vaishnav,Thomas Serre

Humans continue to outperform modern AI systems in their ability to flexibly parse and understand complex visual scenes. Here, we present a novel module for visual reasoning, the Guided Attention Model for (visual) Reasoning ($\textit{GAMR}$), which instantiates an active vision theory -- positing that the brain solves complex visual reasoning problems dynamically -- via sequences of attention shifts to select and route task-relevant visual information into memory. Experiments on an array of visual reasoning tasks and datasets demonstrate GAMR's ability to learn visual routines in a robust and sample-efficient manner. In addition, GAMR is shown to be capable of zero-shot generalization on completely novel reasoning tasks. Overall, our work provides computational support for cognitive theories that postulate the need for a critical interplay between attention and memory to dynamically maintain and manipulate task-relevant visual information to solve complex visual reasoning tasks.

Voint Cloud: Multi-View Point Cloud Representation for 3D Understanding
Abdullah Hamdi,Silvio Giancola,Bernard Ghanem

Multi-view projection methods have demonstrated promising performance on 3D understanding tasks like 3D classification and segmentation. However, it remains unclear how to combine such multi-view methods with the widely available 3D point clouds. Previous methods use unlearned heuristics to combine features at the point level. To this end, we introduce the concept of the multi-view point cloud (Voint cloud), representing each 3D point as a set of features extracted from several view-points. This novel 3D Voint cloud representation combines the compactness of 3D point cloud representation with the natural view-awareness of multi-view representation. Naturally, we can equip this new representation with convolutional and pooling operations. We deploy a Voint neural network (VointNet) to learn representations in the Voint space. Our novel representation achieves state-of-the-art performance on 3D classification, shape retrieval, and robust 3D part segmentation on standard benchmarks (ScanObjectNN, ShapeNet Core55, and ShapeNet Parts). Further analysis shows that VointNet improves the robustness to occlusion compared to other methods.

QuAnt: Quantum Annealing with Learnt Couplings
Marcel Seelbach Benkner,Maximilian Krahn,Edith Tretschk,Zorah Lähner,Michael Moeller,Vladislav Golyanik

Modern quantum annealers can find high-quality solutions to combinatorial optimisation objectives given as quadratic unconstrained binary optimisation (QUBO) problems. Unfortunately, obtaining suitable QUBO forms in computer vision remains challenging and currently requires problem-specific analytical derivations. Moreover, such explicit formulations impose tangible constraints on solution encodings. In stark contrast to prior work, this paper proposes to learn QUBO forms from data through gradient backpropagation instead of deriving them. As a result, the solution encodings can be chosen flexibly and compactly. Furthermore, our methodology is general and virtually independent of the specifics of the target problem type. We demonstrate the advantages of learnt QUBOs on the diverse problem types of graph matching, 2D point cloud alignment and 3D rotation estimation. Our results are competitive with the previous quantum state of the art while requiring much fewer logical and physical qubits, enabling our method to scale to larger problems. The code and the new dataset are available at https://4dqv.mpi-inf.mpg.de/QuAnt/.

Understanding Gradient Regularization in Deep Learning: Efficient Finite-Difference Computation and Implicit Bias
Ryo Karakida,Tomoumi Takase,Tomohiro Hayase,Kazuki Osawa

Gradient regularization (GR) is a method that penalizes the gradient norm of the training loss during training. Although some studies have reported that GR improves generalization performance in deep learning, little attention has been paid to it from the algorithmic perspective, that is, the algorithms of GR that efficiently improve performance. In this study, we first reveal that a specific finite-difference computation, composed of both gradient ascent and descent steps, reduces the computational cost for GR. In addition, this computation empirically achieves better generalization performance. Next, we theoretically analyze a solvable model, a diagonal linear network, and clarify that GR has a desirable implicit bias. Learning with GR chooses better minima in a certain problem, and the finite-difference GR chooses even better ones as the ascent step size becomes larger. Finally, we demonstrate that finite-difference GR is closely related to some other algorithms based on iterative ascent and descent steps for exploring flat minima: sharpness-aware minimization and the flooding method. In particular, we reveal that flooding performs finite-difference GR in an implicit way. Thus, this work broadens our understanding of GR in both practice and theory.

Approximate Nearest Neighbor Search through Modern Error-Correcting Codes
Noam Touitou,Nissim Halabi
A locality-sensitive hash (or LSH) is a function that can efficiently map dataset points into a latent space while preserving pairwise distances. Such LSH functions have been used in approximate nearest-neighbor search (ANNS) in the following classic way, which we call classic hash clustering (CHC): first, the dataset points are hashed into a low-dimensional binary space using the LSH function; then, the points are clustered by these hash values. Upon receiving a query, its nearest neighbors are sought within its hash-cluster and nearby hash-clusters (i.e., multi-probe). However, CHC mandates a low-dimensional latent space for the LSH function, which distorts distances from the (high-dimensional) original real space; this results in inferior recall. This is often mitigated through using multiple hash tables at additional storage and memory costs.

In this paper, we introduce a better way of using LSH functions for ANNS. Our method, called the Polar Code Nearest-Neighbor (PCNN) algorithm, uses modern error-correcting codes (specifically polar codes) to maintain a manageable number of clusters inside a high-dimensional latent space. Allowing the LSH function to embed into this high-dimensional latent space results in higher recall, as the embedding faithfully captures distances in the original space. The crux of PCNN is using polar codes for probing: we present a multi-probe scheme for PCNN which uses efficient list-decoding methods for polar codes, with time complexity independent of the dataset size. Fixing the choice of LSH, experiment results demonstrate significant performance gains of PCNN over CHC; in particular, PCNN with a single table outperforms CHC with multiple tables, obviating the need for large memory and storage.

Social and environmental impact of recent developments in machine learning on biology and chemistry research
Daniel Probst
Potential societal and environmental effects such as the rapidly increasing resource use and the associated environmental impact, reproducibility issues, and exclusivity, the privatization of ML research leading to a public research brain-drain, a narrowing of the research effort caused by a focus on deep learning, and the introduction of biases through a lack of sociodemographic diversity in data and personnel caused by recent developments in machine learning are a current topic of discussion and scientific publications. However, these discussions and publications focus mainly on computer science-adjacent fields, including computer vision and natural language processing or basic ML research. Using bibliometric analysis of the complete and full-text analysis of the open-access literature, we show that the same observations can be made for applied machine learning in chemistry and biology. These developments can potentially affect basic and applied research, such as drug discovery and development, beyond the known issue of bi

ased data sets.

When to Make and Break Commitments?

Alihan Hüyük,Zhaozhi Qian,Mihaela van der Schaar

In many scenarios, decision-makers must commit to long-term actions until their resolution before receiving the payoff of said actions, and usually, staying committed to such actions incurs continual costs. For instance, in healthcare, a newly-discovered treatment cannot be marketed to patients until a clinical trial is conducted, which both requires time and is also costly. Of course in such scenarios, not all commitments eventually pay off. For instance, a clinical trial might end up failing to show efficacy. Given the time pressure created by the continual cost of keeping a commitment, we aim to answer: When should a decision-maker break a commitment that is likely to fail—either to make an alternative commitment or to make no further commitments at all? First, we formulate this question as a new type of optimal stopping/switching problem called the optimal commitment problem (OCP). Then, we theoretically analyze OCP, and based on the insights we gain, propose a practical algorithm for solving it. Finally, we empirically evaluate the performance of our algorithm in running clinical trials with subpopulation selection.

Generalization bounds and algorithms for estimating the effect of multiple treatments and dosage

Alexis Bellot,Anish Dhir,Giulia Prando

Estimating conditional treatment effects has been a longstanding challenge for fields of study such as epidemiology or economics that require a treatment-dosage pair to make decisions, but may not be able to run randomized trials to precisely quantify their effect. In the context of representation learning, there is an extensive literature relating model architectures with regularization techniques to solve this problem using observational data. However, theoretically motivated loss functions and bounds on generalization errors only exist in select circumstances, such as in the presence of binary treatments. In this paper, we introduce new bounds on the counterfactual generalization error in the context of multiple treatments and continuous dosage parameters, which subsume existing results. This result, in a principled manner, guides the definition of new learning objectives that can be used to train representation learning algorithms. We show empirically new state-of-the-art performance results across several benchmark data sets for this problem, including in comparison to doubly-robust estimation methods.

DENSE RGB SLAM WITH NEURAL IMPLICIT MAPS

Heng Li,Xiaodong Gu,Weihao Yuan,luwei yang,Zilong Dong,Ping Tan

There is an emerging trend of using neural implicit functions for map representation in Simultaneous Localization and Mapping (SLAM). Some pioneer works have achieved encouraging results on RGB-D SLAM. In this paper, we present a dense RGB SLAM method with neural implicit map representation. To reach this challenging goal without depth input, we introduce a hierarchical feature volume to facilitate the implicit map decoder. This design effectively fuses shape cues across different scales to facilitate map reconstruction. Our method simultaneously solves the camera motion and the neural implicit map by matching the rendered and input video frames. To facilitate optimization, we further propose a photometric warping loss in the spirit of multi-view stereo to better constrain the camera pose and scene geometry. We evaluate our method on commonly used benchmarks and compare it with modern RGB and RGB-D SLAM systems. Our method achieves favorable results than previous methods and even surpasses some recent RGB-D SLAM methods.The code is at poptree.github.io/DIM-SLAM/.

Monocular Scene Reconstruction with 3D SDF Transformers

Weihao Yuan,Xiaodong Gu,Heng Li,Zilong Dong,Siyu Zhu

Monocular scene reconstruction from posed images is challenging due to the complexity of a large environment. Recent volumetric methods learn to directly predic t the TSDF volume and have demonstrated promising results in this task. However, most methods focus on how to extract and fuse the 2D features to a 3D feature volume, but none of them improve the way how the 3D volume is aggregated. In this work, we propose an SDF transformer network, which replaces the role of 3D CNN for better 3D feature aggregation. To reduce the explosive computation complexity of the 3D multi-head attention, we propose a sparse window attention module, where the attention is only calculated between the non-empty voxels within a local window. Then a top-down-bottom-up 3D attention network is built for 3D feature aggregation, where a dilate-attention structure is proposed to prevent geometry degeneration, and two global modules are employed to equip with global receptive fields. The experiments on multiple datasets show that this 3D transformer network generates a more accurate and complete reconstruction, which outperforms previous methods by a large margin. Remarkably, the mesh accuracy is improved by 41.8%, and the mesh completeness is improved by 25.3% on the ScanNet dataset. The code of our method will be made public.

Learning Heterogeneous Interaction Strengths by Trajectory Prediction with Graph Neural Network

Seungwoong Ha,Hawoong Jeong

Dynamical systems with interacting agents are universal in nature, commonly modeled by a graph of relationships between their constituents. Recently, various works have been presented to tackle the problem of inferring those relationships from the system trajectories via deep neural networks, but most of the studies assume binary or discrete types of interactions for simplicity. In the real world, the interaction kernels often involve continuous interaction strengths, which cannot be accurately approximated by discrete relations. In this work, we propose the relational attentive inference network (RAIN) to infer continuously weighted interaction graphs without any ground-truth interaction strengths. Our model employs a novel pairwise attention (PA) mechanism to refine the trajectory representations and a graph transformer to extract heterogeneous interaction weights for each pair of agents. We show that our RAIN model with the PA mechanism accurately infers continuous interaction strengths for simulated physical systems in an unsupervised manner. Further, RAIN with PA successfully predicts trajectories from motion capture data with an interpretable interaction graph, demonstrating the virtue of modeling unknown dynamics with continuous weights.

From t-SNE to UMAP with contrastive learning

Sebastian Damrich,Niklas Böhm,Fred A Hamprecht,Dmitry Kobak

Neighbor embedding methods t-SNE and UMAP are the de facto standard for visualizing high-dimensional datasets. Motivated from entirely different viewpoints, their loss functions appear to be unrelated. In practice, they yield strongly differing embeddings and can suggest conflicting interpretations of the same data. The fundamental reasons for this and, more generally, the exact relationship between t-SNE and UMAP have remained unclear. In this work, we uncover their conceptual connection via a new insight into contrastive learning methods. Noise-contrastive estimation can be used to optimize t-SNE, while UMAP relies on negative sampling, another contrastive method. We find the precise relationship between these two contrastive methods, and provide a mathematical characterization of the distortion introduced by negative sampling. Visually, this distortion results in UMAP generating more compact embeddings with tighter clusters compared to t-SNE. We exploit this new conceptual connection to propose and implement a generalization of negative sampling, allowing us to interpolate between (and even extrapolate beyond) t-SNE and UMAP and their respective embeddings. Moving along this spectrum of embeddings leads to a trade-off between discrete / local and continuous / global structures, mitigating the risk of over-interpreting ostensible features of any single embedding. We provide a PyTorch implementation.

On the optimal precision of GANs

Thibaut Issenhuth,Ugo Tanielian,Jeremie Mary,David Picard

Generative adversarial networks (GANs) are known to face model misspecification when learning disconnected distributions. Indeed, continuous mapping from a unimodal latent distribution to a disconnected one is impossible, so GANs necessarily generate samples outside of the support of the target distribution. In this paper, we make the connection between the performance of GANs and their latent space configuration. In particular, we raise the following question: what is the latent space partition that minimizes the measure of out-of-manifold samples? Building on a recent result of geometric measure theory, we prove there exist optimal GANs when the dimension of the latent space is larger than the number of modes. In particular, we show that these generators structure their latent space as a `simplicial cluster' - a Voronoi partition where centers are equally distant. We derive both an upper and a lower bound on the optimal precision of GANs learning disconnected manifolds. Interestingly, these two bounds have the same order of decrease: $\sqrt{\log m}$, m being the number of modes. Finally, we perform several experiments to exhibit the geometry of the latent space and experimentally show that GANs have a geometry with similar properties to the theoretical one.

D4AM: A General Denoising Framework for Downstream Acoustic Models

Chi-Chang Lee,Yu Tsao,Hsin-Min Wang,Chu-Song Chen

The performance of acoustic models degrades notably in noisy environments. Speech enhancement (SE) can be used as a front-end strategy to aid automatic speech recognition (ASR) systems. However, existing training objectives of SE methods are not fully effective at integrating speech-text and noise-clean paired data for training toward unseen ASR systems. In this study, we propose a general denoising framework, D4AM, for various downstream acoustic models. Our framework fine-tunes the SE model with the backward gradient according to a specific acoustic model and the corresponding classification objective. In addition, our method aims to consider the regression objective as an auxiliary loss to make the SE model generalize to other unseen acoustic models. To jointly train an SE unit with regression and classification objectives, D4AM uses an adjustment scheme to directly estimate suitable weighting coefficients rather than undergoing a grid search process with additional training costs. The adjustment scheme consists of two parts: gradient calibration and regression objective weighting. The experimental results show that D4AM can consistently and effectively provide improvements to various unseen acoustic models and outperforms other combination setups. Specifically, when evaluated on the Google ASR API with real noisy data completely unseen during SE training, D4AM achieves a relative WER reduction of 24.65% compared with the direct feeding of noisy input. To our knowledge, this is the first work that deploys an effective combination scheme of regression (denoising) and classification (ASR) objectives to derive a general pre-processor applicable to various unseen ASR systems. Our code is available at https://github.com/ChangLee0903/D4AM.

Adaptive Budget Allocation for Parameter-Efficient Fine-Tuning

Qingru Zhang,Minshuo Chen,Alexander Bukharin,Pengcheng He,Yu Cheng,Weizhu Chen,Tuo Zhao

Fine-tuning large pre-trained language models on downstream tasks has become an important paradigm in NLP. However, common practice fine-tunes all of the parameters in a pre-trained model, which becomes prohibitive when a large number of downstream tasks are present. Therefore, many fine-tuning methods are proposed to learn incremental updates of pre-trained weights in a parameter efficient way, e.g., low-rank increments. These methods often evenly distribute the budget of incremental updates across all pre-trained weight matrices, and overlook the varying importance of different weight parameters. As a consequence, the fine-tuning performance is suboptimal. To bridge this gap, we propose AdaLoRA, which adaptively allocates the parameter budget among weight matrices according to their importance score. In particular, AdaLoRA parameterizes the incremental updates in the form of singular value decomposition. Such a novel approach allows us to effectively prune the singular values of unimportant updates, which is essentially to reduce their parameter budget but circumvent intensive exact SVD computations.

We conduct extensive experiments with several pre-trained models on natural language processing, question answering, and natural language generation to validate the effectiveness of AdaLoRA. Results demonstrate that AdaLoRA manifests notable improvement over baselines, especially in the low budget settings. Our code is publicly available at https://github.com/QingruZhang/AdaLoRA .

On Intriguing Layer-Wise Properties of Robust Overfitting in Adversarial Training

Duke Nguyen,Chaojian Yu,Vinoth Nandakumar,Young Lee,Tongliang Liu

Adversarial training has proven to be one of the most effective methods to defend against adversarial attacks. Nevertheless, robust overfitting is a common obstacle in adversarial training of deep networks. There is a common belief that the features learned by different network layers have different properties, however, existing works generally investigate robust overfitting by considering a DNN as a single unit and hence the impact of different network layers on robust overfitting remains unclear. In this work, we divide a DNN into a series of layers and investigate the effect of different network layers on robust overfitting. We find that different layers exhibit distinct properties towards robust overfitting, and in particular, robust overfitting is mostly related to the optimization of latter parts of the network. Based upon the observed effect, we propose a robust adversarial training (RAT) prototype: in a mini-batch, we optimize the front parts of the network as usual, and adopt additional measures to regularize the optimization of the latter parts. Based on the prototype, we designed two realizations of RAT, and extensive experiments demonstrate that RAT can eliminate robust overfitting and boost adversarial robustness over the standard adversarial training.

Does Federated Learning Really Need Backpropagation?

Haozhe Feng,Tianyu Pang,Chao Du,Wei Chen,Shuicheng YAN,Min Lin

Federated learning (FL) provides general principles for decentralized clients to train a server model collectively without sharing local data. FL is a promising framework with practical applications, but its standard training paradigm requires the clients to backpropagate through the model to compute gradients. Since these clients are typically edge devices and not fully trusted, executing backpropagation on them incurs computational and storage overhead as well as white-box vulnerability. In light of this, we develop backpropagation-free federated learning, dubbed BAFFLE, in which backpropagation is replaced by multiple forward processes to estimate gradients. BAFFLE is 1) memory-efficient and easily fits uploading bandwidth; 2) compatible with inference-only hardware optimization and model quantization or pruning; and 3) well-suited to trusted execution environments, because the clients in BAFFLE only execute forward propagation and return a set of scalars to the server. In experiments, we demonstrate that BAFFLE-trained models can achieve empirically comparable performance to conventional FL models.

****

Teaching Others is Teaching Yourself Regularization For Controllable Language Models

Han Liu,Bingning Wang,Ting Yao,Haijin Liang,Jianjin Xu,Xiaolin Hu

Large-scale pre-trained language models have achieved great success on natural language generation tasks. However, it is difficult to control the pre-trained language models to generate sentences with the expected attribute such as topic and sentiment. Recent efforts on controllable language generation employ an additional attribute classifier, which guides the generation of large-scale pre-trained language models, have been shown to be efficient in controllable language generation. These methods are named ''classifier-guided language models'' (CGLMs).

However, we find that the probabilities predicted by the attribute classifiers usually approaches 0 or 1, which make it hard to distinguish sentences with different matching degrees to the expected attribute. The problem is named \textit{the biased probability distribution} (BPD) problem.

To address the problem, we investigate different methods for adjusting probability distribution and propose a ''Teaching Others is Teaching Yourself'' (TOTY) re gularization method to smooth the probability distribution.

Experiments on sentiment control and topic control tasks show that CGLMs can get better performance with guiding classifiers trained with TOTY.

Specialization of Sub-paths for Adaptive Depth Networks

Woochul Kang

We present a novel approach to anytime networks that can control network depths instantly at runtime to provide various accuracy-efficiency trade-offs. While controlling the depth of a network is an effective way to obtain actual inference speed-up, previous adaptive depth networks require either additional intermediate classifiers or decision networks, that are challenging to train properly. Unlike previous approaches, our adaptive depth networks require virtually no architectural changes from baseline networks. Instead, we introduce a novel training method that enforces some sub-paths of the baseline networks to have a special property, with which the sub-paths do not change the semantic level of input features, but only refine them to reduce prediction errors. Those specialized sub-paths can be skipped at test time, if needed, to save computation at marginal loss of prediction accuracy. We first formally present the rationale behind the sub-paths specialization, and based on that, we propose a simple and practical training method to specialize sub-paths for adaptive depth networks. While minimal architectural changes and training efforts are required, we demonstrate that our approach significantly outperforms non-adaptive baselines in various tasks, including ImageNet classification, COCO object detection and instance segmentation. Further, we show that the smallest sub-networks of our adaptive depth networks achieve competitive model compression effect compared to recent state-of-the-art techniques.

Towards Effective and Interpretable Human-Agent Collaboration in MOBA Games: A Communication Perspective

Yiming Gao,Feiyu Liu,Liang Wang,Zhenjie Lian,Weixuan Wang,Siqin Li,Xianliang Wang,Xianhan Zeng,Rundong Wang,jiawei wang,QIANG FU,Yang Wei,Lanxiao Huang,Wei Liu

MOBA games, e.g., Dota2 and Honor of Kings, have been actively used as the testbed for the recent AI research on games, and various AI systems have been developed at the human level so far. However, these AI systems mainly focus on how to compete with humans, less on exploring how to collaborate with humans. To this end, this paper makes the first attempt to investigate human-agent collaboration in MOBA games. In this paper, we propose to enable humans and agents to collaborate through explicit communication by designing an efficient and interpretable Meta-Command Communication-based framework, dubbed MCC, for accomplishing effective human-agent collaboration in MOBA games. The MCC framework consists of two pivotal modules: 1) an interpretable communication protocol, i.e., the Meta-Command, to bridge the communication gap between humans and agents; 2) a meta-command value estimator, i.e., the Meta-Command Selector, to select a valuable meta-command for each agent to achieve effective human-agent collaboration. Experimental results in Honor of Kings demonstrate that MCC agents can collaborate reasonably well with human teammates and even generalize to collaborate with different levels and numbers of human teammates. Videos are available at https://sites.google.com/view/mcc-demo.

How Normalization and Weight Decay Can Affect SGD? Insights from a Simple Normalized Model

Ruosi Wan,Qiaosen Wang,Xiangyu Zhang,Yu-Wing Tai,Jian Sun,Chi-Keung Tang

Recent works(Li et al., 2020, Wan et al., 2021) characterize an important mechanism of normalized model trained with SGD and WD (Weight Decay), called Spherical Motion Dynamics (SMD), confirming its widespread effects in practice. However, no theoretical study is available on the influence of SMD on the training process of normalized models in literature. In this work, we seek to understand the effect of SMD by theoretically analyzing a simple normalized model, named as Noisy Rayleigh Quotient (NRQ). On NRQ, We theoretically prove SMD can dominate the whole training process via controlling the evolution of angular update (AU), an es sential feature of SMD. Specifically, we show: 1) within equilibrium state of SMD, the convergence rate and limiting risk of NRQ are mainly determined by the theoretical value of AU; and 2) beyond equilibrium state, the evolution of AU can interfere the optimization trajectory, causing odd phenomena such as ``escape'' behavior. We further show the insights drawn from NRQ is consistent with empirical observations in experiments on real datasets. We believe our theoretical results shed new light on the role of normalization techniques during the training of modern deep learning models.

Generalize Learned Heuristics to Solve Large-scale Vehicle Routing Problems in Real-time

Qingchun Hou,Jingwei Yang,Yiqiang Su,Xiaoqing Wang,Yuming Deng

Large-scale Vehicle Routing Problems (VRPs) are widely used in logistics, transportation, supply chain, and robotic systems. Recently, data-driven VRP heuristics are proposed to generate real-time VRP solutions with up to 100 nodes. Despite this progress, current heuristics for large-scale VRPs still face three major challenges: 1) Difficulty in generalizing the heuristics learned on small-scale VRPs to large-scale VRPs without retraining; 2) Challenge in generating real-time solutions for large-scale VRPs; 3) Difficulty in embedding global constraints into learned heuristics. We contribute in the three directions: We propose a Two-stage Divide Method (TAM) to generate sub-route sequence rather than node sequence for generalizing the heuristics learned on small-scale VRPs to solve large-scale VRPs in real-time. A two-step reinforcement learning method with new reward and padding techniques is proposed to train our TAM. A global mask function is proposed to keep the global constraints satisfied when dividing a large-scale VRP into several small-scale Traveling Salesman Problems (TSPs). As result, we can solve the small-scale TSPs in parallel quickly. The experiments on synthetic and real-world large-scale VRPs show our method could generalize the learned heuristics trained on datasets of VRP 100 to solve VRPs with over 5000 nodes in real-time while keeping the solution quality better than data-driven heuristics and competitive with traditional heuristics.

RetinexUTV: ROBUST RETINEX MODEL WITH UNFOLDING TOTAL VARIATION

Guiyu Guo,Daming shi,Zunjin Zhao,Muhammad Tahir Rasheed

Digital images are underexposed due to poor scene lighting or hardware limitations, reducing visibility and level of detail in the image, which will affect subsequent high-level tasks and image aesthetics. Therefore, it is of great practical significance to enhance low-light images. Among existing low-light image enhancement techniques, retinex-based methods are the focus today. However, most retinex methods either ignore or poorly handle noise during enhancement, which can produce unpleasant visual effects in low-light image enhancement and affect high-level tasks. In this paper, we propose a robust low-light image enhancement method RetinexUTV, which aims to enhance low-light images well while suppressing noise. In RetinexUTV, we propose an adaptive illumination estimation unfolded total variational network, which approximates the noise level of the real low-light image by learning the balance parameter of the total variation regularization term of the model, obtains the noise level map and the smooth noise-free sub-map of the image. The initial illumination map is then estimated by obtaining the illumination information of the smooth sub-map. The initial reflection map is obtained through the initial illumination map and original image. Under the guidance of the noise level map, the noise of the reflection map is suppressed, and finally it is multiplied by the adjusted illumination map to obtain the final enhancement result. We test our method on real low-light datasets LOL, VELOL, and experiments demonstrate that our method outperforms state-of-the-art methods.

****

Towards the Generalization of Contrastive Self-Supervised Learning

Weiran Huang,Mingyang Yi,Xuyang Zhao,Zihao Jiang

Recently, self-supervised learning has attracted great attention, since it only requires unlabeled data for model training. Contrastive learning is one popular method for self-supervised learning and has achieved promising empirical perform ance. However, the theoretical understanding of its generalization ability is still limited. To this end, we define a kind of (σ,δ)-measure to mathematically quantify the data augmentation, and then provide an upper bound of the downstream classification error rate based on the measure. It reveals that the generalization ability of contrastive self-supervised learning is related to three key factors: alignment of positive samples, divergence of class centers, and concentration of augmented data. The first two factors are properties of learned representations, while the third one is determined by pre-defined data augmentation. We further investigate two canonical contrastive losses, InfoNCE and cross-correlation, to show how they provably achieve the first two factors. Moreover, we conduct experiments to study the third factor, and observe a strong correlation between downstream performance and the concentration of augmented data.

Towards Controllable Policy through Goal-Masked Transformers

Xinyao Niu,Tong Sang,Yuchen Sun,Xiangjun Wang

Offline goal-conditioned supervised learning (GCSL) can learn to achieve various goals from purely offline datasets without reward information, enhancing control over the policy. However, we argue that learning a composite policy switchable among different goals seamlessly should be an essential task for obtaining a controllable policy. This feature should be learnable if the dataset contains enough data about such switches. Unfortunately, most existing datasets either partially or entirely lack such switching demonstrations. Current GCSL approaches that use hindsight information concentrate primarily on reachability at the state or return level. They might not work as expected when the goal is changed within an episode. To this end, we present Goal-Masked Transformers (GMT), an efficient GCSL algorithm based on transformers with goal masking. GMT makes use of trajectory-level hindsight information, which is automatically gathered and can be adjusted for various statistics of interest. Due to the autoregressive nature of GMT, we can change the goal and control the policy at any time. We empirically evaluate GMT on MuJoCo continuous control benchmarks and Atari discrete control games with image states to compare GMT against baselines. We illustrate that GMT can infer the missing switching processes from the given dataset and thus switch smoothly among different goals. As a result, GMT demonstrates its ability to control policy and succeeds on all the tasks with low variance, while existing GCSL works can hardly succeed in goal-switching.

Comparative Analysis between Vision Transformers and CNNs from the view of Neuroscience

Xiuyuan Hu,Hao Zhang,Yang Zhao

Neuroscience has provide many inspirations for the development of artificial intelligence, especially for neural networks for computer vision tasks. Recent research on animals' visual systems builds the connection between neural sparsity and animals' levels of evolution, based on which comparisons between two most influential vision architecture, Transformer and CNN, are carried out. In particular, the sparsity of attentions in Transformers is comprehensively studied, and previous knowledge on sparsity of neurons in CNNs is reviewed. In addition, a novel metric for neural sparsity is defined and ablation experiments are launched on various types of Transformer and CNN models. Finally, we draw the conclusion that more layers in models will result in higher sparsity, however, too many heads in Transformers may cause reduction of sparsity, which attributes to the significant overlap among effects of attention units.

****

Uncertainty-Aware Meta-Learning for Multimodal Task Distributions

Cesar Almecija,Apoorva Sharma,Navid Azizan

Meta-learning or learning to learn is a popular approach for learning new tasks with limited data (i.e., few-shot learning) by leveraging the commonalities among different tasks. However, meta-learned models can perform poorly when context data is limited, or when data is drawn from an out-of-distribution (OoD) task. Especially in safety-critical settings, this necessitates an uncertainty-aware ap proach to meta-learning. In addition, the often multimodal nature of task distributions can pose unique challenges to meta-learning methods. In this work, we present UnLiMTD (Uncertainty-aware meta-Learning for Multimodal Task Distributions), a novel method for meta-learning that (1) makes probabilistic predictions on in-distribution tasks efficiently, (2) is capable of detecting OoD context data at test time, and (3) performs on heterogeneous, multimodal task distributions. To achieve this goal, we take a probabilistic perspective and train a parametric, tuneable distribution over tasks on the meta-dataset. We construct this distribution by performing Bayesian inference on a linearized neural network, leveraging Gaussian process theory. We demonstrate that UnLiMTD’s predictions compare to, and outperform in most cases, the standard baselines, especially in the low-data regime. Furthermore, we show that UnLiMTD is effective in detecting data from OoD tasks. Finally, we confirm that both of these findings continue to hold in the multimodal task-distribution setting.

Neural Operator Variational Inference based on Regularized Stein Discrepancy for Deep Gaussian Processes

JIAN XU,Shian Du,Junmei Yang,Qianli Ma,Delu Zeng

A Deep Gaussian Process (DGP) model is a hierarchical composition of GP models that provides a deep Bayesian nonparametric approach to infer the posterior. Exact Bayesian inference is usually intractable for DGPs, motivating the use of various approximations. We theoretically demonstrate that the traditional alternative of mean-field Gaussian assumptions across the hierarchy leads to lack of expressiveness and efficacy of DGP models, whilst stochastic approximation often incurs a significant computational cost. To address this issue, we propose Neural Operator Variational Inference (NOVI) for Deep Gaussian Processes, where a sampler is obtained from a neural generator through minimizing Regularized Stein Discrepancy in L2 space between the approximate distribution and true posterior. Wherein a minimax problem is obtained and solved by Monte Carlo estimation and subsampling stochastic optimization. We experimentally demonstrate the effectiveness and efficiency of the proposed model, by applying it to a more flexible and wider class of posterior approximations on data ranging in size from hundreds to tens of thousands. By comparison, NOVI is superior to previous methods in both classification and regression.

On the complexity of nonsmooth automatic differentiation

Jerome Bolte,Ryan Boustany,Edouard Pauwels,Béatrice Pesquet-Popescu

Using the notion of conservative gradient, we provide a simple model to estimate the computational costs of the backward and forward modes of algorithmic differentiation for a wide class of nonsmooth programs. The complexity overhead of the backward mode turns out to be independent of the dimension when using programs with locally Lipschitz semi-algebraic or definable elementary functions. This extends considerably the Baur-Strassen's smooth cheap gradient principle. We illustrate our results by establishing fast backpropagation results of conservative gradients through feedforward neural networks with standard activation and loss functions. Nonsmooth backpropagation's cheapness contrasts with concurrent forward approaches, which have, to this day, dimensional-dependent worst case overhead estimates. We provide further results suggesting the superiority of backward propagation of conservative gradients. Indeed, we relate the complexity of computing a large number of directional derivatives to that of matrix multiplication, and we show that finding two subgradients in the Clarke subdifferential of a function is a NP-hard problem.

CO3: Cooperative Unsupervised 3D Representation Learning for Autonomous Driving

Runjian Chen,Yao Mu,Runsen Xu,Wenqi Shao,Chenhan Jiang,Hang Xu,Yu Qiao,Zhenguo Li,Ping Luo

Unsupervised contrastive learning for indoor-scene point clouds has achieved great successes. However, unsupervised representation learning on outdoor-scene point clouds remains challenging because previous methods need to reconstruct the whole scene and capture partial views for the contrastive objective. This is infe asible in outdoor scenes with moving objects, obstacles, and sensors. In this paper, we propose CO3, namely {Co}operative {Co}ntrastive Learning and {Co}ntextual Shape Prediction, to learn 3D representation for outdoor-scene point clouds in an unsupervised manner. CO3 has several merits compared to existing methods. (1) It utilizes LiDAR point clouds from vehicle-side and infrastructure-side to build views that differ enough but meanwhile maintain common semantic information for contrastive learning, which are more appropriate than views built by previous methods. (2) Alongside the contrastive objective, we propose contextual shape prediction to bring more task-relevant information for unsupervised 3D point cloud representation learning and we also provide a theoretical analysis for this pre-training goal. (3) As compared to previous methods, representation learned by CO3 is able to be transferred to different outdoor scene dataset collected by different type of LiDAR sensors. (4) CO3 improves current state-of-the-art methods on Once, KITTI and NuScenes datasets by up to 2.58 mAP in 3D object detection task and 3.54 mIoU in LiDAR semantic segmentation task. Codes and models will be released.

Bag of Tricks for Unsupervised Text-to-Speech

Yi Ren,Chen Zhang,Shuicheng YAN

Unsupervised text-to-speech (TTS) aims to train TTS models for a specific language without any paired speech-text training data in that language. Existing methods either use speech and corresponding pseudo text generated by an unsupervised automatic speech recognition (ASR) model as training data, or employ the back-translation technique. Though effective, they suffer from low robustness to low-quality data and heavy dependence on the lexicon of a language that is sometimes unavailable, leading to difficulty in convergence, especially in low-resource language scenarios. In this work, we introduce a bag of tricks to enable effective unsupervised TTS. Specifically, 1) we carefully design a voice conversion model to normalize the variable and noisy information in the low-quality speech data while preserving the pronunciation information; 2) we employ the non-autoregressive TTS model to overcome the robustness issue; and 3) we explore several tricks applied in back-translation, including curriculum learning, length augmentation and auxiliary supervised loss to stabilize the back-translation and improve its effectiveness. Through experiments, it has been demonstrated that our method achieves better intelligibility and audio quality than all previous methods, and that these tricks are very essential to the performance gain.

FedSpeed: Larger Local Interval, Less Communication Round, and Higher Generalization Accuracy

Yan Sun,Li Shen,Tiansheng Huang,Liang Ding,Dacheng Tao

Federated learning (FL) is an emerging distributed machine learning framework which jointly trains a global model via a large number of local devices with data privacy protections. Its performance suffers from the non-vanishing biases introduced by the local inconsistent optimal and the rugged client-drifts by the local over-fitting. In this paper, we propose a novel and practical method, FedSpeed, to alleviate the negative impacts posed by these problems. Concretely, FedSpeed applies the prox-correction term on the current local updates to efficiently reduce the biases introduced by the prox-term, a necessary regularizer to maintain the strong local consistency. Furthermore, FedSpeed merges the vanilla stochastic gradient with a perturbation computed from an extra gradient ascent step in the neighborhood, thereby alleviating the issue of local over-fitting. Our theoretical analysis indicates that the convergence rate is related to both the communication rounds T and local intervals K with a tighter upper bound $\mathcal{O}(\frac{1}{T})$ if $K=\mathcal{O}(T)$. Moreover, we conduct extensive experiments on the real-world dataset to demonstrate the efficiency of our proposed FedSpeed, which converges significantly faster and achieves the state-of-the-art (SOTA) performance on the general FL experimental settings than several baselines including FedAvg, FedProx, FedCM, FedAdam, SCAFFOLD, FedDyn, FedADMM, etc.

Holistically Explainable Vision Transformers

Moritz Böhle,Mario Fritz,Bernt Schiele

Transformers increasingly dominate the machine learning landscape across many tasks and domains, which increases the importance for understanding their outputs. While their attention modules provide partial insight into their inner workings, the attention scores have been shown to be insufficient for explaining the models as a whole. To address this, we propose B-cos transformers, which inherently provide holistic explanations for their decisions. Specifically, we formulate each model component—such as the multi-layer perceptrons, attention layers, and the tokenisation module—to be dynamic linear, which allows us to faithfully summarise the entire transformer via a single linear transform. We apply our proposed design to Vision Transformers (ViTs) and show that the resulting models, dubbed Bcos-ViTs, are highly interpretable and perform competitively to baseline ViTs on ImageNet. Code will be available at: github.com/anonymous/authors.

Neural Volumetric Mesh Generator

Yan Zheng,Lemeng Wu,Xingchao Liu,Zhen Chen,qiang liu,Qixing Huang

Deep generative models have shown success in generating 3D shapes with different representations. In this work, we propose Neural Volumetric Mesh Generator (NVMG), which can generate novel and high-quality volumetric meshes. Unlike the previous 3D generative model for point cloud, voxel, and implicit surface, the volumetric mesh representation is a ready-to-use representation in industry with details on both the surface and interior. Generating this such highly-structured data thus brings a significant challenge. We first propose a diffusion-based generative model to tackle this problem by generating voxelized shapes with close-to-reality outlines and structures. We can simply obtain a tetrahedral mesh as a template with the voxelized shape. Further, we use a voxel-conditional neural network to predict the smooth implicit surface conditioned on the voxels, and progressively project the tetrahedral mesh to the predicted surface under regularization. The regularization terms are carefully designed so that they can (1) get rid of the defects like flipping and high distortion; (2) force the regularity of the interior and surface structure during the deformation procedure for a high-quality final mesh. As shown in the experiments, our pipeline can generate high-quality artifact-free volumetric and surface meshes from random noise or a reference image without any post-processing. Compared with the state-of-the-art voxel-to-mesh deformation method, we show more robustness and better performance when taking generated voxels as input.

****

PathFusion: Path-consistent Lidar-Camera Deep Feature Fusion

Lemeng Wu,Dilin Wang,Meng Li,Yunyang Xiong,Raghuraman Krishnamoorthi,qiang liu,Vikas Chandra

Fusing camera with LiDAR is a promising technique to improve the accuracy of 3D detection due to its complementary physical properties.

While most existing methods focus on fusing camera features directly with raw LiDAR point clouds or shallow 3D features, it is observed that direct deep 3D feature fusion achieves inferior accuracy due to feature mis-alignment. The mis-alignment that originates from the feature aggregation across large receptive fields becomes increasingly severe for deep network stages. In this paper, we propose PathFusion to enable path-consistent LiDAR-camera deep feature fusion. PathFusion introduces a path consistency loss between shallow and deep features, which encourages the 2D backbone and its fusion path to transform 2D features in a way that is semantically aligned with the transform of the 3D backbone. We apply PathFusion to the prior-art fusion baseline, Focals Conv, and observe more than 1.2% mAP improvements on the nuScenes test split consistently with and without testing-time augmentations. Moreover, PathFusion also improves KITTI AP 3D (R11) by more than 0.6% on moderate level.

****

DADAO: Decoupled Accelerated Decentralized Asynchronous Optimization

Adel Nabli,Edouard Oyallon

DADAO is a novel decentralized asynchronous stochastic first order algorithm to minimize a sum of L-smooth and μ-strongly convex functions distributed ove r a time-varying connectivity network of size n. We model the local gradient updates and gossip communication procedures with separate independent Poisson Point Processes, decoupling the computation and communication steps in addition to making the whole approach completely asynchronous. Our method employs primal gradients and does not use a multi-consensus inner loop nor other ad-hoc mechanisms such as Error Feedback, Gradient Tracking, or a Proximal operator. By relating the inverse of the smallest positive eigenvalue χ^*_1 and the effective resistance χ_2^* of our graph to a necessary minimal communication rate between nodes of the network, we show that our algorithm requires $\mathcal{O}(n\sqrt{\frac{L}{\mu}}\log \epsilon)$ local gradients and only $\mathcal{O}(n\sqrt{\chi_1^*\chi_2^*}\sqrt{\frac{L}{\mu}}\log \epsilon)$ communications to reach a precision ϵ. If SGD with uniform noise σ^2 is used, we reach a precision ϵ with same speed, up to a bias term in $\mathcal{O}(\frac{\sigma^2}{\sqrt{\mu L}})$. This improves upon the bounds obtained with current state-of-the-art approaches, our simulations validating the strength of our relatively unconstrained method.

Advancing Radiograph Representation Learning with Masked Record Modeling

Hong-Yu Zhou,Chenyu Lian,Liansheng Wang,Yizhou Yu

Modern studies in radiograph representation learning (R^{2}L) rely on either self-supervision to encode invariant semantics or associated radiology reports to incorporate medical expertise, while the complementarity between them is barely noticed. To explore this, we formulate the self- and report-completion as two complementary objectives and present a unified framework based on masked record modeling (MRM). In practice, MRM reconstructs masked image patches and masked report tokens following a multi-task scheme to learn knowledge-enhanced semantic representations. With MRM pre-training, we obtain pre-trained models that can be well transferred to various radiography tasks. Specifically, we find that MRM offers superior performance in label-efficient fine-tuning. For instance, MRM achieves 88.5% mean AUC on CheXpert using 1% labeled data, outperforming previous R^{2}L methods with 100% labels. On NIH ChestX-ray, MRM outperforms the best performing counterpart by about 3% under small labeling ratios. Besides, MRM surpasses self- and report-supervised pre-training in identifying the pneumonia type and the pneumothorax area, sometimes by large margins.

Instance-wise Batch Label Restoration via Gradients in Federated Learning

Kailang Ma,Yu Sun,Jian Cui,Dawei Li,Zhenyu Guan,Jianwei Liu

Gradient inversion attacks have posed a serious threat to the privacy of federated learning. The attacks search for the optimal pair of input and label best matching the shared gradients and the search space of the attacks can be reduced by pre-restoring labels. Recently, label restoration technique allows for the extraction of labels from gradients analytically, but even the state-of-the-art remains limited to identify the presence of categories (i.e., the class-wise label restoration). This work considers the more real-world settings, where there are multiple instances of each class in a training batch. An analytic method is proposed to perform instance-wise batch label restoration from only the gradient of the final layer. On the basis of the approximate recovered class-wise embeddings and post-softmax probabilities, we establish linear equations of the gradients, probabilities and labels to derive the Number of Instances (NoI) per class by the Moore-Penrose pseudoinverse algorithm. Our experimental evaluations reach over 99% Label existence Accuracy (LeAcc) and exceed 96% Label number Accuracy (LnAcc) in most cases on three image datasets and four classification models. The two metrics are used to evaluate class-wise and instance-wise label restoration accuracy, respectively. And the recovery is made feasible even with a batch size of 4096 and partially negative activations (e.g., Leaky ReLU and Swish). Furthermore, we demonstrate that our method facilitates the existing gradient inversion attacks by exploiting the recovered labels, with an increase of 6-7 in PSNR on both MNIST and CIFAR100. Our code is
available at https://github.com/BUAA-CST/iLRG.

Re-parameterizing Your Optimizers rather than Architectures

Xiaohan Ding,Honghao Chen,Xiangyu Zhang,Kaiqi Huang,Jungong Han,Guiguang Ding

The well-designed structures in neural networks reflect the prior knowledge incorporated into the models. However, though different models have various priors, we are used to training them with model-agnostic optimizers such as SGD. In this paper, we propose to incorporate model-specific prior knowledge into optimizers by modifying the gradients according to a set of model-specific hyper-parameters. Such a methodology is referred to as Gradient Re-parameterization, and the optimizers are named RepOptimizers. For the extreme simplicity of model structure, we focus on a VGG-style plain model and showcase that such a simple model trained with a RepOptimizer, which is referred to as RepOpt-VGG, performs on par with or better than the recent well-designed models. From a practical perspective, RepOpt-VGG is a favorable base model because of its simple structure, high inference speed and training efficiency. Compared to Structural Re-parameterization, which adds priors into models via constructing extra training-time structures, RepOptimizers require no extra forward/backward computations and solve the problem of quantization. We hope to spark further research beyond the realms of model structure design. Code and models https://github.com/DingXiaoH/RepOptimizers.

Protein Representation Learning via Knowledge Enhanced Primary Structure Reasoning

Hong-Yu Zhou,Yunxiang Fu,Zhicheng Zhang,Bian Cheng,Yizhou Yu

Protein representation learning has primarily benefited from the remarkable development of language models (LMs). Accordingly, pre-trained protein models also suffer from a problem in LMs: a lack of factual knowledge. The recent solution models the relationships between protein and associated knowledge terms as the knowledge encoding objective. However, it fails to explore the relationships at a more granular level, i.e., the token level. To mitigate this, we propose Knowledge-exploited Auto-encoder for Protein (KeAP), which performs token-level knowledge graph exploration for protein representation learning. In practice, non-masked amino acids iteratively query the associated knowledge tokens to extract and integrate helpful information for restoring masked amino acids via attention. We show that KeAP can consistently outperform the previous counterpart on 9 representative downstream applications, sometimes surpassing it by large margins. These results suggest that KeAP provides an alternative yet effective way to perform knowledge enhanced protein representation learning.

The Provable Benefit of Unsupervised Data Sharing for Offline Reinforcement Learning

Hao Hu,Yiqin Yang,Qianchuan Zhao,Chongjie Zhang

Self-supervised methods have become crucial for advancing deep learning by leveraging data itself to reduce the need for expensive annotations. However, the question of how to conduct self-supervised offline reinforcement learning (RL) in a principled way remains unclear.

In this paper, we address this issue by investigating the theoretical benefits of utilizing reward-free data in linear Markov Decision Processes (MDPs) within a semi-supervised setting. Further, we propose a novel, Provable Data Sharing algorithm (PDS) to utilize such reward-free data for offline RL. PDS uses additional penalties on the reward function learned from labeled data to prevent overestimation, ensuring a conservative algorithm. Our results on various offline RL tasks demonstrate that PDS significantly improves the performance of offline RL algorithms with reward-free data. Overall, our work provides a promising approach to leveraging the benefits of unlabeled data in offline RL while maintaining theoretical guarantees. We believe our findings will contribute to developing more robust self-supervised RL methods.

Federated Learning for Inference at Anytime and Anywhere

Zicheng Liu,Da Li,Javier Fernandez-Marques,Stefanos Laskaridis,Yan Gao,■ukasz Dudziak,Stan Z. Li,Shell Xu Hu,Timothy Hospedales

Federated learning has been predominantly concerned with collaborative training of deep networks from scratch, and especially the many challenges that arise, such as communication cost, robustness to heterogeneous data, and support for diverse device capabilities. However, there is no unified framework that addresses all these problems together. This paper studies the challenges and opportunities of exploiting pre-trained Transformer models in FL. In particular, we propose to efficiently adapt such pre-trained models by injecting a novel attention-based adapter module at each transformer block that both modulates the forward pass and makes an early prediction. Training only the lightweight adapter by FL leads to fast and communication-efficient learning even in the presence of heterogeneous data and devices. Extensive experiments on standard FL benchmarks, including CIFAR- 100, FEMNIST and SpeechCommandsv2 demonstrate that this simple framework provides fast and accurate FL while supporting heterogenous device capabilities, efficient personalization, and scalable-cost anytime inference.

Modeling Sequential Sentence Relation to Improve Cross-lingual Dense Retrieval
Shunyu Zhang,Yaobo Liang,MING GONG,Daxin Jiang,Nan Duan
Recently multi-lingual pre-trained language models (PLM) such as mBERT and XLM-R have achieved impressive strides in cross-lingual dense retrieval. Despite its successes, they are general-purpose PLM while the multilingual PLM tailored for cross-lingual retrieval is still unexplored. Motivated by an observation that the sentences in parallel documents are approximately in the same order, which is universal across languages, we propose to model this sequential sentence relation to facilitate cross-lingual representation learning. Specifically, we propose a multilingual PLM called masked sentence model (MSM), which consists of a sentence encoder to generate the sentence representations, and a document encoder applied to a sequence of sentence vectors from a document. The document encoder is shared for all languages to model the universal sequential sentence relation across languages. To train the model, we propose a masked sentence prediction task, which masks and predicts the sentence vector via a hierarchical contrastive loss with sampled negatives. Comprehensive experiments on four cross-lingual retrieval tasks show MSM significantly outperforms existing advanced pre-training models, demonstrating the effectiveness and stronger cross-lingual retrieval capabilities of our approach.

A Robustly and Effectively Optimized Pretraining Approach for Masked Autoencoder
Ruijia Xu,Yixiao Ge,Kun Yi,XUYUAN XU,Yexin Wang,Ying-Cong Chen,Hao Chen,Ying Shan
Recently, Masked Image Modeling (MIM) has increasingly reshaped the status quo of self-supervised visual pre-training. This paper does not describe a novel MIM method, but to unravel several fundamental ingredients to robustly and effectively pre-train a Masked AutoEncoder (MAE) with improved downstream performance as a byproduct. We highlight the great significance for the whole autoencoder to encourage high-variance interactions across different tokens, while simultaneously for the reconstructed target to smooth the inter-patch variances. First, at the decoding phase, we apply the standard dropout upon the attention probabilities as noise to randomly mask out the edge connection across different tokens. Otherwise, their shortcut interactions might hinder the emergence of meaningful contextual representation. Second, we point out that the per-patch normalization will fail unless the patch pixels rely on some population statistics to reduce inter-patch variance and then smooth the reconstruction. Third, we show that autoencoders with different capacities encounter the issue to varying degrees and the learnable masked tokens can be employed to manipulate the variance dependent on its inserted position and ratio in the model. The proposed techniques here are simple and effective to benefit the pre-training of a masked autoencoder stably and obtain superior performance across different downstream tasks.

Diffusion Posterior Sampling for General Noisy Inverse Problems
Hyungjin Chung,Jeongsol Kim,Michael Thompson Mccann,Marc Louis Klasky,Jong Chul Ye

Diffusion models have been recently studied as powerful generative inverse problem solvers, owing to their high quality reconstructions and the ease of combining existing iterative solvers. However, most works focus on solving simple linear inverse problems in noiseless settings, which significantly under-represents the complexity of real-world problems. In this work, we extend diffusion solvers to efficiently handle general noisy (non)linear inverse problems via the Laplace approximation of the posterior sampling. Interestingly, the resulting posterior sampling scheme is a blended version of diffusion sampling with the manifold constrained gradient without a strict measurement consistency projection step, yielding a more desirable generative path in noisy settings compared to the previous studies. Our method demonstrates that diffusion models can incorporate various measurement noise statistics such as Gaussian and Poisson, and also efficiently handle noisy nonlinear inverse problems such as Fourier phase retrieval and non-uniform deblurring.

Low-Rank Graph Neural Networks Inspired by the Weak-balance Theory in Social Networks

Langzhang Liang,Xiangjing Hu,Zenglin Xu,Zixing Song,Irwin King

Graph Neural Networks (GNNs) have achieved state-of-the-art performance on node classification tasks by exploiting both the graph structures and node features. Generally, most existing GNNs depend on the implicit homophily assumption that nodes belonging to the same class are more likely to be connected. However, GNNs may fail to model heterophilious graphs where nodes with different labels tend to be linked, as shown in recent studies. To address this issue, we propose a generic GNN applicable to both homophilious and heterophilious graphs, namely Low-Rank Graph Neural Network (LRGNN). In detail, we aim at computing a coefficient matrix such that the sign of each coefficient reveals whether the corresponding two nodes belong to the same class, which is similar to the sign inference problem. In Signed Social Networks (SSNs), the sign inference problem can be modeled as a low-rank matrix factorization (LRMF) problem due to the global low-rank structure described by the weak balance theory. In this paper, we show that signed graphs are naturally generalized weakly-balanced when considering node classification tasks. Motivated by this observation, we propose to leverage LRMF to recover a coefficient matrix from a partially observed signed adjacency matrix. To effectively capture the node similarity, we further incorporate the low-rank representation (LRR) method. Our theoretical result shows that under our update rule of node representations, LRR obtained by solving a subspace clustering problem can recover the subspace structure of node representations. To solve the corresponding optimization problem, we utilize an iterative optimization algorithm with a convergence guarantee and develop a neural-style initialization manner that enables fast convergence. Finally, extensive experimental evaluation on both real-world and synthetic graphs has validated the superior performance of LRGNN over various state-of-the-art GNNs. In particular, LRGNN can offer clear performance gains in a scenario when the node features are not informative enough.

Do We Need Neural Collapse? Learning Diverse Features for Fine-grained and Long-tail Classification

Jiawei Ma,Chong You,Sashank J. Reddi,Sadeep Jayasumana,Himanshu Jain,Felix Yu,Shih-Fu Chang,Sanjiv Kumar

Feature extractors learned from supervised training of deep neural networks have demonstrated superior performance over handcrafted ones. Recently, it is shown that such learned features have a neural collapse property, where within-class features collapse to the class mean and different class means are maximally separated. This paper examines the neural collapse property in the context of fine-grained classification tasks, where a feature extractor pretrained from a classification task with coarse labels is used for generating features for a downstream classification task with fine-grained labels. We argue that the within-class feature collapse is an undesirable property for fine-grained classification. Hence, we introduce a geometric arrangement of features called the maximal-separating-cone, where within-class features lie in a cone of nontrivial radius instead of collapsing to the class mean, and cones of different classes are maximally separated. We present a technique based on classifier weight and training loss design to produce such an arrangement. Experimentally we demonstrate an improved fine-grained classification performance with a feature extractor pretrained by our method. Moreover, our technique also provides benefits for the classification on data with long-tail distribution over classes. Our work may motivate future efforts on the design of better geometric arrangements of deep features.

HRBP: Hardware-friendly Regrouping towards Block-wise Pruning for Sparse Training

Haoyu Ma,Chengming Zhang,lizhi xiang,Xiaolong Ma,Geng Yuan,Wenkai Zhang,Shiwei Liu,Tianlong Chen,Dingwen Tao,Yanzhi Wang,Zhangyang Wang,Xiaohui Xie

Recently, pruning at initialization and training a sparse network from scratch (sparse training) become increasingly popular. However, most sparse training literature addresses only the unstructured sparsity, which in practice brings little benefit to the training acceleration on GPU due to the irregularity of non-zero weights. In this paper, we work on sparse training with fine-grained structured sparsity, by extracting a few dense blocks from unstructured sparse weights. For Convolutional Neural networks (CNN), however, the extracted dense blocks will be broken in backpropagation due to the shape transformation of convolution filters implemented by GEMM. Thus, previous block-wise pruning methods can only be used to accelerate the forward pass of sparse CNN training. To this end, we propose the Hardware-friendly Regrouping towards Block-based Pruning (HRBP), where the grouping is conducted on the kernel-wise mask. With HRBP, extracted dense blocks are preserved in backpropagation. We further propose HRBP++ to reduce zero kernels by extracting common sparse kernel patterns on all kernels within one block. Extensive experiments on CIFAR-10, CIFAR-100, and ImageNet demonstrate that HRBP (HRBP++) can almost match the accuracy of unstructured sparse training methods while achieving a huge acceleration on hardware.

DepthFL : Depthwise Federated Learning for Heterogeneous Clients

Minjae Kim,Sangyoon Yu,Suhyun Kim,Soo-Mook Moon

Federated learning is for training a global model without collecting private local data from clients. As they repeatedly need to upload locally-updated weights or gradients instead, clients require both computation and communication resources enough to participate in learning, but in reality their resources are heterogeneous. To enable resource-constrained clients to train smaller local models, width scaling techniques have been used, which reduces the channels of a global model. Unfortunately, width scaling suffers from heterogeneity of local models when averaging them, leading to a lower accuracy than when simply excluding resource-constrained clients from training. This paper proposes a new approach based on depth scaling called DepthFL. DepthFL defines local models of different depths by pruning the deepest layers off the global model, and allocates them to clients depending on their available resources. Since many clients do not have enough resources to train deep local models, this would make deep layers partially-trained with insufficient data, unlike shallow layers that are fully trained. DepthFL alleviates this problem by mutual self-distillation of knowledge among the classifiers of various depths within a local model. Our experiments show that depth-scaled local models build a global model better than width-scaled ones, and that self-distillation is highly effective in training data-insufficient deep layers.

Masked Image Modeling with Denoising Contrast

Kun Yi,Yixiao Ge,Xiaotong Li,Shusheng Yang,Dian Li,Jianping Wu,Ying Shan,Xiaohu Qie

Since the development of self-supervised visual representation learning from contrastive learning to masked image modeling (MIM), there is no significant difference in essence, that is, how to design proper pretext tasks for vision dictionary look-up. MIM recently dominates this line of research with state-of-the-art performance on vision Transformers (ViTs), where the core is to enhance the patch

-level visual context capturing of the network via denoising auto-encoding mechanism. Rather than tailoring image tokenizers with extra training stages as in previous works, we unleash the great potential of contrastive learning on de- noising auto-encoding and introduce a pure MIM method, ConMIM, to produce simple intra-image inter-patch contrastive constraints as the sole learning objectives for masked patch prediction. We further strengthen the denoising mechanism with asymmetric designs, including image perturbations and model progress rates, to improve the network pre-training. ConMIM-pretrained models with various scales achieve competitive results on downstream image classification, semantic segmentation, object detection, and instance segmentation tasks, e.g., on ImageNet-1K classification, we achieve 83.9% top-1 accuracy with ViT-Small and 85.3% with ViT-Base without extra data for pre-training. Code will be available at https://github.com/TencentARC/ConMIM.

Monkeypox with Cross Infection Hypothesis via Epidemiological Mode
Tahir Khan,zhiqiang xu
A new re-emerging infectious disease of monkeypox 2022 is structurally related to smallpox that is induced by the monkeypox viruses and has caused 59,606 active cases with 18 deaths up to September 15, 2022. To end this ongoing epidemic, there is a need for population-wide control policies like reducing social interaction by keeping social distance, treatment of infected individuals, and restriction on animals, etc. We forecast the progression of the epidemic and come up with an efficient control mechanism by formulating a mathematical model. The biological feasibility and dynamical behavior of the proposed model are then investigated together with sensitivity analysis to obtain the effect of various epidemic parameters mitigating the spread of the disease. Subsequently, by taking non-pharmaceutical and pharmaceutical intervention strategies as control measures, an optimal control theory is applied to mitigate the fatality of the disease to minimize the infectious population and reduce the cost of controls, we construct an objective functional and solve it by using Pontryagin’s maximum principle. Finally, extensive numerical simulations are performed to show the impact of the application of intervention mechanisms in controlling the transmission of the monkeypox epidemic.

LPMARL: Linear Programming based Implicit Task Assignment for Hierarchical Multi-agent Reinforcement Learning
Kyuree Ahn,Jinkyoo Park
Training a multi-agent reinforcement learning (MARL) model with sparse reward is notoriously difficult because the terminal reward is induced by numerous interactions among agents. In this study, we propose linear programming-based hierarchical MARL (LPMARL) to learn effective coperative strategy among agents. LPMARL is composed of two hierarchical decision-making schemes: (1) solving an agent-task assignment problem and (2) solving a local cooperative game among agents that are assigned to the same task. For the first step, LPMARL formulates the agent-task assignment problem as linear programming (LP) using the state-dependent cost parameters generated by a graph neural network (GNN). Solving the LP can be considered as assigning tasks to agents, which decomposes the original problem into a set of task-dependent sub-problems. After solving the formulated LP, LPMARL employs a general MARL strategy to derive a lower-level policy to solve each sub-task in a cooperative manner. We train the LP-parameter generating GNN layer and the low-level MARL policy network, which are the essential components for making hierarchical decisions, in an end-to-end manner using the implicit function theorem. We empirically demonstrate that LPMARL learns an optimal agent-task allocation and the subsequent local cooperative control policy among agents in sub-groups for solving various mixed cooperative-competitive environments.

Transmission Dynamics of Hepatitis B: Analysis and Control
Tahir Khan,zhiqiang xu,Xin Cao
The infection of hepatitis B attacks the liver and can produce acute and chronic

diseases, while it is a major health problem and life-threatening around the globe. The control of this infection is a difficult task due to several reasons such as variation of human behavior, proper medication, vaccination, and existence of a large number of carries, etc., but understanding the dynamics of the infection helps to design appropriate control strategies. Thus, a proper complex dynamical system is needed to find the stability conditions and propose intervention strategies for forecasting the control of hepatitis B virus transmission. We formulate a model that will be helpful to investigate the temporal dynamics and suggest control strategies for hepatitis B infection. The well-posedness of the proposed model will be shown, and used to find the threshold parameter to analyze the model equilibria and its stability. We also perform the sensitive analysis of the threshold quantity to quantify the most sensitive epidemic parameters. Based on the temporal dynamics and sensitivity, we investigate effective methods to minimize the infection of hepatitis B, and develop the algorithms to support the theoretical results with the help of numerical simulations.

Mass-Editing Memory in a Transformer

Kevin Meng,Arnab Sen Sharma,Alex J Andonian,Yonatan Belinkov,David Bau

Recent work has shown exciting promise in updating large language models with new memories, so as to replace obsolete information or add specialized knowledge. However, this line of work is predominantly limited to updating single associations. We develop MEMIT, a method for directly updating a language model with many memories, demonstrating experimentally that it can scale up to thousands of associations for GPT-J (6B) and GPT-NeoX (20B), exceeding prior work by an order of magnitude. Our code and data will be open-sourced upon publication.

Enhancement and Numerical Assessment of Novel SARS-CoV-2 Virus Transmission Model

Tahir Khan,zhiqiang xu

Recent pandemic of the coronavirus started in December 2019, which has affected almost all groups of humankind. In this regard, accurate epidemic models are not only crucial for demonstrating the mitigation of the current pandemic but also helpful for forecasting their future dynamics. In this work, we propose a model for SARS-CoV-2 virus transmission to forecast the temporal dynamics of the novel coronavirus disease by considering the characteristics of the disease and the recent literature. Due to the nondeterministic and stochastic nature of the novel-coronavirus disease, we present the model with the aid of stochastic differential equations by considering two infectious phases: pre-symptomatic and symptomatic, because both are significant in the spread of SARS-CoV-2 virus transmission. We ensure that the model is well-posed and identify the necessary conditions for disease eradication by proving the existence, uniqueness, and extinction analysis. The efficacy of the model and the importance of the current study are demonstrated using the actual data. Finally, the model will be simulated using Euler-Maruyama and Milstein’s numerical schemes to support the theoretical findings and show the significance of the results obtained.

GoBigger: A Scalable Platform for Cooperative-Competitive Multi-Agent Interactive Simulation

Ming Zhang,Shenghan Zhang,Zhenjie Yang,Lekai Chen,Jinliang Zheng,Chao Yang,Chuming Li,Hang Zhou,Yazhe Niu,Yu Liu

The emergence of various multi-agent environments has motivated powerful algorithms to explore agents' cooperation or competition. Even though this has greatly promoted the development of multi-agent reinforcement learning (MARL), it is still not enough to support further exploration on the behavior of swarm intelligence between multiple teams, and cooperation between multiple agents due to their limited scalability. To alleviate this, we introduce GoBigger, a scalable platform for cooperative-competition multi-agent interactive simulation. GoBigger is an enhanced environment for the Agar-like game, enabling the simulation of multiple scales of agent intra-team cooperation and inter-team competition. Compared with existing multi-agent simulation environments, our platform supports multi-t eam games with more than two teams simultaneously, which dramatically expands the diversity of agent cooperation and competition, and can more effectively simulate the swarm intelligent agent behavior. Besides, in GoBigger, the cooperation between the agents in a team can lead to much higher performance. We offer a diverse set of challenging scenarios, built-in bots, and visualization tools for best practices in benchmarking. We evaluate several state-of-the-art algorithms on GoBigger and demonstrate the potential of the environment. We believe this platform can inspire various emerging research directions in MARL, swarm intelligence, and large-scale agent interactive learning. Both GoBigger and its related benchmark are open-sourced. More information could be found at https://github.com/opendilab/GoBigger.

Masked Unsupervised Self-training for Label-free Image Classification

Junnan Li,Silvio Savarese,Steven Hoi

State-of-the-art computer vision models are mostly trained with supervised learning using human-labeled images, which limits their scalability due to the expensive annotation cost. While self-supervised representation learning has achieved impressive progress, it still requires a second stage of finetuning on labeled data. On the other hand, models pre-trained with large-scale text supervision (e.g., CLIP) have enabled zero-shot transfer to downstream image classification tasks. However, the zero-shot performance of CLIP-like models are often insufficient for real-world adoption. In this paper, we aim to leverage the abundant unlabeled data from a target domain to improve the performance of a pre-trained zero-shot classifier, by unsupervised finetuning of the pre-trained model. We propose Masked Unsupervised Self-Training (MUST), a new approach which leverages two different and complimentary sources of training signals: pseudo-labels and raw images. MUST jointly optimizes three objectives to learn both class-level global feature and pixel-level local feature and enforces a regularization between the two. We demonstrate the efficacy of MUST on 8 downstream tasks across a variety of domains, where it improves upon CLIP by a large margin. MUST also outperforms supervised few-shot adaptation methods. It achieves a top-1 accuracy of 77.7% on ImageNet using ViT-B, +9.4% higher than CLIP, and +6.2% higher than 16-shot CLIP adaptation. Our code is available at https://github.com/salesforce/MUST.

Recursion of Thought: Divide and Conquer Reasoning with Language Models

Soochan Lee,Gunhee Kim

With the recent advances in language models, attempts are being made to apply them to solving multi-step reasoning problems. A major breakthrough in this line of research is to let language models generate intermediate steps, often called Chain of Thought (CoT), before producing a final answer. However, language models have an upper bound on the context size, i.e., the number of input tokens, such as 2048 for the recent GPT-3 and PaLM. Although several thousand tokens are enough to handle various tasks, solving more complex reasoning tasks can require orders of magnitude more tokens. Therefore, the context limit imposes a fundamental limit on the model's reasoning capability. Inspired by human's incredible reasoning ability based on abstraction and recursion, we propose Recursion of Thought (RoT) as a model-agnostic framework with the novel paradigm of teaching a language model to divide and conquer complex problems by recursively creating multiple contexts. Since RoT casts the context-related operations as tokens, a language model can trigger the recursion operations by simply producing the corresponding tokens. On multiple arithmetic and algorithmic reasoning tasks, we demonstrate that RoT dramatically improves the recent large-scale language model GPT-3 to solve extremely complex problems. Moreover, RoT can make tiny, randomly initialized Transformers or LSTMs to solve problems that even humans find daunting.

GeneFace: Generalized and High-Fidelity Audio-Driven 3D Talking Face Synthesis

Zhenhui Ye,Ziyue Jiang,Yi Ren,Jinglin Liu,Jinzheng He,Zhou Zhao

Generating photo-realistic video portraits with arbitrary speech audio is a crucial problem in film-making and virtual reality. Recently, several works explore the usage of neural radiance field (NeRF) in this task to improve 3D realness an d image fidelity. However, the generalizability of previous NeRF-based methods is limited by the small scale of training data. In this work, we propose GeneFace, a generalized and high-fidelity NeRF-based talking face generation method, which can generate natural results corresponding to various out-of-domain audio. Specifically, we learn a variational motion generator on a large lip-reading corpus, and introduce a domain adaptative post-net to calibrate the result. Moreover, we learn a NeRF-based renderer conditioned on the predicted motion. A head-aware torso-NeRF is proposed to eliminate the head-torso separation problem. Extensive experiments show that our method achieves more generalized and high-fidelity talking face generation compared to previous methods. Video samples and source code are available at https://geneface.github.io .

Learning the Positions in CountSketch

Yi Li,Honghao Lin,Simin Liu,Ali Vakilian,David Woodruff

We consider sketching algorithms which first compress data by multiplication with a random sketch matrix, and then apply the sketch to quickly solve an optimization problem, e.g., low-rank approximation and regression. In the learning-based sketching paradigm proposed by Indyk et al., the sketch matrix is found by choosing a random sparse matrix, e.g., CountSketch, and then the values of its non-zero entries are updated by running gradient descent on a training data set. Despite the growing body of work on this paradigm, a noticeable omission is that the locations of the non-zero entries of previous algorithms were fixed, and only their values were learned.

In this work, we propose the first learning-based algorithms that also optimize the locations of the non-zero entries. Our first proposed algorithm is based on a greedy algorithm. However, one drawback of the greedy algorithm is its slower training time. We fix this issue and propose approaches for learning a sketching matrix for both low-rank approximation and Hessian approximation for second-order optimization. The latter is helpful for a range of constrained optimization problems, such as LASSO and matrix estimation with a nuclear norm constraint. Both approaches achieve good accuracy with a fast running time. Moreover, our experiments suggest that our algorithm can still reduce the error significantly even if we only have a very limited number of training matrices.

****

Towards the gradient adjustment by loss status for Neural Network Optimization

Jiexin Wang,Wenwen Qiang,Bing Su

Gradient descent-based algorithms are crucial in neural network optimization, and most of them only depend on local properties such as the first and second-order momentum of gradients to determine the local optimization directions. As a result, such algorithms often converge slowly in the case of a small gradient and easily fall into the local optimum. Since the goal of optimization is to minimize the loss function, the status of the loss indicates the overall progress of the optimization but has not been fully explored. In this paper, we propose a loss-aware gradient adjusting strategy (LGA) based on the loss status. LGA automatically adjusts the update magnitude of parameters to accelerate convergence and escape local optimums by introducing a loss-incentive correction term monitoring the loss and adapting gradient experience. The proposed strategy can be applied to various gradient descent-based optimization algorithms. We provide theoretical analysis on the convergence rate and empirical evaluations on different datasets to demonstrate the effectiveness of our method.

On the Necessity of Disentangled Representations for Downstream Tasks

Ruiqian Nai,Zixin Wen,Ji Li,Yuanzhi Li,Yang Gao

A disentangled representation encodes generative factors of data in a separable and compact pattern. Thus it is widely believed that such a representation format benefits downstream tasks. In this paper, we challenge the necessity of disentangled representation in downstream applications. Specifically, we show that dimension-wise disentangled representations are not necessary for downstream tasks using neural networks that take learned representations as input. We provide extensive empirical evidence against the necessity of disentanglement, covering mu ltiple datasets, representation learning methods, and downstream network architectures. Moreover, our study reveals that the informativeness of representations best accounts for downstream performance. The positive correlation between informativeness and disentanglement explains the claimed usefulness of disentangled representations in previous works.

Linear Video Transformer with Feature Fixation

Kaiyue Lu,ZeXiang Liu,Jianyuan Wang,Weixuan Sun,Zhen Qin,Dong Li,Xuyang Shen,Hui Deng,Xiaodong Han,Yuchao Dai,Yiran Zhong

Vision Transformers have achieved impressive performance in video classification, while suffering from the quadratic complexity caused by the Softmax attention mechanism. Some studies alleviate the computational costs by reducing the number of tokens attended in attention calculation, but the complexity is still quadratic. Another promising way is to replace Softmax attention with linear attention, which owns linear complexity but presents a clear performance drop. We find that such a drop in linear attention results from the lack of attention concentration to critical features. Therefore, we propose a feature fixation module to reweight feature importance of the query and key prior to computing linear attention. Specifically, we regard the query, key, and value as latent representations of the input token, and learn the feature fixation ratio by aggregating Query-Key-Value information. This is beneficial for measuring the feature importance comprehensively. Furthermore, we improve the feature fixation by neighborhood association, which leverages additional guidance from spatial and temporal neighboring tokens. Our proposed method significantly improves the linear attention baseline, and achieves state-of-the-art performance among linear video Transformers on three popular video classification benchmarks. Our performance is even comparable to some quadratic Transformers with fewer parameters and higher efficiency.

Neural Frailty Machine: Beyond proportional hazard assumption in neural survival regressions

Jiawei Qiao,Ruofan Wu,Mingzhe Wu,Wen Yu,Ming Zheng,Tengfei LIU,Tianyi Zhang,Weiqiang Wang

We present neural frailty machine (NFM), a powerful and flexible neural modeling framework for survival regressions. The NFM framework utilizes the classical idea of multiplicative frailty in survival analysis to capture unobserved heterogeneity among individuals, at the same time being able to leverage the strong approximation power of neural architectures for handling nonlinear covariate dependence. Two concrete models are derived under the framework that extends neural proportional hazard models and nonparametric hazard regression models. Both models allow efficient training under the likelihood objective. Theoretically, for both proposed models, we establish statistical guarantees of neural function approximation with respect to nonparametric components via characterizing their rate of convergence. Empirically, we provide synthetic experiments that verify our theoretical statements. We also conduct experimental evaluations over 6 benchmark datasets of different scales, showing that the proposed NFM models outperform state-of-the-art survival models in terms of predictive performance.

A Closer Look at Dual Batch Normalization and Two-domain Hypothesis In Adversarial Training With Hybrid Samples

Chaoning Zhang,Kang Zhang,Chenshuang Zhang,Axi Niu,Chang D. Yoo,In So Kweon

There is a growing concern about applying batch normalization (BN) in adversarial training (AT), especially when the model is trained on both \textit{adversarial} samples and \textit{clean} samples (termed Hybrid-AT). With the assumption that \textit{adversarial} and \textit{clean} samples are from two different domains, a common practice in prior works is to adopt dual BN, where BN$_{adv}$ and BN$_{clean}$ are used for adversarial and clean branches, respectively. A popular belief for motivating dual BN is that estimating normalization statistics of this mixture distribution is challenging and thus disentangling it for normalization achieves stronger robustness. In contrast to this belief, we reveal that what makes dual BN effective mainly lies in its two sets of affine parameters. Moreov

er, we demonstrate that the domain gap between adversarial and clean samples is actually not very large, which is counter-intuitive considering the significant influence of adversarial perturbation on the model. Overall, our work sheds new light on understanding the mechanism of dual BN in Hybrid-AT as well as its underlying two-domain hypothesis.
****

Generative Recorrupted-to-Recorrupted: An Unsupervised Image Denoising Network for Arbitrary Noise Distribution
wan Bowen,Daming Shi

With the great breakthrough of supervised learning in the field of denoising, more and more works focus on end-to-end learning to train denoisers. The premise of this method is effective is that there is certain data support, but in practice, it is particularly difficult to obtain labels in the training data. To this end, some unsupervised denoisers have emerged in recent years, however, the premise of these methods being effective is that the noise model needs to be known in advance, which will limit the practical use of unsupervised denoising. In addition, inaccurate noise prior from noise estimation algorithms causes low denoising accuracy. Therefore, we design a more practical denoiser that requires neither clean images as training labels nor noise model assumptions. Our method also needs the support of the noise model, the difference is that the model is generated by a residual image and a random mask during the network training process, and then the input and target of the network are generated from a single noisy images and the noise model, at the same time, train an unsupervised module and a pseudo supervised module. Extensive experiments demonstrate the effectiveness of our framework and even surpass the accuracy of supervised denoising.

Provably Learning Diverse Features in Multi-View Data with Midpoint Mixup
Muthu Chidambaram,Xiang Wang,Chenwei Wu,Rong Ge

Mixup is a data augmentation technique that relies on training using random convex combinations of data points and their labels. In recent years, Mixup has become a standard primitive used in the training of state-of-the-art image classification models due to its demonstrated benefits over empirical risk minimization with regards to generalization and robustness. In this work, we try to explain some of this success from a feature learning perspective. We focus our attention on classification problems in which each class may have multiple associated features (or views) that can be used to predict the class correctly. Our main theoretical results demonstrate that, for a non-trivial class of data distributions with two features per class, training a 2-layer convolutional network using empirical risk minimization can lead to learning only one feature for almost all classes while training with a specific instantiation of Mixup succeeds in learning both features for every class. We also show empirically that these theoretical insights extend to the practical settings of image benchmarks modified to have additional synthetic features.

Understanding Catastrophic Overfitting in Fast Adversarial Training From a Non-robust Feature Perspective
Chaoning Zhang,Chenshuang Zhang,Kang Zhang,Axi Niu,In So Kweon,Chang D. Yoo

To make adversarial training (AT) computationally efficient, FGSM AT has attracted significant attention. The fast speed, however, is achieved at the cost of catastrophic overfitting (CO), whose reason remains unclear. Prior works mainly study the phenomenon of a significant PGD accuracy (Acc) drop to understand CO while paying less attention to its FGSM Acc. We highlight an intriguing CO phenomenon that FGSM Acc is higher than accuracy on clean samples and attempt to apply non-robust feature (NRF) to understand it. Our investigation of CO by extending the existing NRF into fine-grained categorization suggests: there exists a certain type of NRF whose usefulness is increased after FGSM attack, and CO in FGSM AT can be seen as a dynamic process of learning such NRF. Therefore, the key to preventing CO lies in reducing its usefulness under FGSM AT, which sheds new light on understanding the success of a SOTA technique for mitigating CO.

BEiT v2: Masked Image Modeling with Vector-Quantized Visual Tokenizers

Zhiliang Peng,Li Dong,Hangbo Bao,Qixiang Ye,Furu Wei

Masked image modeling (MIM) has demonstrated impressive results in self-supervised representation learning by recovering corrupted image patches. However, most existing studies operate on low-level image pixels, which hinders the exploitation of high-level semantics for representation models. In this work, we propose to use a semantic-rich visual tokenizer as the reconstruction target for masked prediction, providing a systematic way to promote MIM from pixel-level to semantic-level. Specifically, we propose vector-quantized knowledge distillation to train the tokenizer, which discretizes a continuous semantic space to compact codes. We then pretrain vision Transformers by predicting the original visual tokens for the masked image patches. Furthermore, we introduce a patch aggregation strategy which associates discrete image patches to enhance global semantic representation. Experiments on image classification and semantic segmentation show that BEiT v2 outperforms all compared MIM methods. On ImageNet-1K (224 size), the base-size BEiT v2 achieves 85.5% top-1 accuracy for fine-tuning and 80.1% top-1 accuracy for linear probing. The large-size BEiT v2 obtains 87.3% top-1 accuracy for ImageNet-1K (224 size) fine-tuning, and 56.7% mIoU on ADE20K for semantic segmentation. The code can be found in the supplementary materials.

HIVE: HIerarchical Volume Encoding for Neural Implicit Surface Reconstruction

Xiaodong Gu,Weihao Yuan,Heng Li,Zilong Dong,Ping Tan

Neural implicit surface reconstruction has become a new trend in reconstructing a detailed 3D shape from images. In previous methods, however, the 3D scene is only encoded by the MLPs which do not have an explicit 3D structure. To better represent 3D shapes, we introduce a volume encoding to explicitly encode the spatial information. We further design hierarchical volumes to encode the scene structures in multiple scales. The high-resolution volumes capture the high-frequency geometry details since spatially varying features could be learned from different 3D points, while the low-resolution volumes enforce the spatial consistency to keep the shape smooth since adjacent locations possess the same low-resolution feature. In addition, we adopt a sparse structure to reduce the memory consumption at high-resolution volumes, and two regularization terms to enhance results smoothness. This hierarchical volume encoding could be appended to any implicit surface reconstruction method as a plug-and-play module, and can generate a smooth and clean reconstruction with more details. Superior performance is demonstrated in DTU, EPFL, and BlendedMVS datasets with significant improvement on the standard metrics. The code of our method will be made public.

Communication-Efficient Federated Learning with Accelerated Client Gradient

Geeho Kim,Jinkyu Kim,Bohyung Han

Federated learning often suffers from slow and unstable convergence due to heterogeneous characteristics of participating client datasets.

Such a tendency is aggravated when the client participation ratio is low since the information collected from the clients is prone to have large variations.

To tackle this challenge, we propose a novel federated learning framework, which improves the consistency across clients and facilitates the convergence of the server model.

This is achieved by making the server broadcast a global model with a gradient acceleration.

By adopting the strategy, the proposed algorithm conveys the projective global update information to participants effectively with no extra communication cost and relieves the clients from storing the previous models.

We also regularize local updates by aligning each of the clients with the overshot global model to reduce bias and improve the stability of our algorithm.

We perform comprehensive empirical studies on real data under various settings and demonstrate remarkable performance gains of the proposed method in terms of accuracy and communication efficiency compared to the state-of-the-art methods, especially with low client participation rates.

We will release our code to facilitate and disseminate our work.

DINO: DETR with Improved DeNoising Anchor Boxes for End-to-End Object Detection

Hao Zhang,Feng Li,Shilong Liu,Lei Zhang,Hang Su,Jun Zhu,Lionel Ni,Heung-Yeung Shum

We present DINO (DETR with Improved deNoising anchOr boxes), a strong end-to-end object detector. DINO improves over previous DETR-like models in performance and efficiency by using a contrastive way for denoising training, a look forward twice scheme for box prediction, and a mixed query selection method for anchor initialization. DINO achieves 49.4AP in 12 epochs and 51.3AP in 24 epochs on COCO with a ResNet-50 backbone and multi-scale features, yielding a significant improvement of +6.0AP and +2.7AP, respectively, compared to DN-DETR, the previous best DETR-like model. DINO scales well in both model size and data size. Without bells and whistles, after pre-training on the Objects365 dataset with a SwinL backbone, DINO obtains the best results on both COCO val2017 (63.2AP) and test-dev (63.3AP) with model size under 1 billion parameters. Compared to other models on the leaderboard, DINO significantly reduces its model size and pre-training data size while achieving better results. The code will be available.

Simultaneously Learning Stochastic and Adversarial Markov Decision Process with Linear Function Approximation

Fang Kong,XiangCheng Zhang,Baoxiang Wang,Shuai Li

Reinforcement learning (RL) has been commonly used in practice. To deal with the numerous states and actions in real applications, the function approximation method has been widely employed to improve the learning efficiency, among which the linear function approximation has attracted great interest both theoretically and empirically. Previous works on the linear Markov Decision Process (MDP) mainly study two settings, the stochastic setting where the reward is generated in a stochastic way and the adversarial setting where the reward can be chosen arbitrarily by an adversary. All these works treat these two environments separately. However, the learning agents often have no idea of how rewards are generated and a wrong reward type can severely disrupt the performance of those specially designed algorithms. So a natural question is whether an algorithm can be derived that can efficiently learn in both environments but without knowing the reward type. In this paper, we first consider such best-of-both-worlds problem for linear MDP with the known transition. We propose an algorithm and prove it can simultaneously achieve $O(\text{poly} \log K)$ regret in the stochastic setting and $O(\sqrt{K})$ regret in the adversarial setting where $K$ is the horizon. To the best of our knowledge, it is the first such result for linear MDP.

****

Statistical Efficiency of Score Matching: The View from Isoperimetry

Frederic Koehler,Alexander Heckett,Andrej Risteski

Deep generative models parametrized up to a normalizing constant (e.g. energy-based models) are difficult to train by maximizing the likelihood of the data because the likelihood and/or gradients thereof cannot be explicitly or efficiently written down. Score matching is a training method, whereby instead of fitting the likelihood $\log p(x)$ for the training data, we instead fit the score function $\nabla_x \log p(x)$ --- obviating the need to evaluate the partition function. Though this estimator is known to be consistent, its unclear whether (and when) its statistical efficiency is comparable to that of maximum likelihood --- which is known to be (asymptotically) optimal. We initiate this line of inquiry in this paper, and show a tight connection between statistical efficiency of score matching and the isoperimetric properties of the distribution being estimated --- i.e. the Poincar\'e, log-Sobolev and isoperimetric constant --- quantities which govern the mixing time of Markov processes like Langevin dynamics. Roughly, we show that the score matching estimator is statistically comparable to the maximum likelihood when the distribution has a small isoperimetric constant. Conversely, if the distribution has a large isoperimetric constant --- even for simple families of distributions like exponential families with rich enough sufficient statistics --- score matching will be substantially less efficient than maxim um likelihood. We suitably formalize these results both in the finite sample regime, and in the asymptotic regime. Finally, we identify a direct parallel in the discrete setting, where we connect the statistical properties of pseudolikelihood estimation with approximate tensorization of entropy and the Glauber dynamics.

Quadratic models for understanding neural network dynamics
Libin Zhu,Chaoyue Liu,Adityanarayanan Radhakrishnan,Misha Belkin

In this work, we show that recently proposed quadratic models capture optimization and generalization properties of wide neural networks that cannot be captured by linear models. In particular, we prove that quadratic models for shallow ReLU networks exhibit the "catapult phase" from Lewkowycz et al. (2020) that arises when training such models with large learning rates. We then empirically show that the behaviour of quadratic models parallels that of neural networks in generalization, especially in the catapult phase regime. Our analysis further demonstrates that quadratic models are an effective tool for analysis of neural networks.

****
Revisiting Graph Adversarial Attack and Defense From a Data Distribution Perspective
Kuan Li,Yang Liu,Xiang Ao,Qing He

Recent studies have shown that structural perturbations are significantly effective in degrading the accuracy of Graph Neural Networks (GNNs) in the semi-supervised node classification (SSNC) task. However, why the gradient-based methods are so destructive is rarely explored. In this work, we discover an interesting phenomenon: the adversarial edges are not uniformly distributed on the graph. Nearly all perturbations are generated around the training nodes in poisoning attack. Combined with this phenomenon, we provide an explanation for the effectiveness of the gradient-based attack method from a data distribution perspective and revisit both poisoning attack and evasion attack in SSNC. From this new perspective, we empirically and theoretically discuss some other attack tendencies. Based on the analysis, we provide nine practical tips on both attack and defense and meanwhile leverage them to improve existing attack and defense methods. Moreover, we design a fast attack method and a self-training defense method, which outperform the state-of-the-art methods and can effectively scale to large graphs like ogbn-arxiv. We conduct extensive experiments on four benchmark datasets to verify our claims.

****
Gated Domain Units for Multi-source Domain Generalization
Simon Föll,Alina Dubatovka,Eugen Ernst,Martin Maritsch,Patrik Okanovic,Gudrun Thaeter,Joachim M. Buhmann,Felix Wortmann,Krikamol Muandet

Distribution shift (DS) is a common problem that deteriorates the performance of learning machines. To tackle this problem, we postulate that real-world distributions are composed of elementary distributions that remain invariant across different environments. We call this an invariant elementary distribution (I.E.D.) assumption. The I.E.D. assumption implies an invariant structure in the solution space that enables knowledge transfer to unseen domains. To exploit this property in domain generalization (DG), we developed a modular neural network layer that consists of Gated Domain Units (GDUs). Each GDU learns an embedding of an individual elementary distribution that allows us to encode the domain similarities during the training. During inference, the GDUs compute similarities between an observation and each of the corresponding elementary distributions which are then used to form a weighted ensemble of learning machines. Because our layer is trained with backpropagation, it can naturally be integrated into existing deep learning frameworks. Our evaluation on image, text, graph, and time-series data shows a significant improvement in the performance on out-of-training target domains without domain information and any access to data from the target domains. This finding supports the practicality of the I.E.D. assumption and demonstrates that our GDUs can learn to represent these elementary distributions.

Learning large-scale Kernel Networks

Amirhesam Abedsoltan,Parthe Pandit,Misha Belkin

This paper concerns large-scale training of *Kernel Networks*, a generalization of kernel machines that allows the model to have arbitrary centers. We propose a scalable training algorithm -- EigenPro 3.0 -- based on alternating projections with preconditioned SGD for the alternating steps. In contrast to classical kernel machines, but similar to neural networks, our algorithm enables decoupling the learned model from the training set. This empowers kernel models to take advantage of modern methodologies in deep learning, such as data augmentation. We demonstrate the promise of EigenPro 3.0 on several experiments over large datasets. We also show data augmentation can improve performance of kernel models.

****

Provable Sim-to-real Transfer in Continuous Domain with Partial Observations

Jiachen Hu,Han Zhong,Chi Jin,Liwei Wang

Sim-to-real transfer, which trains RL agents in the simulated environments and then deploys them in the real world, has been widely used to overcome the limitations of gathering samples in the real world. Despite the empirical success of the sim-to-real transfer, its theoretical foundation is much less understood. In this paper, we study the sim-to-real transfer in continuous domain with partial observations, where the simulated environments and real-world environments are modeled by linear quadratic Gaussian (LQG) systems. We show that a popular robust adversarial training algorithm is capable of learning a policy from the simulated environment that is competitive to the optimal policy in the real-world environment. To achieve our results, we design a new algorithm for infinite-horizon average-cost LQGs and establish a regret bound that depends on the intrinsic complexity of the model class. Our algorithm crucially relies on a novel history clipping scheme, which might be of independent interest.

****

Local Coefficient Optimization in Federated Learning

Congliang Chen,Chi Zhang,Bingzhe Wu,Yatao Bian,Zhi-Quan Luo,Peilin Zhao

Federated learning emerges as a promising approach to build a large-scale cooperative learning system among multiple clients without sharing their raw data. However, given a specific global objective, finding the optimal sampling weights for each client remains largely unexplored. This is particularly challenging when clients' data distributions are non-i.i.d. and clients partially participate.

In this paper, we model the above task as a bi-level optimization problem which takes the correlations among different clients into account. We present a double-loop primal-dual-based algorithm to solve the bi-level optimization problem. We further provide rigorous convergence analysis for our algorithm under mild assumptions. Finally, we perform extensive empirical studies under both toy examples and learning models from real datasets to verify the effectiveness of the proposed method.

****

Outcome-directed Reinforcement Learning by Uncertainty \& Temporal Distance-Aware Curriculum Goal Generation

Daesol Cho,Seungjae Lee,H. Jin Kim

Current reinforcement learning (RL) often suffers when solving a challenging exploration problem where the desired outcomes or high rewards are rarely observed. Even though curriculum RL, a framework that solves complex tasks by proposing a sequence of surrogate tasks, shows reasonable results, most of the previous works still have difficulty in proposing curriculum due to the absence of a mechanism for obtaining calibrated guidance to the desired outcome state without any prior domain knowledge. To alleviate it, we propose an uncertainty \& temporal distance-aware curriculum goal generation method for the outcome-directed RL via solving a bipartite matching problem. It could not only provide precisely calibrated guidance of the curriculum to the desired outcome states but also bring much better sample efficiency and geometry-agnostic curriculum goal proposal capability compared to previous curriculum RL methods. We demonstrate that our algorithm significantly outperforms these prior methods in a variety of challenging navigation tasks and robotic manipulation tasks in a quantitative and qualitative way.

Synergistic Neuromorphic Federated Learning with ANN-SNN Conversion For Privacy Protection
Yingni Chen,Shikuang Deng,Yuhang Li,Xin Dong,Shi Gu

Federated Learning (FL) has been widely explored for the growing public data privacy issues, where only model parameters are communicated instead of private data. However, recent studies debunk the privacy protection of FL, showing that private data can be leaked from the communicated gradients or parameters updates. In this paper, we propose a framework called Synergistic Neuromorphic Federated Learning (SNFL) that enhances privacy during FL. Before uploading the updates of the client model, SNFL first converts clients' Artificial Neural Networks (ANNs) to Spiking Neural Networks (SNNs) via calibration algorithms. In a way that not only loses almost no accuracy but also encrypts the client model's parameters, SNFL manages to obtain a more performant model with high privacy. After aggregation of various SNNs parameters, server distributes the parameters back to clients to continue training under ANN architecture, providing smooth convergence. The proposed framework is demonstrated to be private, introducing a lightweight overhead as well as yielding prominent performance boosts. Extensive experiments with different kinds of datasets have demonstrated the efficacy and practicability of our method. In most of our experimental IID and not extreme Non-IID scenarios, the SNFL technique has significantly enhanced the model performance. For instance, SNFL improve the accuracy of FedAvg on Tiny-ImageNet by 13.79%. In the IID situation of tiny-ImageNet, for instance, the SNFL method is 13.79% more accurate than FedAvg. Also, the original image cannot be reconstructed after 280 iterations of attacks with the SNFL method, whereas it can be reconstructed after just 70 iterations with FedAvg.

Federated Semi-supervised Learning with Dual Regulator
Sikai Bai,Shuaicheng Li,Weiming Zhuang,Kunlin Yang,Jun Hou,Shuai Yi,Shuai Zhang,Junyu Gao,Song Guo

Federated learning emerges as a powerful method to learn from decentralized heterogeneous data while protecting data privacy. Federated semi-supervised learning (FSSL) is even more practical and challenging, where only a fraction of data can be labeled due to high annotation cost. Existing FSSL methods, however, assume independent and identically distributed (IID) labeled data across clients and consistent class distribution between labeled and unlabeled data within a client. In this work, we propose a novel FSSL framework with dual regulator, FedDure, to optimize and customize model training according to specific data distributions of clients. FedDure lifts the previous assumption with a coarse-grained regulator (C-reg) and a fine-grained regulator (F-reg): C-reg regularizes the updating of local model by tracking the learning effect on labeled data distribution; F-reg learns an adaptive weighting scheme tailored for unlabeled instances in each client. We further formulate the client model training as bi-level optimization that adaptively optimize the model in the client with two regulators. Theoretically, we show the convergence guarantee of dual regulator. Empirically, we demonstrate that FedDure is superior to the existing methods across wide range of settings, notably by more than 12% on CIFAR-10 and CINIC-10 datasets.

Path Regularization: A Convexity and Sparsity Inducing Regularization for Parallel ReLU Networks
Tolga Ergen,Mert Pilanci

Understanding the fundamental principles behind the success of deep neural networks is one of the most important open questions in the current literature. To this end, we study the training problem of deep neural networks and introduce an analytic approach to unveil hidden convexity in the optimization landscape. We consider a deep parallel ReLU network architecture, which also includes standard d eep networks and ResNets as its special cases. We then show that pathwise regularized training problems can be represented as an exact convex optimization problem. We further prove that the equivalent convex problem is regularized via a group sparsity inducing norm. Thus, a path regularized parallel ReLU network can be viewed as a parsimonious convex model in high dimensions. More importantly, we show that the computational complexity required to globally optimize the equivalent convex problem is fully polynomial-time in feature dimension and number of samples. Therefore, we prove polynomial-time trainability of path regularized ReLU networks with global optimality guarantees. We also provide experiments corroborating our theory.

Globally Optimal Training of Neural Networks with Threshold Activation Functions

Tolga Ergen,Halil Ibrahim Gulluk,Jonathan Lacotte,Mert Pilanci

Threshold activation functions are highly preferable in neural networks due to their efficiency in hardware implementations. Moreover, their mode of operation is more interpretable and resembles that of biological neurons. However, traditional gradient based algorithms such as Gradient Descent cannot be used to train the parameters of neural networks with threshold activations since the activation function has zero gradient except at a single non-differentiable point. To this end, we study weight decay regularized training problems of deep neural networks with threshold activations. We first show that regularized deep threshold network training problems can be equivalently formulated as a standard convex optimization problem, which parallels the LASSO method, provided that the last hidden layer width exceeds a certain threshold. We also derive a simplified convex optimization formulation when the dataset can be shattered at a certain layer of the network. We corroborate our theoretical results with various numerical experiments.

Molecule Generation For Target Protein Binding with Structural Motifs

ZAIXI ZHANG,Yaosen Min,Shuxin Zheng,Qi Liu

Designing ligand molecules that bind to specific protein binding sites is a fundamental problem in structure-based drug design. Although deep generative models and geometric deep learning have made great progress in drug design, existing works either sample in the 2D graph space or fail to generate valid molecules with realistic substructures. To tackle these problems, we propose a Fragment-based LigAnd Generation framework (FLAG), to generate 3D molecules with valid and realistic substructures fragment-by-fragment. In FLAG, a motif vocabulary is constructed by extracting common molecular fragments (i.e., motif) in the dataset. At each generation step, a 3D graph neural network is first employed to encode the intermediate context information. Then, our model selects the focal motif, predicts the next motif type, and attaches the new motif. The bond lengths/angles can be quickly and accurately determined by cheminformatics tools. Finally, the molecular geometry is further adjusted according to the predicted rotation angle and the structure refinement. Our model not only achieves competitive performances on conventional metrics such as binding affinity, QED, and SA, but also outperforms baselines by a large margin in generating molecules with realistic substructures.

Bag of Tricks for FGSM Adversarial Training

Zichao Li,Li Liu,Zeyu Wang,Yuyin Zhou,Cihang Xie

Adversarial training (AT) with samples generated by Fast Gradient Sign Method (FGSM), also known as FGSM-AT, is a computationally simple method to train robust networks. However, during its training procedure, an unstable mode of ``catastrophic overfitting'' has been identified in [Wong2020FastIB], where the robust accuracy abruptly drops to zero within a single training step. Existing methods use gradient regularizers or random initialization tricks to attenuate this issue, whereas they either take high computational cost or lead to lower robust accuracy. In this work, we provide the first study, which thoroughly examines a collection of tricks from three perspectives: Data Initialization, Network Structure, and Optimization, to overcome the catastrophic overfitting in FGSM-AT.

Surprisingly, we find that simple tricks, i.e., a) masking partial pixels (even without randomness), b) setting a large convolution stride and smooth activation functions, or c) regularizing the weights of the first convolutional layer, can effectively tackle the overfitting issue.

Extensive results on a range of network architectures validate the effectiveness of each proposed trick, and the combinations of tricks are also investigated. For example, trained with PreActResNet-18 on CIFAR-10, our method attains 49.8% accuracy against PGD-50 attacker and 46.4% accuracy against AutoAttack, demonstrating that pure FGSM-AT is capable of enabling robust learners.

Towards Robustness Certification Against Universal Perturbations

Yi Zeng,Zhouxing Shi,Ming Jin,Feiyang Kang,Lingjuan Lyu,Cho-Jui Hsieh,Ruoxi Jia

In this paper, we investigate the problem of certifying neural network robustness against universal perturbations (UPs), which have been widely used in universal adversarial attacks and backdoor attacks. Existing robustness certification methods aim to provide robustness guarantees for each sample with respect to the worst-case perturbations given a neural network. However, those sample-wise bounds will be loose when considering the UP threat model as they overlook the important constraint that the perturbation should be shared across all samples. We propose a method based on a combination of linear relaxation-based perturbation analysis and Mixed Integer Linear Programming to establish the first robust certification method for UP. In addition, we develop a theoretical framework for computing error bounds on the entire population using the certification results from a randomly sampled batch. Aside from an extensive evaluation of the proposed certification, we further show how the certification facilitates efficient comparison of robustness among different models or efficacy among different universal adversarial attack defenses and enables accurate detection of backdoor target classes.

Deep Generative Modeling on Limited Data with Regularization by Nontransferable Pre-trained Models

Yong Zhong,Hong Tao Liu,Xiaodong Liu,Fan Bao,Weiran Shen,Chongxuan Li

Deep generative models (DGMs) are data-eager because learning a complex model on limited data suffers from a large variance and easily overfits. Inspired by the classical perspective of the bias-variance tradeoff, we propose regularized deep generative model (Reg-DGM), which leverages a nontransferable pre-trained model to reduce the variance of generative modeling with limited data. Formally, Reg-DGM optimizes a weighted sum of a certain divergence and the expectation of an energy function, where the divergence is between the data and the model distributions, and the energy function is defined by the pre-trained model w.r.t. the model distribution. We analyze a simple yet representative Gaussian-fitting case to demonstrate how the weighting hyperparameter trades off the bias and the variance. Theoretically, we characterize the existence and the uniqueness of the global minimum of Reg-DGM in a non-parametric setting and prove its convergence with neural networks trained by gradient-based methods. Empirically, with various pre-trained feature extractors and a data-dependent energy function, Reg-DGM consistently improves the generation performance of strong DGMs with limited data and achieves competitive results to the state-of-the-art methods. Our implementation is available at https://github.com/ML-GSAI/Reg-ADA-APA.

Defense against Backdoor Attacks via Identifying and Purifying Bad Neurons

Mingyuan Fan,Yang Liu,Cen Chen,Ximeng Liu,Wenzhong Guo

Recent studies reveal the vulnerability of neural networks to backdoor attacks. By embedding backdoors into the hidden neurons with poisoned training data, the backdoor attacker can override normal predictions of the victim model to the attacker-chosen ones whenever the backdoor pattern is present in a testing input. In this paper, to mitigate public concerns about the attack, we propose a novel backdoor defense via identifying and purifying the backdoored neurons of the victim neural network. Specifically, we first define a new metric, called benign sal ience. By combining the first-order gradient to retain the connections between neurons, benign salience can identify the backdoored neurons with high accuracy. Then, a new Adaptive Regularization (AR) mechanism is proposed to assist in purifying these identified bad neurons via fine-tuning. Due to the ability to adapt to different magnitudes of parameters, AR can provide faster and more stable convergence than the common regularization mechanisms in neuron purifying. Finally, we test the defense effect of our method on ten different backdoor attacks with three benchmark datasets. Experimental results show that our method can decrease the attack success rate by more than 95% on average, which is the best among six state-of-the-art defense methods.

Basic Binary Convolution Unit for Binarized Image Restoration Network

Bin Xia,Yulun Zhang,Yitong Wang,Yapeng Tian,Wenming Yang,Radu Timofte,Luc Van Gool

Lighter and faster image restoration (IR) models are crucial for the deployment on resource-limited devices. Binary neural network (BNN), one of the most promising model compression methods, can dramatically reduce the computations and parameters of full-precision convolutional neural networks (CNN). However, there are different properties between BNN and full-precision CNN, and we can hardly use the experience of designing CNN to develop BNN. In this study, we reconsider components in binary convolution, such as residual connection, BatchNorm, activation function, and structure, for IR tasks. We conduct systematic analyses to explain each component's role in binary convolution and discuss the pitfalls. Specifically, we find that residual connection can reduce the information loss caused by binarization; BatchNorm can solve the value range gap between residual connection and binary convolution; The position of the activation function dramatically affects the performance of BNN. Based on our findings and analyses, we design a simple yet efficient basic binary convolution unit (BBCU). Furthermore, we divide IR networks into four parts and specially design variants of BBCU for each part to explore the benefit of binarizing these parts. We conduct experiments on different IR tasks, and our BBCU significantly outperforms other BNNs and lightweight models, which shows that BBCU can serve as a basic unit for binarized IR networks. All codes and models will be released.

DSP: Dynamic Semantic Prototype for Generative Zero-Shot Learning

Shiming Chen,Hou Wen Jin,Ziming Hong,Yibing Song,Tongliang Liu,Xinge You,Kun Zhang

Generative models (e.g., generative adversarial network (GAN)) have advanced zero-shot learning (ZSL). Studies on the generative ZSL methods typically produce visual features of unseen classes to mitigate the issue of lacking unseen samples based on the predefined class semantic prototypes. As these empirically designed prototypes are not able to faithfully represent the actual semantic prototypes of visual features (i.e., visual prototypes), existing methods limit their ability to synthesize visual features that accurately represent real features and prototypes. We formulate this phenomenon as a visual-semantic domain shift problem. It prevents the generative models from further improving the ZSL performance. In this paper, we propose a dynamic semantic prototype learning (DSP) method to align the empirical and actual semantic prototypes for synthesizing accurate visual features. The alignment is conducted by jointly refining semantic prototypes and visual features so that the generator synthesizes visual features which are close to the real ones. We utilize a visual$\rightarrow$semantic mapping network (V2SM) to map both the synthesized and real features into the class semantic space. The V2SM benefits the generator to synthesize visual representations with rich semantics. The real/synthesized visual features supervise our visual-oriented semantic prototype evolving network (VOPE) where the predefined class semantic prototypes are iteratively evolved to become dynamic semantic prototypes. Such prototypes are then fed back to the generative network as conditional supervision. Finally, we enhance visual features by fusing the evolved semantic prototypes into their corresponding visual features. Our extensive experiments on three benchmark datasets show that our DSP improves existing generative ZSL methods, \t extit{e.g.}, the average improvements of the harmonic mean over four baselines (e.g., CLSWGAN, f-VAEGAN, TF-VAEGAN and FREE) by 8.5\%, 8.0\% and 9.7\% on CUB, SUN and AWA2, respectively.

Analyzing the Latent Space of GAN through Local Dimension Estimation

Jaewoong Choi,Geonho Hwang,Hyunsoo Cho,Myungjoo Kang

The impressive success of style-based GANs (StyleGANs) in high-fidelity image synthesis has motivated research to understand the semantic properties of their latent spaces. Recently, a close relationship was observed between the semantically disentangled local perturbations and the local PCA components in the learned latent space $\mathcal{W}$. However, understanding the number of disentangled perturbations remains challenging. Building upon this observation, we propose a local dimension estimation algorithm for an arbitrary intermediate layer in a pre-trained GAN model. The estimated intrinsic dimension corresponds to the number of disentangled local perturbations. In this perspective, we analyze the intermediate layers of the mapping network in StyleGANs. Our analysis clarifies the success of $\mathcal{W}$-space in StyleGAN and suggests a method for finding an alternative. Moreover, the intrinsic dimension estimation opens the possibility of unsupervised evaluation of global-basis-compatibility and disentanglement for a latent space. Our proposed metric, called Distortion, measures an inconsistency of intrinsic tangent space on the learned latent space. The metric is purely geometric and does not require any additional attribute information. Nevertheless, the metric shows a high correlation with the global-basis-compatibility and supervised disentanglement score. Our findings pave the way towards an unsupervised selection of globally disentangled latent space among the intermediate latent spaces in a GAN.

A Causal Approach to Detecting Multivariate Time-series Anomalies and Root Causes

Wenzhuo Yang,Kun Zhang,Steven Hoi

Detecting anomalies and the corresponding root causes in multivariate time series plays an important role in monitoring the behaviors of various real-world systems, e.g., IT system operations or manufacturing industry. Previous anomaly detection approaches model the joint distribution without considering the underlying mechanism of multivariate time series, making them computationally hungry and hard to identify root causes. In this paper, we formulate the anomaly detection problem from a causal perspective and view anomalies as instances that do not follow the regular causal mechanism to generate the multivariate data. We then propose a causality-based framework for detecting anomalies and root causes. It first learns the causal structure from data and then infers whether an instance is an anomaly relative to the local causal mechanism whose conditional distribution can be directly estimated from data. In light of the modularity property of causal systems (the causal processes to generate different variables are irrelevant modules), the original problem is divided into a series of separate, simpler, and low-dimensional anomaly detection problems so that where an anomaly happens (root causes) can be directly identified. We evaluate our approach with both simulated and public datasets as well as a case study on real-world AIOps applications, showing its efficacy, robustness, and practical feasibility.

Quark: A Gradient-Free Quantum Learning Framework for Classification Tasks

Zhihao Zhang,Zhuoming Chen,Heyang Huang,Zhihao Jia

As more practical and scalable quantum computers emerge, much attention has been focused on realizing quantum supremacy in machine learning. Existing quantum ML methods either (1) embed a classical model into a target Hamiltonian to enable quantum optimization or (2) represent a quantum model using variational quantum circuits and apply classical gradient-based optimization. The former method leverages the power of quantum optimization but only supports simple ML models, while the latter provides flexibility in model design but relies on gradient calculation, resulting in barren plateau (i.e., gradient vanishing) and frequent classical-quantum interactions. To address the limitations of existing quantum ML meth

ods, we introduce Quark, a gradient-free quantum learning framework that optimizes quantum ML models using quantum optimization. Quark does not rely on gradient computation and therefore avoids barren plateau and frequent classical-quantum interactions. In addition, Quark can support more general ML models than prior quantum ML methods and achieves a dataset-size-independent optimization complexity. Theoretically, we prove that Quark can outperform classical gradient-based methods by reducing model query complexity for highly non-convex problems; empirically, evaluations on the Edge Detection and Tiny-MNIST tasks show that Quark can support complex ML models and significantly reduce the number of measurements needed for discovering near-optimal weights for these tasks.

Cross-modal Graph Contrastive Learning with Cellular Images
Shuangjia Zheng,Jiahua Rao,Jixian Zhang,Cohen Ethan,Chengtao Li,Yuedong Yang
Constructing discriminative representations of molecules lies at the core of a number of domains such as drug discovery, material science, and chemistry. State-of-the-art methods employ graph neural networks (GNNs) and self-supervised learning (SSL) to learn the structural representations from unlabeled data, which can then be fine-tuned for downstream tasks. Albeit powerful, these methods that are pre-trained solely on molecular structures cannot generalize well to the tasks involved in intricate biological processes. To cope with this challenge, we propose using high-content cell microscopy images to assist in learning molecular representation. The fundamental rationale of our method is to leverage the correspondence between molecular topological structures and the caused perturbations at the phenotypic level. By including cross-modal pre-training with different types of contrastive loss functions in a unified framework, our model can efficiently learn generic and informative representations from cellular images, which are complementary to molecular structures. Empirical experiments demonstrated that the model transfers non-trivially to a variety of downstream tasks and is often competitive with the existing SSL baselines, e.g., a 15.4\% absolute Hit@10 gains in graph-image retrieval task and a 4.0\% absolute AUC improvements in clinical outcome predictions. Further zero-shot case studies show the potential of the approach to be applied to real-world drug discovery.

A Closer Look at Self-supervised Lightweight Vision Transformers
Shaoru Wang,Jin Gao,Zeming Li,Weiming Hu
Self-supervised learning on large-scale Vision Transformers (ViTs) as pre-training methods has achieved promising downstream performance. Yet, how much these pre-training paradigms promote lightweight ViTs' performance is considerably less studied. In this work, we mainly develop and benchmark self-supervised pre-training methods, e.g., contrastive-learning-based MoCo-v3, masked-image-modeling-based MAE on image classification tasks, and some downstream dense prediction tasks. We surprisingly find that if proper pre-training is adopted, even vanilla lightweight ViTs show comparable performance on ImageNet to previous SOTA networks with delicate architecture design. We also point out some defects of such pre-training, \eg, failing to benefit from large-scale pre-training data and showing inferior performance on data-insufficient downstream tasks. Furthermore, we analyze and clearly show the effect of such pre-training by analyzing the properties of the layer representation and attention maps for related models. Finally, based on the above analyses, a distillation strategy during pre-training is developed, which leads to further downstream performance improvement for MAE-based pre-training.
****

MANDERA: Malicious Node Detection in Federated Learning via Ranking
Wanchuang Zhu,Benjamin Zi Hao Zhao,Simon Luo,Tongliang Liu,Ke Deng
Byzantine attacks hinder the deployment of federated learning algorithms. Although we know that the benign gradients and Byzantine attacked gradients are distributed differently, to detect the malicious gradients is challenging due to (1) the gradient is high-dimensional and each dimension has its unique distribution and (2) the benign gradients and the attacked gradients are always mixed (two-sample test methods cannot apply directly). To address the above, for the first tim

e, we propose MANDERA which is theoretically guaranteed to efficiently detect all malicious gradients under Byzantine attacks with no prior knowledge or history about the number of attacked nodes.
Specifically, we transfer the original updating gradient matrix into a ranking matrix. By such an operation, the scales of different dimensions of the gradients in the ranking space become identical. The high-dimensional benign gradients and the malicious gradients can be easily separated. The effectiveness of MANDERA is further confirmed by experimentation on four Byzantine attack implementations (Gaussian, Zero Gradient, Sign Flipping, Shifted Mean), comparing with state-of-the-art defenses. The experiments cover both IID and Non-IID datasets.

MQSP: Micro-Query Sequence Parallelism for Linearly Scaling Long Sequence Transformer

Ying Zhong,Jianjiang Zhu,PengCheng Yang,Xiaoming Zhang,Ke Zhang

Long sequence modeling of Transformer gains prevalence in fields involving long texts and high-resolution images and videos but suffers from quadratic memory complexity. Existing work investigates low-complexity variants or parallel methods to handle it. The former attempts to approximate full attention and is limited by a single device's capacity. The latter struggles to manage quadratic memory of attention maps, leading to insufficient sequence scalability. In this work, we propose a novel parallel method named $\textbf{M}$icro-$\textbf{Q}$uery $\textbf{S}$equence $\textbf{P}$arallelism. MQSP slices sequences across devices and projects local queries, keys, and values in self-attention. For communication and memory efficiency, MQSP all-gathers the queries while keys and values remain locally to acquire the local attention map, on which a distributed softmax gets conducted to amortize memory by column. Meanwhile, the queries get further partitioned as Micro-Q to divide the computation and recycle the attention map by row, jointly decomposing the quadratic memory to achieve linear scalability. The evaluation result shows that MQSP scales up sequence length linearly and achieves 4.5$\times$ sequence length of ColossalAI's sequence parallelism and 4.3$\times$ of Megatron-LM3, enabling training BERT-large of 78848 sequence length on 32 A100 GPUs. MQSP can reduce up to 78.6$\%$ of memory occupation and achieve up to 3.3$\times$ throughput when training on 17408 sequence length. The convergence quality experiment proves that MQSP provides the means for long sequences with guaranteed convergence, bringing the potential for the Transformer to explore longer sequences.

****

DSPNet: Towards Slimmable Pretrained Networks based on Discriminative Self-supervised Learning

Shaoru Wang,Zeming Li,Jin Gao,Weiming Hu

Self-supervised learning (SSL) has achieved promising downstream performance. However, when facing various resource budgets in real-world applications, it costs a huge computation burden to pretrain multiple networks of various sizes one by one. In this paper, we propose Discriminative-SSL-based Slimmable Pretrained Networks (DSPNet), which can be trained once and then slimmed to multiple sub-networks of various sizes, each of which faithfully learns good representation and can serve as good initialization for downstream tasks with various resource budgets. Specifically, we extend the idea of slimmable networks to a discriminative SSL paradigm, by integrating SSL and knowledge distillation gracefully. We show comparable or improved performance of DSPNet on ImageNet to the networks individually pretrained one by one under the linear evaluation and semi-supervised evaluation protocols, while reducing large training cost. The pretrained models also generalize well on downstream detection and segmentation tasks. Code will be made public.

Generative Multi-Flow Networks: Centralized, Independent and Conservation

Yinchuan Li,Haozhi Wang,Shuang Luo,yunfeng shao,Jianye HAO

Generative flow networks utilize the flow matching loss to learn a stochastic policy for generating objects from a sequence of actions, such that the probability of generating a pattern can be proportional to the corresponding given reward.

However, existing works can only handle single flow model tasks and cannot directly generalize to multi-agent flow networks due to limitations such as flow estimation complexity and independent sampling. In this paper, we propose the framework of generative multi-flow networks (GMFlowNets) that can be applied to multiple agents to generate objects collaboratively through a series of joint actions. Then, the centralized flow network algorithm is proposed for centralized training GMFlowNets, while the independent flow network algorithm is proposed to achieve decentralized execution of GMFlowNets. Based on the independent global conservation condition, the flow conservation network algorithm is then proposed to realize centralized training with decentralized execution paradigm. Theoretical analysis proves that using the multi-flow matching loss function can train a unique Markovian flow, and the flow conservation network can ensure independent policies can generate samples with probability proportional to the reward function. Experimental results demonstrate the performance superiority of the proposed algorithms compared to reinforcement learning and MCMC-based methods.

A Laplace-inspired Distribution on SO(3) for Probabilistic Rotation Estimation
Yingda Yin,Yang Wang,He Wang,Baoquan Chen
Estimating the 3DoF rotation from a single RGB image is an important yet challenging problem. Probabilistic rotation regression has raised more and more attention with the benefit of expressing uncertainty information along with the prediction. Though modeling noise using Gaussian-resembling Bingham distribution and matrix Fisher distribution is natural, they are shown to be sensitive to outliers for the nature of quadratic punishment to deviations. In this paper, we draw inspiration from multivariate Laplace distribution and propose a novel Rotation Laplace distribution on SO(3). Rotation Laplace distribution is robust to the disturbance of outliers and enforces much gradient to the low-error region, resulting in a better convergence. Our extensive experiments show that our proposed distribution achieves state-of-the-art performance for rotation regression tasks over both probabilistic and non-probabilistic baselines. Our project page is at pku-epic.github.io/RotationLaplace.

ContraGen: Effective Contrastive Learning For Causal Language Model
Nihal Jain,Dejiao Zhang,Wasi Uddin Ahmad,Zijian Wang,Feng Nan,Xiaopeng Li,Ming Tan,Ramesh Nallapati,Baishakhi Ray,Parminder Bhatia,Xiaofei Ma,Bing Xiang
Despite exciting progress in large-scale language generation, the expressiveness of its representations is severely limited by the \textit{anisotropy} issue where the hidden representations are distributed into a narrow cone in the vector space. To address this issue, we present ContraGen, a novel contrastive learning framework to improve the representation with better uniformity and discrimination at both sequence-level and token-level. We assess ContraGen on a wide range of downstream tasks in natural and programming languages. We show that ContraGen can effectively enhance both uniformity and discrimination of the representations and lead to the desired improvement on various language understanding tasks where discriminative representations are crucial for attaining good performance. Specifically, we attain 45.9% relative improvement on the Semantic Textual Similarity tasks and 33.5% on Code-to-Code Search tasks. Furthermore, by improving the expressiveness of the representations, ContraGen also boosts the source code generation capability with 9% relative improvement on execution accuracy on HumanEval benchmark.

Time Series Anomaly Detection via Hypothesis Testing for Dynamical Systems
Haowei He,Jingzhao Zhang,Yanan Wang,Benben Jiang,Shaobo Huang,Chen Wang,Yang Zhang,Xuebing Han,Dongxu Guo,Guannan He,Minggao Ouyang
Real world systems---such as robots, weather, energy systems and stock markets---are complicated and high-dimensional. Hence, without prior knowledge of the system dynamics, detecting or forecasting abnormal events from the sequential observations of the system is challenging. In this work, we address the problem caused by high-dimensionality via viewing time series anomaly detection as hypothesis testing on dynamical systems. This perspective can avoid the dimension of the

problem from increasing linearly with time horizon, and naturally leads to a novel anomaly detection model, termed as DyAD (Dynamical system Anomaly Detection). Furthermore, as existing time-series anomaly detection algorithms are usually evaluated on relatively small datasets, we released a large-scale one on detecting battery failures in electric vehicles. We benchmarked several popular algorithms on both public datasets and our released new dataset. Our experiments demonstrated that our proposed model achieves state-of-the-art results.

Schrödinger's FP: Training Neural Networks with Dynamic Floating-Point Containers

Milos Nikolic,Enrique Torres,Jiahui Wang,Ali Hadi Zadeh,Mostafa Mahmoud,Ameer Abdelhadi,Andreas Moshovos

We introduce a software-hardware co-design approach to reduce memory traffic and footprint during training with BFloat16 or FP32, in order to boost energy efficiency and execution time performance. Our methods dynamically adjust the size and format of the floating-point containers used to store activations and weights during training. The different value distributions lead us to different approaches for exponents and mantissas. Gecko exploits the favourable exponent distribution with a lossless delta encoding approach to reduce the total exponent footprint by up to 58% in comparison to the FP32 baseline. To contend with the noisy mantissa distributions, we present two lossy methods to eliminate as many as possible least significant bits without affecting accuracy. Quantum Mantissa is a machine learning mantissa compression method that taps onto the gradient descent algorithm to learn the minimal mantissa bitlengths on a per-layer granularity, and obtain up to 92% reduction in total mantissa footprint. Alternatively, BitChop observes changes in the loss function during training to adjust mantissa bitlength network-wide, yielding a reduction of 81% in footprint. Schrödinger's FP implements hardware encoders/decoders that, guided by Gecko/Quantum Mantissa or Gecko/BitChop, transparently encode/decode values when transferring to/from off-chip memory, boosting energy efficiency and reducing execution time.

Measuring and Narrowing the Compositionality Gap in Language Models

Ofir Press,Muru Zhang,Sewon Min,Ludwig Schmidt,Noah A. Smith,Mike Lewis

We investigate the ability of language models to perform compositional reasoning tasks where the overall solution depends on correctly composing the answers to sub-problems. We measure how often models can correctly answer all sub-problems but not generate the overall solution, a ratio we call the compositionality gap. We evaluate this ratio by asking multi-hop questions with answers that require composing multiple facts unlikely to have been observed together during pretraining. In the GPT-3 family of models, as model size increases we show that the single-hop question answering performance improves faster than the multi-hop performance does, therefore the compositionality gap does not decrease. This surprising result suggests that while more powerful models memorize and recall more factual knowledge, they show no corresponding improvement in their ability to perform this kind of compositional reasoning.

We then demonstrate how elicitive prompting (such as chain of thought) narrows the compositionality gap by reasoning explicitly instead of implicitly. We present a new method, self-ask, that further improves on chain of thought. In our method, the model explicitly asks itself (and then answers) follow-up questions before answering the initial question. We finally show that self-ask's structured prompting lets us easily plug in a search engine to answer the follow-up questions, which additionally improves accuracy.

****

HiViT: A Simpler and More Efficient Design of Hierarchical Vision Transformer

Xiaosong Zhang,Yunjie Tian,Lingxi Xie,Wei Huang,Qi Dai,Qixiang Ye,Qi Tian

There has been a debate on the choice of plain vs. hierarchical vision transformers, where researchers often believe that the former (e.g., ViT) has a simpler design but the latter (e.g., Swin) enjoys higher recognition accuracy. Recently, the emerge of masked image modeling (MIM), a self-supervised visual pre-training method, raised a new challenge to vision transformers in terms of flexibility, i.e., part of image patches or tokens are to be discarded, which seems to claim the advantages of plain vision transformers. In this paper, we delve deep into the comparison between ViT and Swin, revealing that (i) the performance gain of Swin is mainly brought by a deepened backbone and relative positional encoding, (ii) the hierarchical design of Swin can be simplified into hierarchical patch embedding (proposed in this work), and (iii) other designs such as shifted-window attentions can be removed. By removing the unnecessary operations, we come up with a new architecture named HiViT (short for hierarchical ViT), which is simpler and more efficient than Swin yet further improves its performance on fully-supervised and self-supervised visual representation learning. In particular, after pre-trained using masked autoencoder (MAE) on ImageNet-1K, HiViT-B reports a 84.6% accuracy on ImageNet-1K classification, a 53.3% box AP on COCO detection, and a 52.8% mIoU on ADE20K segmentation, significantly surpassing the baseline. Code is available at https://github.com/zhangxiaosong18/hivit.

Style Spectroscope: Improve Interpretability and Controllability through Fourier Analysis

Zhiyu Jin,Xuli Shen,Bin Li,Xiangyang Xue

Universal style transfer (UST) infuses styles from arbitrary reference images into content images. Existing methods, while enjoying many practical successes, are unable of explaining experimental observations, including different performances of UST algorithms in preserving the spatial structure of content images. In addition, methods are limited to cumbersome global controls on stylization, so that they require additional spatial masks for desired stylization. In this work, we provide a systematic Fourier analysis on a general framework for UST. We present an equivalent form of the framework in the frequency domain. The form implies that existing algorithms treat all frequency components and pixels of feature maps equally, except for the zero-frequency component. We connect Fourier amplitude and phase with Gram matrices and a content reconstruction loss in style transfer, respectively. Based on such equivalence and connections, we can thus interpret different structure preservation behaviors between algorithms with Fourier phase. Given the interpretations we have, we propose two manipulations in practice for structure preservation and desired stylization. Both qualitative and quantitative experiments demonstrate the competitive performance of our method against the state-of-the-art methods. We also conduct experiments to demonstrate (1) the abovementioned equivalence, (2) the interpretability based on Fourier amplitude and phase and (3) the controllability associated with frequency components.

Multimodal Federated Learning via Contrastive Representation Ensemble

Qiying Yu,Yang Liu,Yimu Wang,Ke Xu,Jingjing Liu

With the increasing amount of multimedia data on modern mobile systems and IoT infrastructures, harnessing these rich multimodal data without breaching user privacy becomes a critical issue. Federated learning (FL) serves as a privacy-conscious alternative to centralized machine learning. However, existing FL methods extended to multimodal data all rely on model aggregation on single modality level, which restrains the server and clients to have identical model architecture for each modality. This limits the global model in terms of both model complexity and data capacity, not to mention task diversity. In this work, we propose \textit{Contrastive Representation Ensemble and Aggregation for Multimodal FL (CreamFL)}, a multimodal federated learning framework that enables training larger server models from clients with heterogeneous model architectures and data modalities, while only communicating knowledge on public dataset. To achieve better multimodal representation fusion, we design a global-local cross-modal ensemble strategy to aggregate client representations. To mitigate local model drift caused by two unprecedented heterogeneous factors stemming from multimodal discrepancy (\textit{modality gap} and \textit{task gap}), we further propose two inter-modal and intra-modal contrasts to regularize local training, which complements information of the absent modality for uni-modal clients and regularizes local clients to head towards global consensus. Thorough evaluations and ablation studies on image-text retrieval and visual question answering tasks showcase the superiori ty of CreamFL over state-of-the-art FL methods and its practical value.

Eva: Practical Second-order Optimization with Kronecker-vectorized Approximation
Lin Zhang,Shaohuai Shi,Bo Li

Second-order optimization algorithms exhibit excellent convergence properties for training deep learning models, but often incur significant computation and memory overheads. This can result in lower training efficiency than the first-order counterparts such as stochastic gradient descent (SGD). In this work, we present a memory- and time-efficient second-order algorithm named Eva with two novel techniques: 1) we construct the second-order information with the Kronecker factorization of small stochastic vectors over a mini-batch of training data to reduce memory consumption, and 2) we derive an efficient update formula without explicitly computing the inverse of matrices using the Sherman-Morrison formula. We further provide a theoretical interpretation of Eva from a trust-region optimization point of view to understand how it works. Extensive experimental results on different models and datasets show that Eva reduces the end-to-end training time up to $2.05\times$ and $2.42\times$ compared to first-order SGD and second-order algorithms (K-FAC and Shampoo), respectively.

Identifying Weight-Variant Latent Causal Models
Yuhang Liu,Zhen Zhang,Dong Gong,Mingming Gong,Biwei Huang,Anton van den Hengel,Kun Zhang,Javen Qinfeng Shi

The task of causal representation learning aims to uncover latent higher-level causal representations that affect lower-level observations. Identifying true latent causal representations from observed data, while allowing instantaneous causal relations among latent variables, remains a challenge, however. To this end, we start from the analysis of three intrinsic properties in identifying latent space from observations: transitivity, permutation indeterminacy, and scaling indeterminacy. We find that transitivity acts as a key role in impeding the identifiability of latent causal representations. To address the unidentifiable issue due to transitivity, we introduce a novel identifiability condition where the underlying latent causal model satisfies a linear-Gaussian model, in which the causal coefficients and the distribution of Gaussian noise are modulated by an additional observed variable. Under some mild assumptions, we can show that the latent causal representations can be identified up to trivial permutation and scaling. Furthermore, based on this theoretical result, we propose a novel method, termed Structural caUsAl Variational autoEncoder, which directly learns latent causal representations and causal relationships among them, together with the mapping from the latent causal variables to the observed ones. We show that the proposed method learns the true parameters asymptotically. Experimental results on synthetic and real data demonstrate the identifiability and consistency results and the efficacy of the proposed method in learning latent causal representations.

Beyond Single Path Integrated Gradients for Reliable Input Attribution via Randomized Path Sampling
Giyoung Jeon,Haedong Jeong,Jaesik Choi

Input attribution is a widely used explanation method for deep neural networks, especially in visual tasks. Among various attribution methods, Integrated Gradients (IG) is frequently used because of its model-agnostic applicability and desirable axioms. However, previous work has shown that such method often produces noisy and unreliable attributions during the integration of the gradients over the path defined in the input space. In this paper, we tackle this issue by estimating the distribution of the possible attributions according to the integrating path selection. We show that such noisy attribution can be reduced by aggregating attributions from the multiple paths instead of using a single path. Inspired by Stick-Breaking Process, we suggest a random process to generate rich and various sampling of the gradient integrating path. Using multiple input attributions obtained from randomized path, we propose a novel attribution measure using the distribution of attributions at each input features. We identify proposed method qualitatively show less-noisy and object-aligned attribution and its feasibili

ty through the quantitative evaluations.

Sweet Gradient Matters: Designing Consistent and Efficient Estimator for Zero-Shot Neural Architecture Search

Longxing Yang,Yanxin Fu,Shun Lu,Zihao Sun,Jilin Mei,Wenxiao Zhao,Yu Hu

Neural architecture search (NAS) is one of the core technologies of AutoML for designing high-performance networks. Recently, Zero-Shot NAS has gained growing interest due to its training-free property and super-fast search speed. However, existing Zero-Shot estimators commonly suffer from low consistency, which limits the reliability and applicability. In this paper, we observe that Sweet Gradient of parameters, i.e., the absolute gradient values within a certain interval, brings higher consistency in network performance compared to the overall number of parameters. We further demonstrate a positive correlation between the network depth and the parameter ratio of sweet gradients in each layer. Based on the analysis, we propose a training-free method to find the Sweet Gradient interval and obtain an estimator, named Sweetimator. Experiments show that Sweetimator has superior consistency to existing Zero-Shot estimators on four benchmarks with eight search spaces. Moreover, Sweetimator achieves state-of-the-art performance on NAS-Bench-201 and DARTS search spaces.

Neural Collaborative Filtering Bandits via Meta Learning

Yikun Ban,Yunzhe Qi,Tianxin Wei,Jingrui He

Contextual multi-armed bandits provide powerful tools to solve the exploitation-exploration dilemma in decision making, with direct applications in the personalized recommendation. In fact, collaborative effects among users carry the significant potential to improve the recommendation. In this paper, we introduce and study the problem by exploring `Neural Collaborative Filtering Bandits', where the rewards can be non-linear functions and groups are formed dynamically given different specific contents. To solve this problem, we propose a meta-learning based bandit algorithm, Meta-Ban (\textbf{meta-ban}dits), where a meta-learner is designed to represent and rapidly adapt to dynamic groups, along with an informative UCB-based exploration strategy. Furthermore, we analyze that Meta-Ban can achieve the regret bound of $\mathcal{O}(\sqrt{nT\log T})$, which is sharper over state-of-the-art related works. In the end, we conduct extensive experiments showing that Meta-Ban outperforms six strong baselines.

Cascaded Teaching Transformers with Data Reweighting for Long Sequence Time-series Forecasting

Haoyi Zhou,Chonghan Gao,Pengtao Xie,Jianxin Li

The Transformer-based models have shown superior performance in the long sequence time-series forecasting problem. The sparsity assumption on self-attention dot-product reveals that not all inputs are equally significant for Transformers. Instead of implicitly utilizing weighted time-series, we build a new learning framework by cascaded teaching Transformers to reweight samples. We formulate the framework as a multi-level optimization and design three different dataset-weight generators. We perform extensive experiments on five datasets, which shows that our proposed method could significantly outperform the SOTA Transformers.

Can CNNs Be More Robust Than Transformers?

Zeyu Wang,Yutong Bai,Yuyin Zhou,Cihang Xie

The recent success of Vision Transformers is shaking the long dominance of Convolutional Neural Networks (CNNs) in image recognition for a decade. Specifically, in terms of robustness on out-of-distribution samples, recent research finds that Transformers are inherently more robust than CNNs, regardless of different training setups. Moreover, it is believed that such superiority of Transformers should largely be credited to their \emph{self-attention-like architectures per se}. In this paper, we question that belief by closely examining the design of Transformers. Our findings lead to three highly effective architecture designs for boosting robustness, yet simple enough to be implemented in several lines of code, namely a) patchifying input images, b) enlarging kernel size, and c) reducing activation layers and normalization layers. Bringing these components together, we are able to build pure CNN architectures without any attention-like operations that are as robust as, or even more robust than, Transformers. We hope this work can help the community better understand the design of robust neural architectures. The code is publicly available at https://github.com/UCSC-VLAA/RobustCNN.

Decoupled Mixup for Data-efficient Learning

Zicheng Liu,Siyuan Li,Ge Wang,Cheng Tan,Lirong Wu,Stan Z. Li

Mixup is an efficient data augmentation approach that improves the generalization of neural networks by smoothing the decision boundary with mixed data. Recently, dynamic mixup methods have improved previous static policies effectively (e.g., linear interpolation) by maximizing salient regions or maintaining the target in mixed samples. The discrepancy is that the generated mixed samples from dynamic policies are more instance discriminative than the static ones, e.g., the foreground objects are decoupled from the background. However, optimizing mixup policies with dynamic methods in input space is an expensive computation compared to static ones. Hence, we are trying to transfer the decoupling mechanism of dynamic methods from the data level to the objective function level and propose the general decoupled mixup (DM) loss. The primary effect is that DM can adaptively focus on discriminative features without losing the original smoothness of the mixup while avoiding heavy computational overhead. As a result, DM enables static mixup methods to achieve comparable or even exceed the performance of dynamic methods. This also leads to an interesting objective design problem for mixup training that we need to focus on both smoothing the decision boundaries and identifying discriminative features. Extensive experiments on supervised and semi-supervised learning benchmarks across seven classification datasets validate the effectiveness of DM by equipping it with various mixup methods.

FAIRER: Fairness as Decision Rationale Alignment

Tianlin Li,Qing Guo

Deep neural networks (DNNs) have achieved remarkable accuracy, but they often suffer from fairness issues, as deep models typically show distinct accuracy differences among some specific subgroups (e.g., males and females). Existing research addresses this critical issue by employing fairness-aware loss functions to constrain the last-layer outputs and directly regularize DNNs. Although the fairness of DNNs is improved, it is unclear how the trained network makes a fair prediction, which limits future fairness improvements. In this paper, we investigate fairness from the perspective of decision rationale and define neuron parity scores to characterize the fair decision process of networks by analyzing neuron behaviors in various subgroups. Extensive empirical studies show that the unfair issue could arise from the unaligned decision rationales of subgroups. Existing fairness regularization terms fail to achieve decision rationale alignment because they only constrain last-layer outputs while ignoring intermediate neuron alignment. To address the issue, we formulate the fairness as a new task, i.e., decision rationale alignment that requires DNNs’ neurons to have consistent responses on subgroups at both intermediate processes and the final prediction. To make this idea practical during optimization, we relax the naive objective function and propose gradient-guided parity alignment, which encourages gradient-weighted consistency of neurons across subgroups. Extensive experiments on a variety of datasets show that our method can improve fairness while maintaining high accuracy and outperforming other baselines by a large margin. We have released our codes at https://anonymous.4open.science/r/fairer_submission-F176/.

Risk-Aware Reinforcement Learning with Coherent Risk Measures and Non-linear Function Approximation

Thanh Lam,Arun Verma,Bryan Kian Hsiang Low,Patrick Jaillet

We study the risk-aware reinforcement learning (RL) problem in the episodic finite-horizon Markov decision process with unknown transition and reward functions. In contrast to the risk-neutral RL problem, we consider minimizing the risk of having low rewards, which arise due to the intrinsic randomness of the MDPs and imperfect knowledge of the model. Our work provides a unified framework to analyze the regret of risk-aware RL policy with coherent risk measures in conjunction with non-linear function approximation, which gives the first sub-linear regret bounds in the setting. Finally, we validate our theoretical results via empirical experiments on synthetic and real-world data.

A Minimalist Dataset for Systematic Generalization of Perception, Syntax, and Semantics

Qing Li,Siyuan Huang,Yining Hong,Yixin Zhu,Ying Nian Wu,Song-Chun Zhu

Inspired by humans' exceptional ability to master arithmetic and generalize to new problems, we present a new dataset, HINT, to examine machines' capability of learning generalizable concepts at three levels: perception, syntax, and semantics. In HINT, machines are tasked with learning how concepts are perceived from raw signals such as images (i.e., perception), how multiple concepts are structurally combined to form a valid expression (i.e., syntax), and how concepts are realized to afford various reasoning tasks (i.e., semantics), all in a weakly supervised manner. Focusing on systematic generalization, we carefully design a five-fold test set to evaluate both the interpolation and the extrapolation of learned concepts w.r.t the three levels. Further, we design a few-shot learning split to determine whether or not models can rapidly learn new concepts and generalize them to more complex scenarios. To comprehend existing models' limitations, we undertake extensive experiments with various sequence-to-sequence models, including RNNs, Transformers, and GPT-3 (with the chain of thought prompting). The results indicate that current models struggle to extrapolate to long-range syntactic dependency and semantics. Models exhibit a considerable gap toward human-level generalization when evaluated with new concepts in a few-shot setting. Moreover, we discover that it is infeasible to solve HINT by merely scaling up the dataset and the model size; this strategy contributes little to the extrapolation of syntax and semantics. Finally, in zero-shot GPT-3 experiments, the chain of thought prompting exhibits impressive results and significantly boosts the test accuracy. We believe the HINT dataset and the experimental findings are of great interest to the learning community on systematic generalization.%

Bi-level Physics-Informed Neural Networks for PDE Constrained Optimization using Broyden's Hypergradients

Zhongkai Hao,Chengyang Ying,Hang Su,Jun Zhu,Jian Song,Ze Cheng

Deep learning based approaches like Physics-informed neural networks (PINNs) and DeepONets have shown promise on solving PDE constrained optimization (PDECO) problems.

However, existing methods are insufficient to handle those PDE constraints that have a complicated or nonlinear dependency on optimization targets. In this paper, we present a novel bi-level optimization framework to resolve the challenge by decoupling the optimization of the targets and constraints. For the inner loop optimization, we adopt PINNs to solve the PDE constraints only. For the outer loop, we design a novel method by using Broyden's method based on the Implicit Function Theorem (IFT), which is efficient and accurate for approximating hypergradients. We further present theoretical explanations and error analysis of the hypergradients computation. Extensive experiments on multiple large-scale and nonlinear PDE constrained optimization problems demonstrate that our method achieves state-of-the-art results compared with strong baselines.

Hazard Gradient Penalty for Survival Analysis

Seungjae Jung,Kyung-Min Kim

Survival analysis appears in various fields such as medicine, economics, engineering, and business.

Recent studies showed that the Ordinary Differential Equation (ODE) modeling framework integrates many existing survival models while the framework is flexible and widely applicable.

However, naively applying the ODE framework to survival analysis problems may mo

del fiercely changing density function with respect to covariates which may worsen the model’s performance.
Though we can apply L1 or L2 regularizers to the ODE model, their effect on the ODE modeling framework is barely known.
In this paper, we propose hazard gradient penalty (HGP) to enhance the performance of a survival analysis model.
Our method imposes constraints on local data points by regularizing the gradient of hazard function with respect to the data point.
Our method applies to any survival analysis model including the ODE modeling framework and is easy to implement.
We theoretically show that our method is related to minimizing the KL divergence between the density function at a data point and that of the neighborhood points.
Experimental results on three public benchmarks show that our approach outperforms other regularization methods.

Rethink Depth Separation with Intra-layer Links
FENGLEI FAN,Zeyu Li,Huan Xiong,Tieyong Zeng
The depth separation theory is nowadays widely accepted as an effective explanation for the power of depth, which consists of two parts: i) there exists a function representable by a deep network; ii) such a function cannot be represented by a shallow network whose width is lower than a threshold. Here, we report that adding intra-layer links can greatly improve a network's representation capability through the bound estimation, explicit construction, and functional space analysis. Then, we modify the depth separation theory by showing that a shallow network with intra-layer links does not need to go as wide as before to express some hard functions constructed by a deep network. Such functions include the renowned "sawtooth" functions. Our results supplement the existing depth separation theory by examining its limit in a broader domain. Also, our results suggest that once configured with an appropriate structure, a shallow and wide network may have expressive power on a par with a deep network.

Reach the Remote Neighbors: Dual-Encoding Transformer for Graphs
Lingbing Guo,Zequn Sun,Qiang Zhang,Huajun Chen
Despite recent successes in natural language processing and computer vision, Transformer suffers from the scalability problem when dealing with graphs. Computing node-to-node attentions is infeasible on complicated graphs, e.g., knowledge graphs. One solution is to consider only the near neighbors, which, however, will lose the key merit of Transformer that attends to the elements at any distance. In this paper, we propose a new Transformer architecture, named dual-encoding Transformer (DET), which has a structural encoder to aggregate information from near neighbors and a semantic encoder to focus on useful semantically close neighbors. The two encoders can be incorporated to boost each other's performance. Our experiments demonstrate that DET achieves superior performance compared to the respective state-of-the-art attention-based methods in dealing with molecules, networks and knowledge graphs.
****
The Geometry of Self-supervised Learning Models and its Impact on Transfer Learning
Romain Cosentino,Sarath Shekkizhar,Mahdi Soltanolkotabi,Salman Avestimehr,Antonio Ortega
Self-supervised learning~(SSL) has emerged as a desirable paradigm in computer vision due to the inability of supervised models to learn representations that can generalize in domains with limited labels. The recent popularity of SSL has led to the development of several models that make use of diverse training strategies, architectures, and data augmentation policies with no existing unified framework to study or assess their effectiveness in transfer learning.
We propose a data-driven geometric strategy to analyze different SSL models using local neighborhoods in the feature space induced by each. Unlike existing approaches that consider mathematical approximations of the parameters, individual c

omponents, or optimization landscape, our work aims to explore the geometric properties of the representation manifolds learned by SSL models.
Our proposed manifold graph metrics~(MGMs)
provide insights into the geometric similarities and differences between available SSL models, their invariances with respect to specific augmentations, and their performances on transfer learning tasks. Our key findings are two fold: (i) contrary to popular belief, the geometry of SSL models is not tied to its training paradigm (contrastive, non-contrastive, and cluster-based); (ii) we can predict the transfer learning capability for a specific model based on the geometric properties of its semantic and augmentation manifolds.

When Do Models Generalize? A Perspective From Data-Algorithm Compatibility
Jing Xu,Jiaye Teng,Yang Yuan,Andrew C Yao
One of the major open problems in machine learning is to characterize generalization in the overparameterized regime, where most traditional generalization bounds become inconsistent (Nagarajan and Kolter, 2019). In many scenarios, their failure can be attributed to obscuring the crucial interplay between the training algorithm and the underlying data distribution. To address this issue, we propose a concept named compatibility, which quantitatively characterizes generalization in a both data-relevant and algorithm relevant manner. By considering the entire training trajectory and focusing on early-stopping iterates, compatibility exploits the data and the algorithm information and is therefore a more suitable notion for generalization. We validate this by theoretically studying compatibility under the setting of solving overparameterized linear regression with gradient descent. Specifically, we perform a data-dependent trajectory analysis and derive a sufficient condition for compatibility in such a setting. Our theoretical results demonstrate that in the sense of compatibility, generalization holds with significantly weaker restrictions on the problem instance than the previous last iterate analysis.
****

On the Saturation Effect of Kernel Ridge Regression
Yicheng Li,Haobo Zhang,Qian Lin
The saturation effect refers to the phenomenon that the kernel ridge regression (KRR) fails to achieve the information theoretical lower bound when the smoothness of the underground truth function exceeds certain level. The saturation effect has been widely observed in practices and a saturation lower bound of KRR has been conjectured for decades. In this paper, we provide a proof of this long-standing conjecture.
****

Adversarial perturbation based latent reconstruction for domain-agnostic self-supervised learning
Sijie Tian,Kuilin Chen,Chi-Guhn Lee
Most self-supervised learning (SSL) methods rely on domain-specific pretext tasks and data augmentations to learn high-quality representations from unlabeled data. Development of those pretext tasks and data augmentations requires expert domain knowledge. In addition, it is not clear why solving certain pretext tasks leads to useful representations. Those two reasons hinder wider application of SSL to different domains. To overcome such limitations, we propose adversarial perturbation based latent reconstruction (APLR) for domain-agnostic self-supervised learning. In APLR, a neural network is trained to generate adversarial noise to perturb the unlabeled training sample so that domain-specific augmentations are not required. The pretext task in APLR is to reconstruct the latent representation of a clean sample from a perturbed sample. We show that representation learning via latent reconstruction is closely related to multi-dimensional Hirschfeld-Gebelein-Rényi (HGR) maximal correlation and has theoretical guarantees on the linear probe error. To demonstrate the effectiveness of APLR, the proposed method is applied to various domains such as tabular data, images, and audios. Empirical results indicate that APLR not only outperforms existing domain-agnostic SSL methods, but also closes the performance gap to domain-specific SSL methods. In many cases, APLR also outperforms training the full network in a supervised man

ner.

Unsupervised Model Selection for Time Series Anomaly Detection

Mononito Goswami,Cristian Ignacio Challu,Laurent Callot,Lenon Minorics,Andrey Kan

Anomaly detection in time-series has a wide range of practical applications. While numerous anomaly detection methods have been proposed in the literature, a recent survey concluded that no single method is the most accurate across various datasets. To make matters worse, anomaly labels are scarce and rarely available in practice. The practical problem of selecting the most accurate model for a given dataset without labels has received little attention in the literature. This paper answers this question \textit{i.e.} Given an unlabeled dataset and a set of candidate anomaly detectors, how can we select the most accurate model? To this end, we identify three classes of surrogate (unsupervised) metrics, namely, \textit{prediction error}, \textit{model centrality}, and \textit{performance on injected synthetic anomalies}, and show that some metrics are highly correlated with standard supervised anomaly detection performance metrics such as the F_1 score, but to varying degrees. We formulate metric combination with multiple imperfect surrogate metrics as a robust rank aggregation problem. We then provide theoretical justification behind the proposed approach. Large-scale experiments on multiple real-world datasets demonstrate that our proposed unsupervised approach is as effective as selecting the most accurate model based on partially labeled data.

Constrained Hierarchical Deep Reinforcement Learning with Differentiable Formal Specifications

Zikang Xiong,Joe Eappen,Ahmed H Qureshi,Suresh Jagannathan

Formal logic specifications are a useful tool to describe desired agent behavior and have been explored as a means to shape rewards in Deep Reinforcement Learning (DRL) systems over a variety of problems and domains. Prior work, however, has failed to consider the possibility of making these specifications differentiable, which would yield a more informative signal of the objective via the specification gradient. This paper examines precisely such an approach by exploring a Lagrangian method to constrain policy updates using a differentiable style of temporal logic specifications that associates logic formulae with real-valued quantitative semantics. This constrained learning mechanism is then used in a hierarchical setting where a high-level specification-guided neural network path planner works with a low-level control policy to navigate through planned waypoints. The effectiveness of our approach is demonstrated over four robot dynamics with five different types of Linear Temporal Logic (LTL) specifications. Our demo videos are collected at https://sites.google.com/view/schrl.

Topic Aware Transformer: Domain Shift for Unconditional Text Generation Model

Noriaki Kawamae

Our goal is to adapt pre-trained language models (PLMs) to support unconditional text generation tasks.
Because Transformer-based models are pre-trained on more massive and heterogeneous corpora than specific target corpus,
the gap between these corpora and the target corpus raises the question of whether these PLMs will actually benefit this task even after fine-tuning.
As the domain adaptation of PLMs needs to bridge this gap,
we propose a framework, Topic Aware Transformer (TAT), that adapts PLMs for target-aware text generation while alleviating catastrophic forgetting.
The motivation of TAT to distill the target-specific knowledge as topics,
and steer PLMs toward these topics.
This requirement and motivation lead us to introduce a topic steering layer (TSL) as an additional layer,
and Topic Distribution Modeling (TDM) as a training task.
Experiments show that these components resolve the gap as the domain shift,
and can tailor PLMs to generate text to better reflect a given small fine-tuning

corpus.

Protein Representation Learning by Geometric Structure Pretraining
Zuobai Zhang,Minghao Xu,Arian Rokkum Jamasb,Vijil Chenthamarakshan,Aurelie Lozano,Payel Das,Jian Tang

Learning effective protein representations is critical in a variety of tasks in biology such as predicting protein function or structure. Existing approaches usually pretrain protein language models on a large number of unlabeled amino acid sequences and then finetune the models with some labeled data in downstream tasks. Despite the effectiveness of sequence-based approaches, the power of pretraining on known protein structures, which are available in smaller numbers only, has not been explored for protein property prediction, though protein structures are known to be determinants of protein function. In this paper, we propose to pretrain protein representations according to their 3D structures. We first present a simple yet effective encoder to learn the geometric features of a protein. We pretrain the protein graph encoder by leveraging multiview contrastive learning and different self-prediction tasks. Experimental results on both function prediction and fold classification tasks show that our proposed pretraining methods outperform or are on par with the state-of-the-art sequence-based methods, while using much less pretraining data. Our implementation is available at https://github.com/DeepGraphLearning/GearNet.

Conditional Invariances for Conformer Invariant Protein Representations
Balasubramaniam Srinivasan,Vassilis N. Ioannidis,Soji Adeshina,Mayank Kakodkar,George Karypis,Bruno Ribeiro

Representation learning for proteins is an emerging area in geometric deep learning. Recent works have factored in both the relational (atomic bonds) and the geometric aspects (atomic positions) of the task, notably bringing together graph neural networks (GNNs) with neural networks for point clouds. The equivariances and invariances to geometric transformations (group actions such as rotations and translations) so far treats large molecules as rigid structures. However, in many important settings, proteins can co-exist as an ensemble of multiple stable conformations. The conformations of a protein, however, cannot be described as input-independent transformations of the protein: Two proteins may require different sets of transformations in order to describe their set of viable conformations. To address this limitation, we introduce the concept of conditional transformations (CT). CT can capture protein structure, while respecting the restrictions posed by constraints on dihedral (torsion) angles and steric repulsions between atoms. We then introduce a Markov chain Monte Carlo framework to learn representations that are invariant to these conditional transformations. Our results show that endowing existing baseline models with these conditional transformations helps improve their performance without sacrificing computational cost.
****

Learning PDE Solution Operator for Continuous Modeling of Time-Series
Yesom Park,Jaemoo Choi,Changyeon Yoon,Chang hoon Song,Myungjoo Kang

Learning underlying dynamics from data is important and challenging in many real-world scenarios. Incorporating differential equations (DEs) to design continuous networks has drawn much attention recently, the most prominent of which is Neural ODE. Most prior works make specific assumptions on the type of DEs or restrict them to first or second-order DEs, making the model specialized for certain problems. Furthermore, due to the use of numerical integration, they suffer from computational expensiveness and numerical instability. Building upon recent Fourier neural operator (FNO), this work proposes a partial differential equation (PDE) based framework which improves the dynamics modeling capability and circumvents the need for costly numerical integration. FNO is hard to be directly applied to real applications because it is mainly confined to physical PDE problems. To fill this void, we propose a continuous-in-time FNO to deal with irregularly-sampled time series and provide a theoretical result demonstrating its universality. Moreover, we reveal an intrinsic property of PDEs that increases the stability of the model. Several numerical evidence shows that our method represents a b roader range of problems, including synthetic, image classification, and irregular time-series. Our framework opens up a new way for a continuous representation of neural networks that can be readily adopted for real-world applications.

Quantum-Inspired Tensorized Embedding with Application to Node Representation Learning

Hao Xiong,Yehui Tang,Wei Tan,Yunlin He,Junchi Yan

Node representation learning a.k.a. network embedding (NE) is an essential technique for network analysis by representing nodes as vectors, which also serves downstream tasks or as initial input for GNN models. Most of existing NE algorithms require a space complexity linear to the multiplication of the number of nodes and embedding dimension to store embeddings. Such a conventional embedding paradigm has two defects: i) it brings challenge to the deployment of NE algorithms for large-scale networks on devices of limited memory/storage space; ii) model expressiveness is constrained due to the limited embedding dimension. Impressed and inspired by the large Hilbert space of quantum systems, we propose a brand new NE algorithm \emph{node2ket} by imitating behaviors of quantum systems. Theoretically, we give analysis on how it unifies existing embedding methods including both conventional ones and tensorized ones, and explore the ultimate compressive power of the embedding model on the space complexity compared with conventional ones. Experiments are conducted on five public real-world networks where methods are evaluated through tasks of network reconstruction and link prediction. On BlogCatalog, our method achieves to outperform all baselines with 1/32 training parameters and 1/16 running time on the same machine. On DBLP, the reconstruction precision of node2ket achieves to be 3 times higher than the best baseline i.e. LouvainNE. Source code will be made publicly available.

Identifying Latent Causal Content for Multi-Source Domain Adaptation

Yuhang Liu,Zhen Zhang,Dong Gong,Mingming Gong,Biwei Huang,Kun Zhang,Javen Qinfeng Shi

Multi-source domain adaptation (MSDA) learns to predict the labels in target domain data, under the setting that data from multiple source domains are labelled and data from the target domain are unlabelled. Most methods for this task focus on learning invariant representations across domains. However, their success relies heavily on the assumption that the label distribution remains consistent across domains, which may not hold in general real-world problems. In this paper, we propose a new and more flexible assumption, termed \textit{latent covariate shift}, where a latent content variable $\mathbf{z}_c$ and a latent style variable $\mathbf{z}_s$ are introduced in the generative process, with the marginal distribution of $\mathbf{z}_c$ changing across domains and the conditional distribution of the label given $\mathbf{z}_c$ remaining invariant across domains. We show that although (completely) identifying the proposed latent causal model is challenging, the latent content variable can be identified up to scaling by using its dependence with labels from source domains, together with the identifiability conditions of nonlinear ICA. This motivates us to propose a novel method for MSDA, which learns the invariant label distribution conditional on the latent content variable, instead of learning invariant representations. Empirical evaluation on simulation and real data demonstrates the effectiveness of the proposed method.

****

Trainable Weight Averaging: Efficient Training by Optimizing Historical Solutions

Tao Li,Zhehao Huang,Qinghua Tao,Yingwen Wu,Xiaolin Huang

Stochastic gradient descent (SGD) and its variants are considered as the de-facto methods to train deep neural networks (DNNs). While recent improvements to SGD mainly focus on the descent algorithm itself, few works pay attention to utilizing the historical solutions---as an iterative method, SGD has gone through substantial explorations before convergence. Recently, an interesting attempt is stochastic weight averaging (SWA), which significantly improves the generalization by simply averaging the solutions at the tail stage of training. In this paper,

we realize that the averaging coefficients could be determined in a trainable manner and propose Trainable Weight Averaging (TWA), a novel optimization method in the reduced subspace spanned by historical solutions. TWA has much greater flexibility and can be applied to the head stage of training to achieve training efficiency while preserving good generalization capability. Further, we propose a distributed training scheme to resolve the memory burden of large-scale training with efficient parallel computation. In the extensive numerical experiments, (i) TWA achieves consistent improvements over SWA with less sensitivity to learning rate; (ii) applying TWA in the head stage of training largely speeds up the convergence, resulting in over 40% time saving on CIFAR and 30% on ImageNet with improved generalization compared with regular training.
****
Revealing Single Frame Bias for Video-and-Language Learning
Jie Lei,Tamara L Berg,Mohit Bansal
Training an effective video-and-language model intuitively requires multiple frames as model inputs.
However, it is unclear whether using multiple frames is beneficial to downstream tasks, and if yes, whether the performance gain is worth the drastically-increased computation and memory costs resulting from using more frames.
In this work, we explore single-frame models for video-and-language learning.
On a diverse set of video-and-language tasks (including text-to-video retrieval and video question answering), we show the surprising result that, with large-scale pre-training and a proper frame ensemble strategy at inference time, a single-frame trained model that does not consider temporal information can achieve better performance than existing methods that use multiple frames for training.
This result reveals the existence of a strong ``static appearance bias'' in popular video-and-language datasets.
Therefore, to allow for a more comprehensive evaluation of video-and-language models, we propose two new retrieval tasks based on existing fine-grained action recognition datasets that encourage temporal modeling.
Full code and models will be made publicly available upon acceptance.
****
Deep Declarative Dynamic Time Warping for End-to-End Learning of Alignment Paths
Ming Xu,Sourav Garg,Michael Milford,Stephen Gould
This paper addresses learning end-to-end models for time series data that include a temporal alignment step via dynamic time warping (DTW). Existing approaches to differentiable DTW either differentiate through a fixed warping path or apply a differentiable relaxation to the min operator found in the recursive steps used to solve the DTW problem. We instead propose a DTW layer based around bi-level optimisation and deep declarative networks, which we name DecDTW. By formulating DTW as a continuous, inequality constrained optimisation problem, we can compute gradients for the solution of the optimal alignment (with respect to the underlying time series) using implicit differentiation. An interesting byproduct of this formulation is that DecDTW outputs the optimal warping path between two time series as opposed to a soft approximation, recoverable from Soft-DTW. We show that this property is particularly useful for applications where downstream loss functions are defined on the optimal alignment path itself. This naturally occurs, for instance, when learning to improve the accuracy of predicted alignments against ground truth alignments. We evaluate DecDTW on two such applications, namely the audio-to-score alignment task in music information retrieval and the visual place recognition task in robotics, demonstrating state-of-the-art results in both.

DEEAPR: Controllable Depth Enhancement via Adaptive Parametric Feature Rotation
Hanul Shin,Youngchan Song,Soo Min Kang
Understanding depth of an image provides viewers with a better interpretation of the 3D structures within an image. Photographers utilize numerous factors that can affect depth perception to aesthetically improve a scene. Unfortunately, controlling depth perception after the image has been captured is a difficult process as it requires accurate and explicit depth information. Also, defining a quan

titative metric of a subjective quality (i.e., depth perception) is difficult which makes supervised learning a great challenge. To this end, we propose DEpth Enhancement via Adaptive Parametric feature Rotation (DEEAPR), which modulates the perceptual depth of an input scene using a single control parameter without the need for explicit depth information. We first embed content-independent depth perception of a scene by visual representation learning. Then, we train the controllable depth enhancer network with a novel modulator, parametric feature rotation block (PFRB), that allows for continuous modulation of a representative feature. We demonstrate the effectiveness of our proposed approach by verifying each component through an ablation study and comparison to other controllable methods.

Deep Active Anomaly Detection With Diverse Queries

Aodong Li,Chen Qiu,Padhraic Smyth,Marius Kloft,Stephan Mandt,Maja Rudolph

Selecting informative data points for expert feedback can significantly improve the performance of anomaly detection in various contexts, such as medical diagnostics or fraud detection. In this paper, we determine a set of conditions under which the ranking of anomaly scores generalizes from labeled queries to unlabeled data. Inspired by these conditions, we propose a new querying strategy for active anomaly detection that leads to systematic improvements over current approaches for this problem. It selects a diverse set of data points for labeling, achieving high data coverage with a limited budget. These labeled data points provide weak supervision to the unsupervised anomaly detection problem. However, correctly identifying anomalies requires an estimate of the fraction of anomalies in the data. We show how this anomaly rate can be estimated from the query set by importance-weighting, removing the associated bias due to the non-uniform sampling procedure. Extensive experiments on image, tabular, and video data sets show that our approach results in state-of-the-art active anomaly detection performance.

****

Analog Bits: Generating Discrete Data using Diffusion Models with Self-Conditioning

Ting Chen,Ruixiang ZHANG,Geoffrey Hinton

We present Bit Diffusion: a simple and generic approach for generating discrete data with continuous state and continuous time diffusion models. The main idea behind our approach is to first represent the discrete data as binary bits, and then train a continuous diffusion model to model these bits as real numbers which we call analog bits. To generate samples, the model first generates the analog bits, which are then thresholded to obtain the bits that represent the discrete variables. We further propose two simple techniques, namely Self-Conditioning and Asymmetric Time Intervals, which lead to a significant improvement in sample quality. Despite its simplicity, the proposed approach can achieve strong performance in both discrete image generation and image captioning tasks. For discrete image generation, we significantly improve previous state-of-the-art on both CIFAR-10 (which has 3K discrete 8-bit tokens) and ImageNet-64x64 (which has 12K discrete 8-bit tokens), outperforming the best autoregressive model in both sample quality (measured by FID) and efficiency. For image captioning on MS-COCO dataset, our approach achieves competitive results compared to autoregressive models.

Understanding Edge-of-Stability Training Dynamics with a Minimalist Example

Xingyu Zhu,Zixuan Wang,Xiang Wang,Mo Zhou,Rong Ge

Recently, researchers observed that gradient descent for deep neural networks operates in an ``edge-of-stability'' (EoS) regime: the sharpness (maximum eigenvalue of the Hessian) is often larger than stability threshold $2/\eta$ (where η is the step size). Despite this, the loss oscillates and converges in the long run, and the sharpness at the end is just slightly below $2/\eta$. While many other well-understood nonconvex objectives such as matrix factorization or two-layer networks can also converge despite large sharpness, there is often a larger gap between sharpness of the endpoint and $2/\eta$. In this paper, we study EoS phenomenon by constructing a simple function that has the same behavior. We giv e rigorous analysis for its training dynamics in a large local region and explain why the final converging point has sharpness close to $2/\eta$. Globally we observe that the training dynamics for our example has an interesting bifurcating behavior, which was also observed in the training of neural nets.

Learning Proximal Operators to Discover Multiple Optima

Lingxiao Li,Noam Aigerman,Vladimir Kim,Jiajin Li,Kristjan Greenewald,Mikhail Yurochkin,Justin Solomon

Finding multiple solutions of non-convex optimization problems is a ubiquitous yet challenging task. Most past algorithms either apply single-solution optimization methods from multiple random initial guesses or search in the vicinity of found solutions using ad hoc heuristics. We present an end-to-end method to learn the proximal operator of a family of training problems so that multiple local minima can be quickly obtained from initial guesses by iterating the learned operator, emulating the proximal-point algorithm that has fast convergence. The learned proximal operator can be further generalized to recover multiple optima for unseen problems at test time, enabling applications such as object detection. The key ingredient in our formulation is a proximal regularization term, which elevates the convexity of our training loss: by applying recent theoretical results, we show that for weakly-convex objectives with Lipschitz gradients, training of the proximal operator converges globally with a practical degree of over-parameterization. We further present an exhaustive benchmark for multi-solution optimization to demonstrate the effectiveness of our method.

Guiding continuous operator learning through Physics-based boundary constraints

Nadim Saad,Gaurav Gupta,Shima Alizadeh,Danielle C. Maddix

Boundary conditions (BCs) are important groups of physics-enforced constraints that are necessary for solutions of Partial Differential Equations (PDEs) to satisfy at specific spatial locations. These constraints carry important physical meaning, and guarantee the existence and the uniqueness of the PDE solution. Current neural-network based approaches that aim to solve PDEs rely only on training data to help the model learn BCs implicitly, however, there is no guarantee of BC satisfaction by these models during evaluation. In this work, we propose Boundary enforcing Operator Network (BOON) that enables the BC satisfaction of neural operators by making structural changes to the operator kernel. We provide our refinement procedure, and demonstrate the satisfaction of physics-based BCs such as Dirichlet, Neumann, and periodic by the solutions obtained by BOON. Numerical experiments based on multiple PDEs with a wide variety of applications indicate that the proposed approach ensures satisfaction of BCs, and leads to more accurate solutions over the whole domain. The proposed method exhibits a (2X-20X) improvement in accuracy (0.000084 relative L^2 error for Burgers' equation). Code available at: https://github.com/amazon-science/boon.

AdaWAC: Adaptively Weighted Augmentation Consistency Regularization for Volumetric Medical Image Segmentation

Yijun Dong,Yuege Xie,Rachel Ward

Sample reweighting is an effective strategy for learning from training data coming from a mixture of different subpopulations. However, existing reweighting algorithms do not fully take advantage of the particular type of data distribution encountered in volumetric medical image segmentation, where the training data images are uniformly distributed but their associated data labels fall into two subpopulations---"label-sparse" and "label-dense"---depending on whether the data image occurs near the beginning/end of the volumetric scan or the middle. For this setting, we propose AdaWAC as an adaptive weighting algorithm that assigns label-dense samples to supervised cross-entropy loss and label-sparse samples to unsupervised consistency regularization. We provide a convergence guarantee for AdaWAC by appealing to the theory of online mirror descent on saddle point problems. Moreover, we empirically demonstrate that AdaWAC not only enhances segmentation performance and sample efficiency but also improves robustness to the subpopulation shift in labels.

Limitations of the NTK for Understanding Generalization in Deep Learning

Nikhil Vyas,Yamini Bansal,Preetum Nakkiran

The “Neural Tangent Kernel” (NTK) (Jacot et al., 2018), and its empirical variants have been proposed as a proxy to capture certain behaviors of real neural networks. In this work, we study NTKs through the lens of scaling laws, and demonstrate that they fall short of explaining important aspects of neural network generalization. In particular, we demonstrate realistic settings where finite-width neural networks have significantly better data scaling exponents as compared to their corresponding empirical and infinite NTKs at initialization. This reveals a more fundamental difference between the real networks and NTKs, beyond just a few percentage points of test accuracy. Further, we show that even if the empirical NTK is allowed to be pre-trained on a constant number of samples, the kernel scaling does not catch up to the neural network scaling. Finally, we show that the empirical NTK continues to evolve throughout most of the training, in contrast with prior work which suggests that it stabilizes after a few epochs of training. Altogether, our work establishes concrete limitations of the NTK approach in understanding generalization of real networks on natural datasets.

Federated Learning of Large Models at the Edge via Principal Sub-Model Training

Yue Niu,Saurav Prakash,Souvik Kundu,Sunwoo Lee,Salman Avestimehr

Limited compute, memory, and communication capabilities of edge users create a significant bottleneck for federated learning (FL) of large models. Current literature typically tackles the challenge with a heterogeneous client setting or allows training to be offloaded to the server. However, the former requires a fraction of clients to train near-full models, which may not be achievable at the edge; while the latter can compromise privacy with sharing of intermediate representations or labels. In this work, we consider a realistic, but much less explored, cross-device FL setting in which no client has the capacity to train a full large model nor is willing to share any intermediate representations with the server. To this end, we present Principal Sub-Model (PriSM) training methodology, which leverages models’ low-rank structure and kernel orthogonality to train sub-models in the orthogonal kernel space. More specifically, by applying singular value decomposition to original kernels in the server model, PriSM first obtains a set of principal orthogonal kernels with importance weighed by their singular values. Thereafter, PriSM utilizes a novel sampling strategy that selects different subsets of the principal kernels independently to create sub-models for clients with reduced computation and communication requirements. Importantly, a kernel with a large singular value is assigned with a high sampling probability. Thus, each sub-model is a low-rank approximation of the full large model, and all clients together achieve nearly full coverage of the principal kernels. To further improve memory efficiency, PriSM exploits low-rank structure in intermediate representations and allows each sub-model to learn only a subset of them while still preserving training performance. Our extensive evaluations on multiple datasets in various resource-constrained settings demonstrate that PriSM can yield an improved performance of up to 10% compared to existing alternatives, when training sub-models with only 20% principal kernels ($\sim 5\%$ of the full server model.).

Implicit Offline Reinforcement Learning via Supervised Learning

Alexandre Piché,Rafael Pardinas,David Vazquez,Igor Mordatch,Igor Mordatch,Christopher Pal

Offline Reinforcement Learning (RL) via Supervised Learning is a simple and effective way to learn robotic skills from a dataset of varied behaviors. It is as simple as supervised learning and Behavior Cloning (BC) but takes advantage of the return information. On BC tasks, implicit models have been shown to match or outperform explicit ones. Despite the benefits of using implicit models to learn robotic skills via BC, Offline RL via Supervised Learning algorithms have been limited to explicit models. We show how implicit models leverage return information and match or outperform explicit algorithms to acquire robotic skills from fi xed datasets. Furthermore, we show how closely related our implicit methods are to other popular RL via Supervised Learning algorithms.

Augmentation Backdoors

Joseph Rance,Yiren Zhao,Ilia Shumailov,Robert D. Mullins

Data augmentation is used extensively to improve model generalisation. However, reliance on external libraries to implement augmentation methods introduces a vulnerability into the machine learning pipeline. It is well known that backdoors can be inserted into machine learning models through serving a modified dataset to train on. Augmentation therefore presents a perfect opportunity to perform this modification without requiring an initially backdoored dataset. In this paper we present three backdoor attacks that can be covertly inserted into data augmentation. Our attacks each insert a backdoor using a different type of computer vision augmentation transform, covering simple image transforms, GAN-based augmentation, and composition-based augmentation. By inserting the backdoor using these augmentation transforms, we make our backdoors difficult to detect, while still supporting arbitrary backdoor functionality. We evaluate our attacks on a range of computer vision benchmarks and demonstrate that an attacker is able to introduce backdoors through just a malicious augmentation routine.

Neural Radiance Field Codebooks

Matthew Wallingford,Aditya Kusupati,Alex Fang,Vivek Ramanujan,Aniruddha Kembhavi,Roozbeh Mottaghi,Ali Farhadi

Compositional representations of the world are a promising step towards enabling high-level scene understanding and efficient transfer to downstream tasks. Learning such representations for complex scenes and tasks remains an open challenge. Towards this goal, we introduce Neural Radiance Field Codebooks (NRC), a scalable method for learning object-centric representations through novel view reconstruction. NRC learns to reconstruct scenes from novel views using a dictionary of object codes which are decoded through a volumetric renderer. This enables the discovery of reoccurring visual and geometric patterns across scenes which are transferable to downstream tasks. We show that NRC representations transfer well to object navigation in THOR, outperforming 2D and 3D representation learning methods by 3.1\% success rate. We demonstrate that our approach is able to perform unsupervised segmentation for more complex synthetic (THOR) and real scenes (NYU Depth) better than prior methods (.101 ARI). Finally, we show that NRC improves on the task of depth ordering by 5.5% accuracy in THOR.

Generalized Precision Matrix for Scalable Estimation of Nonparametric Markov Networks

Yujia Zheng,Ignavier Ng,Yewen Fan,Kun Zhang

A Markov network characterizes the conditional independence structure, or Markov property, among a set of random variables. Existing work focuses on specific families of distributions (e.g., exponential families) and/or certain structures of graphs, and most of them can only handle variables of a single data type (continuous or discrete). In this work, we characterize the conditional independence structure in general distributions for all data types (i.e., continuous, discrete, and mixed-type) with a Generalized Precision Matrix (GPM). Besides, we also allow general functional relations among variables, thus giving rise to a Markov network structure learning algorithm in one of the most general settings. To deal with the computational challenge of the problem, especially for large graphs, we unify all cases under the same umbrella of a regularized score matching framework. We validate the theoretical results and demonstrate the scalability empirically in various settings.

****

Determinant regularization for Deep Metric Learning

Kun Song,Ruben Solozabal,Martin Taká■,Fakhri Karray

Distance Metric Learning (DML) aims to learn the distance metric that better reflects the semantical similarities in the data. Current \textit{pair-based} and \textit{proxy-based} methods on DML focus on reducing the distance between simila r samples while expanding the distance of dissimilar ones. However, we reveal that shrinking the distance between similar samples may distort the feature space, increasing the distance between points of the same class region and, therefore, harming the generalization of the model. Traditional regularization terms (such as L_2-norm on weights) cannot be adopted to solve this issue as they are based on linear projection. To alleviate this issue, we adopt the structure of normalizing flow as the deep metric layer and calculate the determinant of the Jacobi Matrix as the regularization term. At last, we conduct experiments on several \textit{pair-based} and \textit{proxy-based} algorithms that demonstrate the benefits of our method.

Data-Efficient and Interpretable Tabular Anomaly Detection

Chun-Hao Chang,Jinsung Yoon,Sercan O Arik,Madeleine Udell,Tomas Pfister

Anomaly detection (AD) plays an important role in numerous applications. In this paper, we focus on two understudied aspects of AD that are critical for integration into real-world applications. First, most AD methods cannot incorporate labeled data that are often available in practice in small quantities and can be crucial to achieve high accuracy. Second, most AD methods are not interpretable, a bottleneck that prevents stakeholders from understanding the reason behind the anomalies. In this paper, we propose a novel AD framework, DIAD, that adapts a white-box model class, Generalized Additive Models, to detect anomalies using a partial identification objective which naturally handles noisy or heterogeneous features. DIAD can incorporate a small amount of labeled data to further boost AD performances in semi-supervised settings. We demonstrate the superiority of DIAD compared to previous work in both unsupervised and semi-supervised settings on multiple datasets. We also present explainability capabilities of DIAD, on its rationale behind predicting certain samples as anomalies.

FiT: Parameter Efficient Few-shot Transfer Learning for Personalized and Federated Image Classification

Aliaksandra Shysheya,John F Bronskill,Massimiliano Patacchiola,Sebastian Nowozin,Richard E Turner

Modern deep learning systems are increasingly deployed in situations such as personalization and federated learning where it is necessary to support i) learning on small amounts of data, and ii) communication efficient distributed training protocols. In this work, we develop FiLM Transfer (FiT) which fulfills these requirements in the image classification setting by combining ideas from transfer learning (fixed pretrained backbones and fine-tuned FiLM adapter layers) and meta-learning (automatically configured Naive Bayes classifiers and episodic training) to yield parameter efficient models with superior classification accuracy at low-shot. The resulting parameter efficiency is key for enabling few-shot learning, inexpensive model updates for personalization, and communication efficient federated learning. We experiment with FiT on a wide range of downstream datasets and show that it achieves better classification accuracy than the leading Big Transfer (BiT) algorithm at low-shot and achieves state-of-the art accuracy on the challenging VTAB-1k benchmark, with fewer than 1% of the updateable parameters. Finally, we demonstrate the parameter efficiency and superior accuracy of FiT in distributed low-shot applications including model personalization and federated learning where model update size is an important performance metric.

A Critical Analysis of Out-of-Distribution Detection for Document Understanding

Jiuxiang Gu,Yifei Ming,Yi Zhou,Jason Kuen,Vlad I Morariu,Handong Zhao,Ruiyi Zhang,Nikolaos Barmpalios,Anqi Liu,Yixuan Li,Tong Sun,Ani Nenkova

Large-scale pretraining is widely used in recent document understanding models. During deployment, one may expect that large-scale pretrained models should trigger a conservative fallback policy when encountering out-of-distribution (OOD) samples, which suggests the importance of OOD detection. However, most existing OOD detection methods focus on single-modal inputs such as images or texts. While

documents are multi-modal in nature, it is underexplored if and how multi-modal information in documents can be exploited for OOD detection. In this work, we first provide a systematic and in-depth analysis on OOD detection for document understanding models. We study the effects of model modality, pretraining, and finetuning across various types of OOD inputs. In particular, we find that spatial information is critical for document OOD detection. To better exploit spatial information, we propose a simple yet effective special-aware adapter, which serves as an add-on module to adapt transformer-based language models to document domain. Extensive experiments show that our method consistently improves ID accuracy and OOD detection performance compared to baselines. We hope our findings can help inspire future works on understanding OOD robustness for documents.

Learnable Visual Words for Interpreting Image Recognition Models
Wenxiao Xiao,Zhengming Ding,Hongfu Liu

To interpret deep models' predictions, attention-based visual cues are widely used in addressing *why* deep models make such predictions. Beyond that, the current research community becomes more interested in reasoning *how* deep models make predictions, where some prototype-based methods employ interpretable representations with their corresponding visual cues to reveal the black-box mechanism of deep model behaviors. However, these pioneering attempts only either learn the category-specific prototypes and deteriorate with their generalization ability deterioration or demonstrate several illustrative examples without a quantitative evaluation of visual-based interpretability narrowing their practical usages. In this paper, we revisit the concept of visual words and propose the Learnable Visual Words (LVW) to interpret the model prediction behaviors with two novel modules: semantic visual words learning and dual fidelity preservation. The semantic visual words learning relaxes the category-specific constraint, enabling the generic visual words shared across multiple categories. Beyond employing the visual words for prediction to align visual words with the base model, our dual fidelity preservation also includes the attention-guided semantic alignment that encourages the learned visual words to focus on the same conceptual regions for prediction. Experiments on six visual benchmarks demonstrate the superior effectiveness of our proposed LVW in both accuracy and interpretation fidelity over the state-of-the-art methods. Moreover, we elaborate on various in-depth analyses to further explore the learned visual words and the generalizability of our method for unseen categories.
****

Compact Bilinear Pooling via General Bilinear Projection
Kun Song,Junwei Han,Feiping Nie,Gong Cheng,Bin Gu,Fakhri Karray

Most factorized bilinear pooling (FBiP) employs Hadamard product-based bilinear projection to learn appropriate projecting directions to reduce the dimension of bilinear features. However, in this paper, we reveal that the Hadamard product-based bilinear projection makes FBiP miss a lot of possible projecting directions, which will significantly harm the performance of outputted compact bilinear features, including compactness and effectiveness. To address this issue, we propose a general matrix-based bilinear projection based on the rank-k matrix base decomposition, where the Hadamard-based bilinear projection is a special case of our proposed one. Using the proposed bilinear projection, we design a novel low-rank factorized bilinear pooling (named RK-FBP), which does not miss any projecting directions. Thus, our RK-FBP can generate better compact bilinear features. To leverage high-order information in local features, we nest several RK-FBP modules together to formulate a multi-linear pooling that outputs compact multi-linear features. At last, we conduct experiments on several fine-grained image tasks to evaluate our models. The experiments show that our models achieve new state-of-the-art classification accuracy by the lowest dimension.

AANG : Automating Auxiliary Learning
Lucio M. Dery,Paul Michel,Mikhail Khodak,Graham Neubig,Ameet Talwalkar

Auxiliary objectives, supplementary learning signals that are introduced to help aid learning on data-starved or highly complex end-tasks, are commonplace in ma chine learning. Whilst much work has been done to formulate useful auxiliary objectives, their construction is still an art which proceeds by slow and tedious hand-design. Intuition for how and when these objectives improve end-task performance has also had limited theoretical backing. In this work, we present an approach for automatically generating a suite of auxiliary objectives. We achieve this by deconstructing existing objectives within a novel unified taxonomy, identifying connections between them, and generating new ones based on the uncovered structure. Next, we theoretically formalize widely-held intuitions about how auxiliary learning improves generalization on the end-task. This leads us to a principled and efficient algorithm for searching the space of generated objectives to find those most useful to a specified end-task.

With natural language processing (NLP) as our domain of study, we demonstrate that our automated auxiliary learning pipeline leads to strong improvements over competitive baselines across continued training experiments on a pre-trained model on 5 NLP end-tasks.

Discrete Contrastive Diffusion for Cross-Modal Music and Image Generation

Ye Zhu,Yu Wu,Kyle Olszewski,Jian Ren,Sergey Tulyakov,Yan Yan

Diffusion probabilistic models (DPMs) have become a popular approach to conditional generation, due to their promising results and support for cross-modal synthesis. A key desideratum in conditional synthesis is to achieve high correspondence between the conditioning input and generated output. Most existing methods learn such relationships implicitly, by incorporating the prior into the variational lower bound. In this work, we take a different route---we explicitly enhance input-output connections by maximizing their mutual information. To this end, we introduce a Conditional Discrete Contrastive Diffusion (CDCD) loss and design two contrastive diffusion mechanisms to effectively incorporate it into the denoising process, combining the diffusion training and contrastive learning for the first time by connecting it with the conventional variational objectives. We demonstrate the efficacy of our approach in evaluations with diverse multimodal conditional synthesis tasks: dance-to-music generation, text-to-image synthesis, as well as class-conditioned image synthesis. On each, we enhance the input-output correspondence and achieve higher or competitive general synthesis quality. Furthermore, the proposed approach improves the convergence of diffusion models, reducing the number of required diffusion steps by more than 35% on two benchmarks, significantly increasing the inference speed.

Diffusion Probabilistic Modeling of Protein Backbones in 3D for the motif-scaffolding problem

Brian L. Trippe,Jason Yim,Doug Tischer,David Baker,Tamara Broderick,Regina Barzilay,Tommi S. Jaakkola

Construction of a scaffold structure that supports a desired motif, conferring protein function, shows promise for the design of vaccines and enzymes. But a general solution to this motif-scaffolding problem remains open. Current machine-learning techniques for scaffold design are either limited to unrealistically small scaffolds (up to length 20) or struggle to produce multiple diverse scaffolds. We propose to learn a distribution over diverse and longer protein backbone structures via an E(3)-equivariant graph neural network. We develop SMCDiff to efficiently sample scaffolds from this distribution conditioned on a given motif; our algorithm is the first to theoretically guarantee conditional samples from a diffusion model in the large-compute limit. We evaluate our designed backbones by how well they align with AlphaFold2-predicted structures. We show that our method can (1) sample scaffolds up to 80 residues and (2) achieve structurally diverse scaffolds for a fixed motif.

NeRF-SOS: Any-View Self-supervised Object Segmentation on Complex Scenes

Zhiwen Fan,Peihao Wang,Yifan Jiang,Xinyu Gong,Dejia Xu,Zhangyang Wang

Neural volumetric representations have shown the potential that Multi-layer Perceptrons (MLPs) can be optimized with multi-view calibrated images to represent scene geometry and appearance without explicit 3D supervision. Object segmentatio n can enrich many downstream applications based on the learned radiance field. However, introducing hand-crafted segmentation to define regions of interest in a complex real-world scene is non-trivial and expensive as it acquires per view annotation. This paper carries out the exploration of self-supervised learning for object segmentation using NeRF for complex real-world scenes. Our framework, called NeRF with Self-supervised Object Segmentation (NeRF-SOS), couples object segmentation and neural radiance field to segment objects in any view within a scene. By proposing a novel collaborative contrastive loss in both appearance and geometry levels, NeRF-SOS encourages NeRF models to distill compact geometry-aware segmentation clusters from their density fields and the self-supervised pre-trained 2D visual features. The self-supervised object segmentation framework can be applied to various NeRF models that both lead to photo-realistic rendering results and convincing segmentation maps for both indoor and outdoor scenarios. Extensive results on the LLFF, BlendedMVS, CO3Dv2, and Tank & Temples datasets validate the effectiveness of NeRF-SOS. It consistently surpasses other 2D-based self-supervised baselines and predicts finer object masks than existing supervised counterparts.

****

RbX: Region-based explanations of prediction models
Ismael Lemhadri,Harrison H Li,Trevor Hastie

We introduce region-based explanations (RbX), a novel, model-agnostic method to generate local explanations of scalar outputs from a black-box prediction model using only query access. RbX is based on a greedy algorithm for building a convex polytope that approximates a region of feature space where model predictions are close to the prediction at some target point. This region is fully specified by the user on the scale of the predictions, rather than on the scale of the features. The geometry of this polytope - specifically the change in each coordinate necessary to escape the polytope - quantifies the local sensitivity of the predictions to each of the features. These “escape distances” can then be standardized to rank the features by local importance. RbX is guaranteed to satisfy a “sparsity” axiom, which requires that features which do not enter into the prediction model are assigned zero importance. At the same time, real data examples and synthetic experiments show how RbX can more readily detect all locally relevant features than existing methods.

****

Rethinking Graph Lottery Tickets: Graph Sparsity Matters
Bo Hui,Da Yan,Xiaolong Ma,Wei-Shinn Ku

Lottery Ticket Hypothesis (LTH) claims the existence of a winning ticket (i.e., a properly pruned sub-network together with original weight initialization) that can achieve competitive performance to the original dense network. A recent work, called UGS, extended LTH to prune graph neural networks (GNNs) for effectively accelerating GNN inference. UGS simultaneously prunes the graph adjacency matrix and the model weights using the same masking mechanism, but since the roles of the graph adjacency matrix and the weight matrices are very different, we find that their sparsifications lead to different performance characteristics. Specifically, we find that the performance of a sparsified GNN degrades significantly when the graph sparsity goes beyond a certain extent. Therefore, we propose two techniques to improve GNN performance when the graph sparsity is high. First, UGS prunes the adjacency matrix using a loss formulation which, however, does not properly involve all elements of the adjacency matrix; in contrast, we add a new auxiliary loss head to better guide the edge pruning by involving the entire adjacency matrix. Second, by regarding unfavorable graph sparsification as adversarial data perturbations, we formulate the pruning process as a min-max optimization problem to gain the robustness of lottery tickets when the graph sparsity is high. We further investigate the question: Can the ``retrainable'' winning ticket of a GNN be also effective for graph transferring learning? We call it the transferable graph lottery ticket (GLT) hypothesis. Extensive experiments were conducted which demonstrate the superiority of our proposed sparsification method over UGS, and which empirically verified our transferable GLT hypothesis.

The Impact of Approximation Errors on Warm-Start Reinforcement Learning: A Finite-time Analysis
Hang Wang,Sen Lin,Junshan Zhang

Warm-Start reinforcement learning (RL), aided by a prior policy obtained from offline training, is emerging as a promising RL approach for practical applications. Recent empirical studies have demonstrated that the performance of Warm-Start RL can be improved \textit{quickly} in some cases but become \textit{stagnant} in other cases, calling for a fundamental understanding, especially when the function approximation is used. To fill this void, we take a finite time analysis approach to quantify the impact of approximation errors on the learning performance of Warm-Start RL. Specifically, we consider the widely used Actor-Critic (A-C) method with a prior policy. We first quantify the approximation errors in the Actor update and the Critic update, respectively. Next, we cast the Warm-Start A-C algorithm   as Newton's method with perturbation, and study the impact of the approximation errors on the finite-time learning performance with inaccurate Actor/Critic updates. Under some general technical conditions, we obtain lower bounds on the sub-optimality gap of the Warm-Start A-C algorithm to quantify the impact of the bias and error propagation. We also derive the upper bounds, which provide insights on achieving the desired finite-learning performance in the Warm-Start A-C algorithm.

****

NeRN: Learning Neural Representations for Neural Networks
Maor Ashkenazi,Zohar Rimon,Ron Vainshtein,Shir Levi,Elad Richardson,Pinchas Mintz,Eran Treister

Neural Representations have recently been shown to effectively reconstruct a wide range of signals from 3D meshes and shapes to images and videos. We show that, when adapted correctly, neural representations can be used to directly represent the weights of a pre-trained convolutional neural network, resulting in a Neural Representation for Neural Networks (NeRN). Inspired by coordinate inputs of previous neural representation methods, we assign a coordinate to each convolutional kernel in our network based on its position in the architecture, and optimize a predictor network to map coordinates to their corresponding weights. Similarly to the spatial smoothness of visual scenes, we show that incorporating a smoothness constraint over the original network's weights aids NeRN towards a better reconstruction. In addition, since slight perturbations in pre-trained model weights can result in a considerable accuracy loss, we employ techniques from the field of knowledge distillation to stabilize the learning process. We demonstrate the effectiveness of NeRN in reconstructing widely used architectures on CIFAR-10, CIFAR-100, and ImageNet. Finally, we present two applications using NeRN, demonstrating the capabilities of the learned representations.

Private Federated Learning Without a Trusted Server: Optimal Algorithms for Convex Losses
Andrew Lowy,Meisam Razaviyayn

This paper studies federated learning (FL)—especially cross-silo FL—with data from people who do not trust the server or other silos. In this setting, each silo (e.g. hospital) has data from different people (e.g. patients) and must maintain the privacy of each person’s data (e.g. medical record), even if the server or other silos act as adversarial eavesdroppers. This requirement motivates the study of Inter-Silo Record-Level Differential Privacy (ISRL-DP), which requires silo i’s communications to satisfy record/item-level differential privacy (DP). ISRL-DP ensures that the data of each person (e.g. patient) in silo i (e.g. hospital i) cannot be leaked. ISRL-DP is different from well-studied privacy notions. Central and user-level DP assume that people trust the server/other silos. On the other end of the spectrum, local DP assumes that people do not trust anyone at all (even their own silo). Sitting between central and local DP, ISRL-DP makes the realistic assumption (in cross-silo FL) that people trust their own silo, but not the server or other silos. In this work, we provide tight (up to logarithms) upper and lower bounds for ISRL-DP FL with convex/strongly convex loss functions and homogeneous (i.i.d.) silo data. Remarkably, we show that similar b

ounds are attainable for smooth losses with arbitrary heterogeneous silo data distributions, via an accelerated ISRL-DP algorithm. We also provide tight upper and lower bounds for ISRL-DP federated empirical risk minimization, and use acceleration to attain the optimal bounds in fewer rounds of communication than the state-of-the-art. Finally, with a secure “shuffler” to anonymize silo messages (but without a trusted server), our algorithm attains the optimal central DP rates under more practical trust assumptions. Numerical experiments show favorable privacy-accuracy tradeoffs for our algorithm in classification and regression tasks.

3D-Aware Video Generation
Sherwin Bahmani,Jeong Joon Park,Despoina Paschalidou,Hao Tang,Gordon Wetzstein,Leonidas Guibas,Luc Van Gool,Radu Timofte
Generative models have emerged as an essential building block for many image synthesis and editing tasks. Recent advances in this field have also enabled high-quality 3D or video content to be generated that exhibits either multi-view or temporal consistency. With our work, we explore 4D generative adversarial networks (GANs) that learn unconditional generation of 3D-aware videos. By combining neural implicit representations with time-aware discriminator, we develop a GAN framework that synthesizes 3D video supervised only with monocular videos. We show that our method learns a rich embedding of decomposable 3D structures and motions that enables new visual effects of spatio-temporal renderings while producing imagery with quality comparable to that of existing 3D or video GANs.

Joint rotational invariance and adversarial training of a dual-stream Transformer yields state of the art Brain-Score for Area V4
William Berrios,Arturo Deza
Modern high-scoring models of vision in the brain score competition do not stem from Vision Transformers. However, in this paper, we provide evidence against the unexpected trend of Vision Transformers (ViT) being not perceptually aligned with human visual representations by showing how a dual-stream Transformer, a CrossViT $~\textit{a la}$ Chen et. al. (2021), under a joint rotationally-invariant and adversarial optimization procedure yields 2nd place in the aggregate Brain-Score 2022 competition (Schrimpf et al., 2020b) averaged across all visual categories, and at the time of the competition held 1st place for the highest explainable variance of area V4. In addition, our current Transformer-based model also achieves greater explainable variance for areas V4, IT, and Behaviour than a biologically-inspired CNN (ResNet50) that integrates a frontal V1-like computation module (Dapello et al., 2020). To assess the contribution of the optimization scheme with respect to the CrossViT architecture, we perform several additional experiments on differently optimized CrossViT's regarding adversarial robustness, common corruption benchmarks, mid-ventral stimuli interpretation, and feature inversion. Against our initial expectations, our family of results provides tentative support for an $\textit{``All roads lead to Rome''}$ argument enforced via a joint optimization rule even for non biologically-motivated models of vision such as Vision Transformers.

AutoSparse: Towards Automated Sparse Training
Abhisek Kundu,Naveen Mellempudi,Dharma Teja Vooturi,Bharat Kaul,Pradeep Dubey
Sparse training is emerging as a promising avenue for reducing the computational cost of training neural networks. Several recent studies have proposed pruning methods using learnable thresholds to efficiently explore the non-uniform distribution of sparsity inherent within the models. In this paper, we propose Gradient Annealing (GA), a gradient driven approach where gradients to pruned out weights are scaled down in a non-linear manner. GA eliminates the need for additional sparsity-inducing regularization by providing an elegant trade-off between sparsity and accuracy. We integrated GA with the latest learnable threshold based pruning methods to create an automated sparse training algorithm called AutoSparse. Our algorithm achieves state-of-the-art accuracy with 80% sparsity for ResNet50 and 75% sparsity for MobileNetV1 on Imagenet-1K. AutoSparse also results in 7

× reduction in inference FLOPS and > 2× reduction in training FLOPS for ResNet50 on ImageNet at 80% sparsity. Finally, GA generalizes well to fixed-budget (Top-K, 80%) sparse training methods, improving the accuracy of ResNet50 on Imagenet-1K, to outperform TopKAST+PP by 0.3%.

Learning to Communicate using Contrastive Learning
Yat Long Lo,Biswa Sengupta,Jakob Nicolaus Foerster,Michael Noukhovitch
Communication is a powerful tool for coordination in multi-agent RL. Inducing an effective, common language has been a difficult challenge, particularly in the decentralized setting. In this work, we introduce an alternative perspective where communicative messages sent between agents are considered as different incomplete views of the environment state. Based on this perspective, we propose to learn to communicate using contrastive learning by maximizing the mutual information between messages of a given trajectory. In communication-essential environments, our method outperforms previous work in both performance and learning speed. Using qualitative metrics and representation probing, we show that our method induces more symmetric communication and captures task-relevant information from the environment. Finally, we demonstrate promising results on zero-shot communication, a first for MARL. Overall, we show the power of contrastive learning, and self-supervised learning in general, as a method for learning to communicate.

Cheap Talk Discovery and Utilization in Multi-Agent Reinforcement Learning
Yat Long Lo,Christian Schroeder de Witt,Samuel Sokota,Jakob Nicolaus Foerster,Shimon Whiteson
By enabling agents to communicate, recent cooperative multi-agent reinforcement learning (MARL) methods have demonstrated better task performance and more coordinated behavior. Most existing approaches facilitate inter-agent communication by allowing agents to send messages to each other through free communication channels, i.e., \emph{cheap talk channels}. Current methods require these channels to be constantly accessible and known to the agents a priori. In this work, we lift these requirements such that the agents must discover the cheap talk channels and learn how to use them. Hence, the problem has two main parts: \emph{cheap talk discovery} (CTD) and \emph{cheap talk utilization} (CTU). We introduce a novel conceptual framework for both parts and develop a new algorithm based on mutual information maximization that outperforms existing algorithms in CTD/CTU settings. We also release a novel benchmark suite to stimulate future research in CTD/CTU.

Motif-induced Graph Normalization
Kaixuan Chen,Shunyu Liu,Tongtian Zhu,Tongya Zheng,Haofei Zhang,Jie Song,Mingli Song
Graph Neural Networks (GNNs) have emerged as a powerful category of learning architecture for handling graph-structured data in the non-Euclidean domain. Despite their success, existing GNNs typically suffer from the insufficient expressive power bottlenecked by Weisfeiler-Lehman (WL) test, and meanwhile are prone to the over-smoothing situation with increasing layer numbers. In this paper, we strive to strengthen the discriminative capabilities of GNNs by devising a dedicated plug-and-play normalization scheme, termed as Motif-induced Normalization (MotifNorm), that explicitly considers the intra-connection information within each node-induced subgraph. To this end, we embed the motif-induced structural weights at the beginning and the end of the standard BatchNorm, as well as incorporate the graph instance-specific statistics for improved distinguishable capabilities. In the meantime, we provide the theoretical analysis to support that, with the proposed elaborated MotifNorm, an arbitrary GNNs is capable of more expressive abilities than the 1-WL test in distinguishing k-regular graphs. Furthermore, the proposed MotifNorm scheme is also exemplified to be able to alleviate the over-smoothing phenomenon. Experimental results on ten popular benchmarks across all the tasks of the graph-, node-, as well as link-level property predictions, demonstrate the effectiveness of the proposed method. Our code is made available in the supplementary material.

Stochastic Gradient Methods with Preconditioned Updates

Abdurakhmon Sadiev,Aleksandr Beznosikov,Dmitry Kamzolov,Rachael Tappenden,Martin Taká■

This work considers non-convex finite sum minimization. There are a number of algorithms for such problems, but existing methods often work poorly when the problem is badly scaled and/or ill-conditioned, and a primary goal of this work is to introduce methods that alleviate this issue. Thus, here we include a preconditioner that is based upon Hutchinson's approach to approximating the diagonal of the Hessian, and couple it with several gradient based methods to give new `scaled' algorithms: Scaled SARAH and Scaled L-SVRG. Theoretical complexity guarantees under smoothness assumptions are presented, and we prove linear convergence when both smoothness and the PL-condition is assumed. Because our adaptively scaled methods use approximate partial second order curvature information, they are better able to mitigate the impact of badly scaled problems, and this improved practical performance is demonstrated in the numerical experiments that are also presented in this work.

Reversible Column Networks

Yuxuan Cai,Yizhuang Zhou,Qi Han,Jianjian Sun,Xiangwen Kong,Jun Li,Xiangyu Zhang

We propose a new neural network design paradigm Reversible Column Network (RevCol). The main body of RevCol is composed of multiple copies of subnetworks, named columns respectively, between which multi-level reversible connections are employed. Such architectural scheme attributes RevCol very different behavior from conventional networks: during forward propagation, features in RevCol are learned to be gradually disentangled when passing through each column, whose total information is maintained rather than compressed or discarded as other network does. Our experiments suggest that CNN-style RevCol models can achieve very competitive performances on multiple computer vision tasks such as image classification, object detection and semantic segmentation, especially with large parameter budget and large dataset. For example, after ImageNet-22K pre-training, RevCol-XL obtains 88.2% ImageNet-1K accuracy. Given more pre-training data, our largest model RevCol-H reaches 90.0% on ImageNet-1K, 63.8% AP$_{box}$ on COCO detection minival set, 61.0% mIoU on ADE20k segmentation. To our knowledge, it is the best COCO detection and ADE20k segmentation result among pure (static) CNN models. Moreover, as a general macro architecture fashion, RevCol can also be introduced into transformers or other neural networks, which is demonstrated to improve the performances in both computer vision and NLP tasks.
We release code and models at https://github.com/megvii-research/RevCol

Formal Mathematics Statement Curriculum Learning

Stanislas Polu,Jesse Michael Han,Kunhao Zheng,Mantas Baksys,Igor Babuschkin,Ilya Sutskever

We explore the use of expert iteration in the context of language modeling applied to formal mathematics. We show that at same compute budget, expert iteration, by which we mean proof search interleaved with learning, dramatically outperforms proof search only. We also observe that when applied to a collection of formal statements of sufficiently varied difficulty, expert iteration is capable of finding and solving a curriculum of increasingly difficult problems, without the need for associated ground-truth proofs. Finally, by applying this expert iteration to a manually curated set of problem statements, we surpass previous state-of-the-art on the miniF2F benchmark, automatically solving multiple challenging problems drawn from high school olympiads.

A Unified Causal View of Domain Invariant Representation Learning

Zihao Wang,Victor Veitch

Machine learning methods can be unreliable when deployed in domains that differ from the domains on which they were trained. One intuitive approach for addressing this is to learn representations of data that are domain-invariant in the sense that they preserve data structure that is stable across domains, but throw ou t spuriously-varying parts. There are many approaches aimed at this kind of representation-learning, including methods based on data augmentation, distributional invariances, and risk invariance. Unfortunately, it is often unclear when a given method actually learns domain-invariant structure, and whether learning domain-invariant structure actually yields robust models. The key issue is that, in general, it's unclear how to formalize ``domain-invariant structure''. The purpose of this paper is to study these questions in the context of a particular natural domain shift notion that admits a natural formal notion of domain invariance.

This notion is a formalization of the idea that causal relationships are invariant, but non-causal relationships (e.g., due to confounding) may vary. We find that whether a given method learns domain-invariant structure, and whether this leads to robust prediction, both depend critically on the true underlying causal structure of the data.

PIPS: Path Integral Stochastic Optimal Control for Path Sampling in Molecular Dynamics

Lars Holdijk,Yuanqi Du,Ferry Hooft,Priyank Jaini,Bernd Ensing,Max Welling

We consider the problem of Sampling Transition Paths: Given two metastable conformational states of a molecular system, \eg\ a folded and unfolded protein, we aim to sample the most likely transition path between the two states. Sampling such a transition path is computationally expensive due to the existence of high free energy barriers between the two states. To circumvent this, previous work has focused on simplifying the trajectories to occur along specific molecular descriptors called Collective Variables (CVs). However, finding CVs is non trivial and requires chemical intuition. For larger molecules, where intuition is not sufficient, using these CV-based methods biases the transition along possibly irrelevant dimensions. In this work, we propose a method for sampling transition paths that considers the entire geometry of the molecules. We achieve this by relating the problem to recent works on the Schr\"odinger bridge problem and stochastic optimal control. Using this relation, we construct a path integral method that incorporates important characteristics of molecular systems such as second-order dynamics and invariance to rotations and translations. We demonstrate our method on commonly studied protein structures like Alanine Dipeptide, and also consider larger proteins such as Polyproline and Chignolin.

ID and OOD Performance Are Sometimes Inversely Correlated on Real-world Datasets

Damien Teney,LIN Yong,Seong Joon Oh,Ehsan Abbasnejad

Several studies have empirically compared in-distribution (ID) and out-of-distribution (OOD) performance of various models. They report frequent positive correlations on benchmarks in computer vision and NLP. Surprisingly, they never observe inverse correlations suggesting necessary trade-offs. This matters to determine whether ID performance can serve as a proxy for OOD generalization. This paper shows that inverse correlations between ID and OOD performance do happen in real-world benchmarks. They could be missed in past studies because of a biased selection of models. We show an example on the WILDS-Camelyon17 dataset, using models from multiple training epochs and random seeds. Our observations are particularly striking with models trained with a regularizer that diversifies the solutions to the ERM objective. We nuance recommendations and conclusions made in past studies. (1) High OOD performance may sometimes require trading off ID performance.(2) Focusing on ID performance alone may not lead to optimal OOD performance: it can lead to diminishing and eventually negative returns in OOD performance. (3) Our example reminds that empirical studies only chart regimes achievable with existing methods: care is warranted in deriving prescriptive recommendations.

Visual Transformation Telling

Xin Hong,Yanyan Lan,Liang Pang,Jiafeng Guo,Xueqi Cheng

In this paper, we propose a new visual reasoning task, called Visual Transformation Telling (VTT). Given a series of states (i.e.~images), a machine is required to describe what happened (i.e.~transformation) between every two adjacent stat es. Different from most existing visual reasoning tasks, which focus on state reasoning, VTT concentrates on transformation reasoning. Moreover, describing the transformation in the form of language is more natural and closer to the real application than the property change way in the previous TVR task. We collect 13,547 samples from two instructional video datasets, i.e.~CrossTask and COIN, and extract desired states and transformation descriptions to form a suitable VTT benchmark dataset. After that, we introduce an end-to-end learning model for VTT, named TTNet. TTNet consists of three components to mimic human's cognition process of reasoning transformation. First, an image encoder, e.g. CLIP, reads content from each image, then a context encoder links the image content together, and at last, a transformation decoder autoregressively generates transformation descriptions between every two adjacent images. This basic version of TTNet is difficult to meet the cognitive challenge of VTT, that is to identify abstract transformations from images with small visual differences, and the descriptive challenge, which asks to describe the transformation consistently. In response to these difficulties, we propose three strategies to improve TTNet. Specifically, TTNet leverages difference features to emphasize small visual gaps, masked transformation model to stress context by forcing attention to neighbor transformations, and auxiliary category and topic classification tasks to make transformations consistent by sharing underlying semantics among representations. We adapt some typical methods from visual storytelling and dense video captioning tasks, considering their similarity with VTT. Our experimental results show that TTNet achieves better performance on transformation reasoning. In addition, our empirical analysis demonstrates the soundness of each module in TTNet, and provides some insight into transformation reasoning.

Predicting Antimicrobial MICs for Nontyphoidal Salmonella Using Multitask Representations Learning

Teng Lin

The antimicrobial resistance (AMR) pathogens have become an increasingly worldwide issue, posing a significant threat to global public health. To obtain an optimized therapeutic effect, the antibiotic sensitivity is usually evaluated in a clinical setting, whereas traditional culture-dependent antimicrobial sensitivity tests are labor-intensive and relatively slow. Rapid methods can greatly optimize antimicrobial therapeutic strategies and improve patient outcomes by reducing the time it takes to test antibiotic sensitivity. The booming development of sequencing technology and machine learning techniques provide promising alternative approaches for antimicrobial resistance prediction based on sequencing. In this study, we used a lightweight Multitask Learning Transformer to predict the MIC of 14 antibiotics for Salmonella strains based on the genomic information, including point mutations, pan-genome structure, and the profile of antibiotic resistance genes from 5,278 publicly available whole genomes of nontyphoidal Salmonella. And we got better prediction results (improved more than 10% for raw accuracy and 3% for accuracy within ±1 2-fold dilution step) and provided better interpretability than the other ML models. Besides the potential clinical application, our models would cast light on mechanistic understanding of key genetic regions influencing AMR.

Bootstrap Motion Forecasting With Self-Consistent Constraints

Maosheng Ye,jiamiao xu,xunnong xu,Tengfei Wang,Tongyi Cao,Qifeng Chen

We present a novel framework to bootstrap Motion forecasting with self-consistent constraints (MISC). The motion forecasting task aims at predicting future trajectories of vehicles by incorporating spatial and temporal information from the past. A key design of MISC is the proposed Dual Consistency Constraints that regularize the predicted trajectories under spatial and temporal perturbation during training. Also, to model the multi-modality in motion forecasting, we design a novel self-ensembling scheme to obtain accurate teacher targets to enforce the self-constraints with multi-modality supervision. With explicit constraints from multiple teacher targets, we observe a clear improvement in the prediction performance. Extensive experiments on the Argoverse motion forecasting benchmark sh

ow that MISC significantly outperforms the state-of-the-art methods. As the proposed strategies are general and can be easily incorporated into other motion forecasting approaches, we also demonstrate that our proposed scheme consistently improves the prediction performance of several existing methods.

Learning to Split for Automatic Bias Detection

Yujia Bao,Regina Barzilay

Classifiers are biased when trained on biased datasets. As a remedy, we propose Learning to Split (ls), an algorithm for automatic bias detection. Given a dataset with input-label pairs, ls learns to split this dataset so that predictors trained on the training split cannot generalize to the testing split. This performance gap suggests that the testing split is under-represented in the dataset, which is a signal of potential bias. Identifying non-generalizable splits is challenging since we have no annotations about the bias. In this work, we show that the prediction correctness of each example in the testing split can be used as a source of weak supervision: generalization performance will drop if we move examples that are predicted correctly away from the testing split, leaving only those that are mispredicted. ls is task-agnostic and can be applied to any supervised learning problem, ranging from natural language understanding and image classification to molecular property prediction. Empirical results show that ls is able to generate astonishingly challenging splits that correlate with human-identified biases. Moreover, we demonstrate that combining robust learning algorithms (such as group DRO) with splits identified by ls enables automatic de-biasing. Compared to previous state-of-the-art, we substantially improve the worst-group performance (23.4% on average) when the source of biases is unknown during training and validation. Our code is included in the supplemental materials and will be publicly available.
****

Modeling Multimodal Aleatoric Uncertainty in Segmentation with Mixture of Stochastic Experts

Zhitong Gao,Yucong Chen,Chuyu Zhang,Xuming He

Equipping predicted segmentation with calibrated uncertainty is essential for safety-critical applications. In this work, we focus on capturing the data-inherent uncertainty (aka aleatoric uncertainty) in segmentation, typically when ambiguities exist in input images. Due to the high-dimensional output space and potential multiple modes in segmenting ambiguous images, it remains challenging to predict well-calibrated uncertainty for segmentation. To tackle this problem, we propose a novel mixture of stochastic experts (MoSE) model, where each expert network estimates a distinct mode of the aleatoric uncertainty and a gating network predicts the probabilities of an input image being segmented in those modes. This yields an efficient two-level uncertainty representation. To learn the model, we develop a Wasserstein-like loss that directly minimizes the distribution distance between the MoSE and ground truth annotations. The loss can easily integrate traditional segmentation quality measures and be efficiently optimized via constraint relaxation. We validate our method on the LIDC-IDRI dataset and a modified multimodal Cityscapes dataset. Results demonstrate that our method achieves the state-of-the-art or competitive performance on all metrics.
****

On the Robustness of Safe Reinforcement Learning under Observational Perturbations

Zuxin Liu,Zijian Guo,Zhepeng Cen,Huan Zhang,Jie Tan,Bo Li,Ding Zhao

Safe reinforcement learning (RL) trains a policy to maximize the task reward while satisfying safety constraints. While prior works focus on the performance optimality, we find that the optimal solutions of many safe RL problems are not robust and safe against carefully designed observational perturbations. We formally analyze the unique properties of designing effective observational adversarial attackers in the safe RL setting. We show that baseline adversarial attack techniques for standard RL tasks are not always effective for safe RL and propose two new approaches - one maximizes the cost and the other maximizes the reward. One interesting and counter-intuitive finding is that the maximum reward attack i s strong, as it can both induce unsafe behaviors and make the attack stealthy by maintaining the reward. We further propose a robust training framework for safe RL and evaluate it via comprehensive experiments. This paper provides a pioneer work to investigate the safety and robustness of RL under observational attacks for future safe RL studies. Code is available at: \url{https://github.com/liuzuxin/safe-rl-robustness}

Behind the Scenes of Gradient Descent: A Trajectory Analysis via Basis Function Decomposition

Jianhao Ma,Lingjun Guo,Salar Fattahi

This work analyzes the solution trajectory of gradient-based algorithms via a novel basis function decomposition. We show that, although solution trajectories of gradient-based algorithms may vary depending on the learning task, they behave almost monotonically when projected onto an appropriate orthonormal function basis. Such projection gives rise to a basis function decomposition of the solution trajectory. Theoretically, we use our proposed basis function decomposition to establish the convergence of gradient descent (GD) on several representative learning tasks. In particular, we improve the convergence of GD on symmetric matrix factorization and provide a completely new convergence result for the orthogonal symmetric tensor decomposition. Empirically, we illustrate the promise of our proposed framework on realistic deep neural networks (DNNs) across different architectures, gradient-based solvers, and datasets. Our key finding is that gradient-based algorithms monotonically learn the coefficients of a particular orthonormal function basis of DNNs defined as the eigenvectors of the conjugate kernel after training.

What Is Missing in IRM Training and Evaluation? Challenges and Solutions

Yihua Zhang,Pranay Sharma,Parikshit Ram,Mingyi Hong,Kush R. Varshney,Sijia Liu

Invariant risk minimization (IRM) has received increasing attention as a way to acquire environment-agnostic data representations and predictions, and also a principled solution for preventing spurious correlations from being learned and improving models’ out-of-distribution generalization. Yet, recent works have found that the optimality of the originally-proposed IRM optimization (IRMV1) may be compromised in practice or could be impossible to achieve in some scenarios. Therefore, a series of advanced IRM algorithms have been developed that show practical improvement over IRMV1. In this work, we revisit these recent IRM advancements and identify and resolve three practical limitations in IRM training and evaluation. First, we find that the effect of batch size during training has been chronically overlooked in previous studies, leaving room for further improvement. We propose small-batch training and highlight the improvements over a set of large-batch optimization techniques. Second, we find that improper selection of evaluation environments could give a false sense of invariance for IRM. To alleviate this effect, we leverage diversified test-time environments to precisely characterize the invariance of IRM when applied in practice. Third, we revisit Ahuja et al. (2020)’s proposal to convert IRM into an ensemble game and identify a limitation when a single invariant predictor is desired instead of an ensemble of individual predictors. We propose a new IRM variant to address this limitation based on a novel viewpoint of ensemble IRM games as consensus-constrained bi-level optimization. Lastly, we conduct extensive experiments (covering 7 existing IRM variants and 7 datasets) to justify the practical significance of revisiting IRM training and evaluation in a principled manner.

Neural Decoding of Visual Imagery via Hierarchical Variational Autoencoders

Eleni Miliotou,Panagiotis Kyriakis,Jason D Hinman,Andrei Irimia,Paul Bogdan

Reconstructing natural images from fMRI recordings is a challenging task of great importance in neuroscience. The current architectures are bottlenecked because they fail to effectively capture the hierarchical processing of visual stimuli that takes place in the human brain. Motivated by that fact, we introduce a novel neural network architecture for the problem of neural decoding. Our architecture uses Hierarchical Variational Autoencoders (HVAEs) to learn meaningful repres entations of natural images and leverages their latent space hierarchy to learn voxel-to-image mappings. By mapping the early stages of the visual pathway to the first set of latent variables and the higher visual cortex areas to the deeper layers in the latent hierarchy, we are able to construct a latent variable neural decoding model that replicates the hierarchical visual information processing. Our model achieves better reconstructions compared to the state of the art and our ablation study indicates that the hierarchical structure of the latent space is responsible for that performance.

Cooperative Adversarial Learning via Closed-Loop Transcription
Rui Xiao,Xinyu Zhao

This paper proposes a generative model that implements cooperative adversarial learning via closed-loop transcription. In the generative model training, the encoder and decoder are trained simultaneously, and not only the adversarial process but also a cooperative process is included. In the adversarial process, the encoder plays as a critic to maximize the distance between the original and transcribed images, in which the distance is measured by rate reduction in the feature space; in the cooperative process, the encoder and the decoder cooperatively minimize the distance to improve the transcription quality. Cooperative adversarial learning possesses the concepts and properties of Auto-Encoding and GAN, and it is unique in that the encoder actively controls the training process as it is trained in both learning processes in two different roles. Experiments demonstrate that without regularization techniques, our generative model is robust to net architectures and easy to train, sample-wise reconstruction performs well in terms of sample features, and disentangled visual attributes are well modeled in independent principal components.

Multi-task Self-supervised Graph Neural Networks Enable Stronger Task Generalization
Mingxuan Ju,Tong Zhao,Qianlong Wen,Wenhao Yu,Neil Shah,Yanfang Ye,Chuxu Zhang

Self-supervised learning (SSL) for graph neural networks (GNNs) has attracted increasing attention from the graph machine learning community in recent years, owing to its capability to learn performant node embeddings without costly label information. One weakness of conventional SSL frameworks for GNNs is that they learn through a single philosophy, such as mutual information maximization or generative reconstruction. When applied to various downstream tasks, these frameworks rarely perform equally well for every task, because one philosophy may not span the extensive knowledge required for all tasks. To enhance the task generalization across tasks, as an important first step forward in exploring fundamental graph models, we introduce PARETOGNN, a multi-task SSL framework for node representation learning over graphs. Specifically, PARETOGNN is self-supervised by manifold pretext tasks observing multiple philosophies. To reconcile different philosophies, we explore a multiple-gradient descent algorithm, such that PARETOGNN actively learns from every pretext task while minimizing potential conflicts. We conduct comprehensive experiments over four downstream tasks (i.e., node classification, node clustering, link prediction, and partition prediction), and our proposal achieves the best overall performance across tasks on 11 widely adopted benchmark datasets. Besides, we observe that learning from multiple philosophies enhances not only the task generalization but also the single task performances, demonstrating that PARETOGNN achieves better task generalization via the disjoint yet complementary knowledge learned from different philosophies. Our code is publicly available at https://github.com/jumxglhf/ParetoGNN.

Analyzing Tree Architectures in Ensembles via Neural Tangent Kernel
Ryuichi Kanoh,Mahito Sugiyama

A soft tree is an actively studied variant of a decision tree that updates splitting rules using the gradient method. Although soft trees can take various architectures, their impact is not theoretically well known. In this paper, we formulate and analyze the Neural Tangent Kernel (NTK) induced by soft tree ensembles for arbitrary tree architectures. This kernel leads to the remarkable finding tha t only the number of leaves at each depth is relevant for the tree architecture in ensemble learning with an infinite number of trees. In other words, if the number of leaves at each depth is fixed, the training behavior in function space and the generalization performance are exactly the same across different tree architectures, even if they are not isomorphic. We also show that the NTK of asymmetric trees like decision lists does not degenerate when they get infinitely deep. This is in contrast to the perfect binary trees, whose NTK is known to degenerate and leads to worse generalization performance for deeper trees.

****

Correcting Data Distribution Mismatch in Offline Meta-Reinforcement Learning with Few-Shot Online Adaptation

Jianhao Wang,Jin Zhang,Haozhe Jiang,Junyu Zhang,Liwei Wang,Chongjie Zhang

Offline meta-reinforcement learning (offline meta-RL) extracts knowledge from a given dataset of multiple tasks and achieves fast adaptation to new tasks. Recent offline meta-RL methods typically use task-dependent behavior policies (e.g., training RL agents on each individual task) to collect a multi-task dataset and learn an offline meta-policy. However, these methods always require extra information for fast adaptation, such as offline context for testing tasks or oracle reward functions. Offline meta-RL with few-shot online adaptation remains an open problem. In this paper, we first formally characterize a unique challenge under this setting: data distribution mismatch between offline training and online adaptation. This distribution mismatch may lead to unreliable offline policy evaluation and the regular adaptation methods of online meta-RL will suffer. To address this challenge, we introduce a novel mechanism of data distribution correction, which ensures the consistency between offline and online evaluation by filtering out out-of-distribution episodes in online adaptation. As few-shot out-of-distribution episodes usually have lower returns, we propose a Greedy Context-based data distribution Correction approach, called GCC, which greedily infers how to solve new tasks. GCC diversely samples “task hypotheses” from the current posterior belief and selects a greedy hypothesis with the highest return to update the task belief. Our method is the first to provide an effective online adaptation without additional information, and can be combined with off-the-shelf context-based offline meta-training algorithms. Empirical experiments show that GCC achieves state-of-the-art performance on the Meta-World ML1 benchmark compared to baselines with/without offline adaptation.

Sharper Rates and Flexible Framework for Nonconvex SGD with Client and Data Sampling

Alexander Tyurin,Lukang Sun,Konstantin Pavlovich Burlachenko,Peter Richtárik

We revisit the classical problem of finding an approximately stationary point of the average of n smooth and possibly nonconvex functions. The optimal complexity of stochastic first-order methods in terms of the number of gradient evaluations of individual functions is $\mathcal{O}\left(n + n^{1/2}\varepsilon^{-1}\right)$, attained by the optimal SGD methods SPIDER (Cong Fang et al., 2018) and PAGE (Zhize Li et al., 2020), for example, where ε is the error tolerance. However, i) the big-$\mathcal{O}$ notation hides crucial dependencies on the smoothness constants associated with the functions, and ii) the rates and theory in these methods assume simplistic sampling mechanisms that do not offer any flexibility. In this work we remedy the situation. First, we generalize the PAGE algorithm so that it can provably work with virtually any (unbiased) sampling mechanism. This is particularly useful in federated learning, as it allows us to construct and better understand the impact of various combinations of client and data sampling strategies. Second, our analysis is sharper as we make explicit use of certain novel inequalities that capture the intricate interplay between the smoothness constants and the sampling procedure. Indeed, our analysis is better even for the simple sampling procedure analyzed in the PAGE paper. However, this already improved bound can be further sharpened by a different sampling scheme which we propose. In summary, we provide the most general and most accurate analysis of optimal SGD in the smooth nonconvex regime. Finally, our theoretical findings are supposed with carefully designed experiments.

Universal embodied intelligence: learning from crowd, recognizing the world, and reinforced with experience

Luo Ji,Longfei Ma,Chang Zhou,Fei Wu,Hongxia Yang

The interactive artificial intelligence in the motion control field is an interesting topic, especially when universal knowledge adaptive to multiple task and universal environments is wanted. Although there are increasing efforts on Reinforcement learning (RL) studies with the assistance of transformers, it might subject to the limitation of the offline training pipeline, in which the exploration and generalization ability is prohibited. Motivated by the cognitive and behavioral psychology, such agent should have the ability to learn from others, recognize the world, and practice itself based its own experience. In this study, we propose the framework of Online Decision MetaMorphFormer (ODM) which attempts to achieve the above learning modes, with a unified model architecture to both highlight its own body perception and produce action and observation predictions. ODM can be applied on any arbitrary agent with a multi-joint body, located in different environments, trained with different type of tasks. Large-scale pretrained dataset are used to warmup ODM while the targeted environment continues to reinforce the universal policy. Substantial interactive experiments as well as few-shot and zero-shot tests in unseen environments and never-experienced tasks verify ODM's performance, and generalization ability. Our study shed some lights on research of general artificial intelligence on the embodied and cognitive field studies.

Exploring The Role of Mean Teachers in Self-supervised Masked Auto-Encoders

Youngwan Lee,Jeffrey Ryan Willette,Jonghee Kim,Juho Lee,Sung Ju Hwang

Masked image modeling (MIM) has become a popular strategy for self-supervised learning (SSL) of visual representations with Vision Transformers. A representative MIM model, the masked auto-encoder (MAE), randomly masks a subset of image patches and reconstructs the masked patches given the unmasked patches. Concurrently, many recent works in self-supervised learning utilize the student/teacher paradigm which provides the student with an additional target based on the output of a teacher composed of an exponential moving average (EMA) of previous students. Although common, relatively little is known about the dynamics of the interaction between the student and teacher.

Through analysis on a simple linear model, we find that the teacher conditionally removes previous gradient directions based on feature similarities which effectively acts as a conditional momentum regularizer. From this analysis, we present a simple SSL method, the Reconstruction-Consistent Masked Auto-Encoder (RC-MAE) by adding an EMA teacher to MAE. We find that RC-MAE converges faster and requires less memory usage than state-of-the-art self-distillation methods during pre-training, which may provide a way to enhance the practicality of prohibitively expensive self-supervised learning of Vision Transformer models. Additionally, we show that RC-MAE achieves more robustness and better performance compared to MAE on downstream tasks such as ImageNet-1K classification, object detection, and instance segmentation.

Multifactor Sequential Disentanglement via Structured Koopman Autoencoders

Nimrod Berman,Ilan Naiman,Omri Azencot

Disentangling complex data to its latent factors of variation is a fundamental task in representation learning. Existing work on sequential disentanglement mostly provides two factor representations, i.e., it separates the data to time-varying and time-invariant factors. In contrast, we consider multifactor disentanglement in which multiple (more than two) semantic disentangled components are generated. Key to our approach is a strong inductive bias where we assume that the underlying dynamics can be represented linearly in the latent space. Under this assumption, it becomes natural to exploit the recently introduced Koopman autoencoder models. However, disentangled representations are not guaranteed in Koopman approaches, and thus we propose a novel spectral loss term which leads to structured Koopman matrices and disentanglement. Overall, we propose a simple and eas y to code new deep model that is fully unsupervised and it supports multifactor disentanglement. We showcase new disentangling abilities such as swapping of individual static factors between characters, and an incremental swap of disentangled factors from the source to the target. Moreover, we evaluate our method extensively on two factor standard benchmark tasks where we significantly improve over competing unsupervised approaches, and we perform competitively in comparison to weakly- and self-supervised state-of-the-art approaches. The code is available at https://github.com/azencot-group/SKD.

Sub-Task Decomposition Enables Learning in Sequence to Sequence Tasks
Noam Wies,Yoav Levine,Amnon Shashua

The field of Natural Language Processing (NLP) has experienced a dramatic leap in capabilities with the recent introduction of huge Language Models (LMs). Despite this success, natural language problems that involve several compounded steps are still practically unlearnable, even by the largest LMs. This complies with experimental failures for end-to-end learning of composite problems that were demonstrated in a variety of domains. An effective mitigation is to introduce intermediate supervision for solving sub-tasks of the compounded problem. Recently, several works have demonstrated high gains by taking a straightforward approach for incorporating intermediate supervision in compounded natural language problems: the sequence-to-sequence LM is fed with an augmented input, in which the decomposed tasks' labels are simply concatenated to the original input. In this paper, we prove a positive learning result that motivates these recent efforts. We show that when concatenating intermediate supervision to the input and training a sequence-to-sequence model on this modified input, unlearnable composite problems can become learnable. We show that this is true for any family of tasks which on the one hand, are unlearnable, and on the other hand, can be decomposed into a polynomial number of simple sub-tasks, each of which depends only on $O(1)$ previous sub-task results. Beyond motivating contemporary empirical efforts for incorporating intermediate supervision in sequence-to-sequence language models, our positive theoretical result is the first of its kind in the landscape of results on the benefits of intermediate supervision for neural-network learning: Until now, all theoretical results on the subject are negative, i.e., show cases where learning is impossible without intermediate supervision, while our result is positive, showing that learning is facilitated in the presence of intermediate supervision.

T2D: Spatiotemporal Feature Learning Based on Triple 2D Decomposition
Yucheng Zhao,Chong Luo,Chuanxin Tang,Dongdong Chen,Noel C Codella,Lu Yuan,Zheng-Jun Zha

In this paper, we propose triple 2D decomposition (T2D) of a 3D vision Transformer (ViT) for efficient spatiotemporal feature learning. The idea is to divide the input 3D video data into three 2D data planes and use three 2D filters, implemented by 2D ViT, to extract spatial and motion features. Such a design not only effectively reduces the computational complexity of a 3D ViT, but also guides the network to focus on learning correlations among more relevant tokens. Compared with other decomposition methods, the proposed T2D is shown to be more powerful at a similar computational complexity. The CLIP-initialized T2D-B model achieves state-of-the-art top-1 accuracy of 85.0% and 70.5% on Kinetics-400 and Something-Something-v2 datasets, respectively. It also outperforms other methods by a large margin on FineGym (+17.9%) and Diving-48 (+1.3%) datasets. Under the zero-shot setting, the T2D model obtains a 2.5% top-1 accuracy gain over X-CLIP on HMDB-51 dataset. In addition, T2D is a general decomposition method that can be plugged into any ViT structure of any model size. We demonstrate this by building a tiny size of T2D model based on a hierarchical ViT structure named DaViT. The resulting DaViT-T2D-T model achieves 82.0\% and 71.3\% top-1 accuracy with only 91 GFLOPs on Kinectics-400 and Something-Something-v2 datasets, respectively. Source code will be made publicly available.

Online Placebos for Class-incremental Learning

Yaoyao Liu,Yingying Li,Bernt Schiele,Qianru Sun

Not forgetting old class knowledge is a key challenge for class-incremental learning (CIL) when the model continuously adapts to new coming classes. A common technique to address this is knowledge distillation (KD) which penalizes prediction inconsistencies between old and new models. Such prediction is made with almost new class data, as old class data is extremely scarce due to the strict memory limitation in CIL. In this paper, we take a deep dive into KD losses and find that “using new class data for KD” not only hinders the model adaption (for learning new classes) but also results in low efficiency for preserving old class knowledge. We address this by “using the placebos of old classes for KD”, where the placebos are chosen from a free image stream, such as Google Images, in an automatical and economical fashion. To this end, we train an online placebo selection policy to quickly evaluate the quality of streaming images (good or bad placebos) and use only good ones for one-time feed-forward computation of KD. We formulate the policy training process as an online Markov Decision Process (MDP), and introduce an online learning algorithm to solve this MDP problem without causing much computation costs. In experiments, we show that our method 1) is surprisingly effective even when there is no class overlap between placebos and original old class data, 2) does not require any additional supervision or memory budget, and 3) significantly outperforms a number of top-performing CIL methods, in particular when using lower memory budgets for old class exemplars, e.g., five exemplars per class. The code is available in the supplementary.

Evaluating Long-Term Memory in 3D Mazes

Jurgis Pašukonis,Timothy P Lillicrap,Danijar Hafner

Intelligent agents need to remember salient information to reason in partially-observed environments. For example, agents with a first-person view should remember the positions of relevant objects even if they go out of view. Similarly, to effectively navigate through rooms agents need to remember the floor plan of how rooms are connected. However, most benchmark tasks in reinforcement learning do not test long-term memory in agents, slowing down progress in this important research direction. In this paper, we introduce the Memory Maze, a 3D domain of randomized mazes specifically designed for evaluating long-term memory in agents. Unlike existing benchmarks, Memory Maze measures long-term memory separate from confounding agent abilities and requires the agent to localize itself by integrating information over time. With Memory Maze, we propose an online reinforcement learning benchmark, a diverse offline dataset, and an offline probing evaluation. Recording a human player establishes a strong baseline and verifies the need to build up and retain memories, which is reflected in their gradually increasing rewards within each episode. We find that current algorithms benefit from training with truncated backpropagation through time and succeed on small mazes, but fall short of human performance on the large mazes, leaving room for future algorithmic designs to be evaluated on the Memory Maze.

Packed Ensembles for efficient uncertainty estimation

Olivier Laurent,Adrien Lafage,Enzo Tartaglione,Geoffrey Daniel,Jean-marc Martinez,Andrei Bursuc,Gianni Franchi

Deep Ensembles (DE) are a prominent approach for achieving excellent performance on key metrics such as accuracy, calibration, uncertainty estimation, and out-of-distribution detection. However, hardware limitations of real-world systems constrain to smaller ensembles and lower-capacity networks, significantly deteriorating their performance and properties. We introduce Packed-Ensembles (PE), a strategy to design and train lightweight structured ensembles by carefully modulating the dimension of their encoding space. We leverage grouped convolutions to parallelize the ensemble into a single shared backbone and forward pass to improve training and inference speeds. PE is designed to operate within the memory limits of a standard neural network. Our extensive research indicates that PE accurately preserves the properties of DE, such as diversity, and performs equally well in terms of accuracy, calibration, out-of-distribution detection, and robustness to distribution shift. We make our code available at https://github.com/ENST

A-U2IS/torch-uncertainty.

Proactive Multi-Camera Collaboration for 3D Human Pose Estimation
Hai Ci,Mickel Liu,Xuehai Pan,fangwei zhong,Yizhou Wang

This paper presents a multi-agent reinforcement learning (MARL) scheme for proactive Multi-Camera Collaboration in 3D Human Pose Estimation in dynamic human crowds. Traditional fixed-viewpoint multi-camera solutions for human motion capture (MoCap) are limited in capture space and susceptible to dynamic occlusions. Active camera approaches proactively control camera poses to find optimal viewpoints for 3D reconstruction. However, current methods still face challenges with credit assignment and environment dynamics. To address these issues, our proposed method introduces a novel Collaborative Triangulation Contribution Reward (CTCR) that improves convergence and alleviates multi-agent credit assignment issues resulting from using 3D reconstruction accuracy as the shared reward. Additionally, we jointly train our model with multiple world dynamics learning tasks to better capture environment dynamics and encourage anticipatory behaviors for occlusion avoidance. We evaluate our proposed method in four photo-realistic UE4 environments to ensure validity and generalizability. Empirical results show that our method outperforms fixed and active baselines in various scenarios with different numbers of cameras and humans.

OpenFE: Automated Feature Generation beyond Expert-level Performance
Tianping Zhang,Zheyu Zhang,Haoyan Luo,Fengyuan Liu,Wei Cao,Jian Li

The goal of automated feature generation is to liberate machine learning experts from the laborious task of manual feature generation, which is crucial for improving the learning performance of tabular data. The major challenge in automated feature generation is to efficiently and accurately identify useful features from a vast pool of candidate features. In this paper, we present OpenFE, an automated feature generation tool that provides competitive results against machine learning experts. OpenFE achieves efficiency and accuracy with two components: 1) a novel feature boosting method for accurately estimating the incremental performance of candidate features. 2) a feature-scoring framework for retrieving effective features from a large number of candidates through successive featurewise halving and feature importance attribution. Extensive experiments on seven benchmark datasets show that OpenFE outperforms existing baseline methods. We further evaluate OpenFE in two famous Kaggle competitions with thousands of data science teams participating. In one of the competitions, features generated by OpenFE with a simple baseline model can beat 99.3% data science teams, demonstrating for the first time that automated feature generation can outperform human experts. In addition to the empirical results, we provide a theoretical perspective to show that feature generation has benefit provably in a simple yet representative setting. Codes and datasets are available in the supplementary materials.

Physics-empowered Molecular Representation Learning
Seunghoon Yi,Youngwoo Cho,Jinhwan Sul,Seung Woo Ko,Soo Kyung Kim,Jaegul Choo,Hongkee Yoon,Joonseok Lee

Estimating the energetic properties of molecular systems is a critical task in material design. With the trade-off between accuracy and computational cost, various methods have been used to predict the energy of materials, including recent neural-net-based models. However, most existing neural-net models are context-free (physics-ignoring) black-box models, limiting their applications to predict energy only within the distribution of the training set and thus preventing from being applied to the real practice of molecular design. Inspired by the physical mechanism of the interatomic potential, we propose a physics-driven energy prediction model using a Transformer. Our model is trained not only on the energy regression in the training set, but also with conditions inspired by physical insights and self-supervision based on Masked Atomic Modeling, making it adaptable to the optimization of molecular structure beyond the range observed during training, taking a step towards realizable molecular structure optimization.

Revisiting Domain Randomization Via Relaxed State-Adversarial Policy Optimization

Yun-Hsuan Lien,Ping-Chun Hsieh,Yu-Shuen Wang

Domain randomization (DR) is widely used in reinforcement learning (RL) to bridge the gap between simulation and reality through maximizing its average returns under the perturbation of environmental parameters. Although effective, the methods have two limitations: (1) Even the most complex simulators cannot capture all details in reality due to finite domain parameters and simplified physical models. (2) Previous methods often assume that the distribution of domain parameters is a specific family of probability functions, such as a normal or a uniform distribution, which may not be correct. To enable robust RL via DR without the aforementioned limitations, we rethink DR from the perspective of adversarial state perturbation, without the need for re-configuring the simulator or relying on prior knowledge about the environment. We point out that perturbing agents to the worst states during training is naive and could make the agents over-conservative. Hence, we present a Relaxed State-Adversarial Algorithm to tackle the over-conservatism issue by simultaneously maximizing the average-case and worst-case performance of policies. We compared our method to the state-of-the-art methods for evaluation. Experimental results and theoretical proofs verified the effectiveness of our method.

Become a Proficient Player with Limited Data through Watching Pure Videos

Weirui Ye,Yunsheng Zhang,Pieter Abbeel,Yang Gao

Recently, RL has shown its strong ability for visually complex tasks. However, it suffers from the low sample efficiency and poor generalization ability, which prevent RL from being useful in real-world scenarios. Inspired by the huge success of unsupervised pre-training methods on language and vision domains, we propose to improve the sample efficiency via a novel pre-training method for model-based RL.

Instead of using pre-recorded agent trajectories that come with their own actions, we consider the setting where the pre-training data are action-free videos, which are more common and available in the real world. We introduce a two-phase training pipeline as follows: for the pre-training phase, we implicitly extract the hidden action embedding from videos and pre-train the visual representation and the environment dynamics network through a novel \Changes{forward-inverse} cycle consistency \Changes{(FICC)} objective based on vector quantization; for down-stream tasks, we finetune with small amount of task data based on the learned models. Our framework can significantly improve the sample efficiency on Atari Games with data of only one hour of game playing. We achieve 118.4\% mean human performance and 36.0\% median performance with only 50k environment steps, which is 85.6\% and 65.1\% better than the scratch EfficientZero model. We believe such pre-training approach can provide an option for solving real-world RL problems. The code is available at \url{https://github.com/YeWR/FICC.git}.

Human MotionFormer: Transferring Human Motions with Vision Transformers

Hongyu Liu,Xintong Han,Chenbin Jin,Lihui Qian,Huawei Wei,Zhe Lin,Faqiang Wang,Haoye Dong,Yibing Song,Jia Xu,Qifeng Chen

Human motion transfer aims to transfer motions from a target dynamic person to a source static one for motion synthesis. An accurate matching between the source person and the target motion in both large and subtle motion changes is vital for improving the transferred motion quality. In this paper, we propose Human MotionFormer, a hierarchical ViT framework that leverages global and local perceptions to capture large and subtle motion matching, respectively. It consists of two ViT encoders to extract input features (i.e., a target motion image and a source human image) and a ViT decoder with several cascaded blocks for feature matching and motion transfer. In each block, we set the target motion feature as Query and the source person as Key and Value, calculating the cross-attention maps to conduct a global feature matching. Further, we introduce a convolutional layer to improve the local perception after the global cross-attention computations. This matching process is implemented in both warping and generation branches to guide the motion transfer. During training, we propose a mutual learning loss to enable the co-supervision between warping and generation branches for better motion representations. Experiments show that our Human MotionFormer sets the new state-of-the-art performance both qualitatively and quantitatively. Project page: https://github.com/KumapowerLIU/Human-MotionFormer.

Entity Divider with Language Grounding in Multi-Agent Reinforcement Learning

Ziluo Ding,Wanpeng Zhang,Junpeng Yue,Xiangjun Wang,Tiejun Huang,Zongqing Lu

We investigate the use of natural language to drive the generalization of policies in multi-agent settings. Unlike single-agent settings, the generalization of policies should also consider the influence of other agents. Besides, with the increasing number of entities in multi-agent settings, more agent-entity interactions are needed for language grounding, and the enormous search space could impede the learning process. Moreover, given a simple general instruction, e.g., beating all enemies, agents are required to decompose it into multiple subgoals and figure out the right one to focus on. Inspired by previous work, we try to address these issues at the entity level and propose a novel framework for language grounding in multi-agent reinforcement learning, entity divider (EnDi). EnDi enables agents to independently learn subgoal division at the entity level and act in the environment based on the associated entities. The subgoal division is regularized by opponent modeling to avoid subgoal conflicts and promote coordinated strategies. Empirically, EnDi demonstrates the strong generalization ability to unseen games with new dynamics and expresses the superiority over existing methods.

Multi-Agent Sequential Decision-Making via Communication

Ziluo Ding,Kefan Su,Weixin Hong,Liwen Zhu,Tiejun Huang,Zongqing Lu

Communication helps agents to obtain information about others so that better coordinated behavior can be learned. Some existing work communicates predicted future trajectory with others, hoping to get clues about what others would do for better coordination. However, circular dependencies sometimes can occur when agents are treated synchronously so it is hard to coordinate decision-making. In this paper, we propose a novel communication scheme, Sequential Communication (SeqComm). SeqComm treats agents asynchronously (the upper-level agents make decisions before the lower-level ones) and has two communication phases. In negotiation phase, agents determine the priority of decision-making by communicating hidden states of observations and comparing the value of intention, which is obtained by modeling the environment dynamics. In launching phase, the upper-level agents take the lead in making decisions and communicate their actions with the lower-level agents. Theoretically, we prove the policies learned by SeqComm are guaranteed to improve monotonically and converge. Empirically, we show that SeqComm outperforms existing methods in various multi-agent cooperative tasks.

Hierarchies of Reward Machines

Daniel Furelos-Blanco,Mark Law,Anders Jonsson,Krysia Broda,Alessandra Russo

Reward machines (RMs) are a recent formalism for representing the reward function of a reinforcement learning task through a finite-state machine whose edges encode landmarks of the task using high-level events. The structure of RMs enables the decomposition of a task into simpler and independently solvable subtasks that help tackle long-horizon and/or sparse reward tasks. We propose a formalism for further abstracting the subtask structure by endowing an RM with the ability to call other RMs, thus composing a hierarchy of RMs (HRM). We exploit HRMs by treating each call to an RM as an independently solvable subtask using the options framework, and describe a curriculum-based method to learn HRMs from traces observed by the agent. Our experiments reveal that exploiting a handcrafted HRM leads to faster convergence than with a flat HRM, and that learning an HRM remains feasible in cases where its equivalent flat representation is not.

****

EfficientTTS 2: Variational End-to-End Text-to-Speech Synthesis and Voice Conver

sion
Chenfeng Miao,Qingying Zhu,Minchuan Chen,Jun Ma,Shaojun Wang,Jing Xiao

Text-to-speech (TTS) field is recently dominated by one-stage text-to-waveform models, in which the speech quality is significantly improved compared to two-stage models. However, the best-performing open-sourced one-stage model, the VITS, is not fully differentiable and suffers from relatively high computation costs. To address these issues, we propose EfficientTTS 2 (EFTS2), a fully differentiable end-to-end TTS framework that is highly efficient. Our method adopts an adversarial training process, with a differentiable aligner and a hierarchical-VAE-based waveform generator. The differentiable aligner is built upon the EfficientTTS. A hybrid attention mechanism and a variational alignment predictor are incorporated into our network to improve the expressiveness of the aligner. The use of the hierarchical-VAE-based waveform generator not only alleviates the one-to-many mapping problem in waveform generation but also allows the model to learn hierarchical and explainable latent variables that control different aspects of the generated speech. We also extend EFTS2 to the voice conversion (VC) task and propose EFTS2-VC, an end-to-end VC model that allows efficient and high-quality conversion. Experimental results suggest that the two proposed models match their strong counterparts in speech quality with a faster inference speed and smaller model size.

****

LatentAugment: Dynamically Optimized Latent Probabilities of Data Augmentation
Koichi Kuriyama

Although data augmentation is a powerful technique for improving the performance of image classification tasks, it is difficult to identify the best augmentation policy. The optimal augmentation policy, which is the latent variable, cannot be directly observed. To address this problem, this study proposes \textit{LatentAugment}, which estimates the latent probability of optimal augmentation. The proposed method is appealing in that it can dynamically optimize the augmentation strategies for each input and model parameter in learning iterations. Theoretical analysis shows that LatentAugment is a general model that includes other augmentation methods as special cases, and it is simple and computationally efficient in comparison with existing augmentation methods. Experimental results show that the proposed LatentAugment has higher test accuracy than previous augmentation methods on the CIFAR-10, CIFAR-100, SVHN, and ImageNet datasets.

Novel Class Discovery under Unreliable Sampling
Haoang Chi,Wenjing Yang,Feng Liu,Long Lan,Tongliang Liu,Tao Qin,Bo Han

When sampling data of specific classes (i.e., known classes) for a scientific task, collectors may encounter unknown classes (i.e., novel classes). Since these novel classes might be valuable for future research, collectors will also sample them and assign them to several clusters with the help of known-class data. This assigning process is also known as novel class discovery (NCD). However, sampling errors are common in practice and may make the NCD process unreliable. To tackle this problem, this paper introduces a new and more realistic setting, where collectors may misidentify known classes and even confuse known classes with novel classes - we name it NCD under unreliable sampling (NUSA). We find that NUSA will empirically degrade existing NCD methods if taking no care of sampling errors. To handle NUSA, we propose an effective solution, named hidden-prototype-based discovery network (HPDN). HPDN first trains a deep network to fully fit the wrongly sampled data, then applies the relatively clean hidden representations yielded by this network into a novel mini-batch K-means algorithm, which further prevents them overfitting to residual errors by detaching noisy supervision timely. Experiments demonstrate that, under NUSA, HPDN significantly outperforms competitive baselines (e.g., 6% more than the best baseline on CIFAR-10) and keeps robust even encountering serious sampling errors.

NEW TRAINING FRAMEWORK FOR SPEECH ENHANCEMENT USING REAL NOISY SPEECH

Szu-Wei Fu,Cheng Yu,Yu Tsao,Vishak Gopal,Jayant Gupchup,Ross Cutler

Recently, deep learning-based speech enhancement (SE) models have gained significant improvements. However, the success is mainly based on using synthetic training data created by adding clean speech with noise. On the other hand, in spite of its large amount, real noisy speech is hard to be applied for SE model training because of lack of its clean reference. In this paper, we propose a novel method to utilize real noisy speech for SE model training based on a non-intrusive speech quality prediction model. The SE model is trained through the guide of the quality prediction model. We also find that a speech quality predictor with better accuracy may not necessarily be an appropriate teacher to guide the SE model. In addition, we show that if the quality prediction model is adversarially robust, then the prediction model itself can also be served as a SE model by modifying the input noisy speech through gradient backpropagation. Objective experiment results show that, under the same SE model structure, the proposed new training method trained on a large amount of real noisy speech can outperform the conventional supervised model trained on synthetic noisy speech. Lastly, the two training methods can be combined to utilize both benefits of synthetic noisy speech (easy to learn) and real noisy speech (large amount) to form semi-supervised learning which can further boost the performance both objectively and subjectively. The code will be released after publication.

PA-LoFTR: Local Feature Matching with 3D Position-Aware Transformer

Chenhao Li,Qisheng Tang,Shuangjiu Xiao,Ying Mao,Deli Dong,Zhifeng Shi,Guoliang Chen,Jiawen Cheng

We propose a novel image feature matching method that utilizes 3D position information to augment feature representation with a deep neural network. The proposed method introduces 3D position embedding to a state-of-the-art feature matcher, LoFTR, and achieves more promising performance. Following the coarse-to-fine matching pipeline of LoFTR, we construct a Transformer-based neural network that generates dense pixel-wise matches. Instead of using 2D position embeddings for transformer, the proposed method generates 3D position embeddings that can precisely capture position correspondence of matches between images. Importantly, in order to guide neural network to learn 3D space information, we augment features with depth information generated by a depth predictor. In this way, our method, PA-LoFTR, can generate 3D position-aware local feature descriptors with Transformer. We experiment on indoor datasets, and results show that PA-LoFTR improves the performance of feature matching compared to state-of-the-art methods.

Policy Contrastive Imitation Learning

Jialei Huang,Zhao-Heng Yin,Yingdong Hu,Yang Gao

Adversarial imitation learning (AIL) is a popular method that has recently achieved much success. However, the performance of AIL is still unsatisfactory on the more challenging tasks. We find that one of the major reasons is due to the low quality of AIL discriminator representation. Since the AIL discriminator is trained via binary classification that does not necessarily discriminate the policy from the expert in a meaningful way, the resulting reward might not be meaningful either. We propose a new method called Policy Contrastive Imitation Learning (PCIL) to resolve this issue. PCIL learns a contrastive representation space by anchoring on different policies and uses a smooth cosine-similarity-based reward to encourage imitation learning. Our proposed representation learning objective can be viewed as a stronger version of the AIL objective and provide a more meaningful comparison between the agent and the policy. From a theoretical perspective, we show the validity of our method using the apprenticeship learning framework. Furthermore, our empirical evaluation on the DeepMind Control suite demonstrates that PCIL can achieve state-of-the-art performance. Finally, qualitative results suggest that PCIL builds a smoother and more meaningful representation space for imitation learning.

****

Backstepping Temporal Difference Learning

Han-Dong Lim,Donghwan Lee

Off-policy learning ability is an important feature of reinforcement learning (RL) for practical applications. However, even one of the most elementary RL algorithms, temporal-difference (TD) learning, is known to suffer form divergence issue when the off-policy scheme is used together with linear function approximation. To overcome the divergent behavior, several off-policy TD learning algorithms have been developed until now. In this work, we provide a unified view of such algorithms from a purely control-theoretic perspective. Our method relies on the backstepping technique, which is widely used in nonlinear control theory.

****

Hidden Markov Transformer for Simultaneous Machine Translation

Shaolei Zhang,Yang Feng

Simultaneous machine translation (SiMT) outputs the target sequence while receiving the source sequence, and hence learning when to start translating each target token is the core challenge for SiMT task. However, it is non-trivial to learn the optimal moment among many possible moments of starting translating, as the moments of starting translating always hide inside the model and can only be supervised with the observed target sequence. In this paper, we propose a Hidden Markov Transformer (HMT), which treats the moments of starting translating as hidden events and the target sequence as the corresponding observed events, thereby organizing them as a hidden Markov model. HMT explicitly models multiple moments of starting translating as the candidate hidden events, and then selects one to generate the target token. During training, by maximizing the marginal likelihood of the target sequence over multiple moments of starting translating, HMT learns to start translating at the moments that target tokens can be generated more accurately. Experiments on multiple SiMT benchmarks show that HMT outperforms strong baselines and achieves state-of-the-art performance.

A General Rank Preserving Framework for Asymmetric Image Retrieval

Hui Wu,Min Wang,Wengang Zhou,Houqiang Li

Asymmetric image retrieval aims to deploy compatible models on platforms of different resources to achieve a balance between computational efficiency and retrieval accuracy. The most critical issue is how to align the output features of different models. Despite the great progress, existing approaches apply strong constraints so that features or neighbor structures are strictly aligned across different models. However, such a one-to-one constraint is too strict to be well preserved for the query models with low capacity. Considering that the primary concern of the users is the rank of the returned images, we propose a generic rank preserving framework, which achieves feature compatibility and the order consistency between query and gallery models simultaneously. Specifically, we propose two alternatives to instantiate the framework. One realizes straightforward rank order preservation by directly preserving the consistency of the sorting results. To make sorting process differentiable, the Heaviside step function in sorting is approximated by the sigmoid function. The other aims to preserve a learnable monotonic mapping relationship between the returned similarity scores of query and gallery models. The mapped similarity scores of gallery model are considered as pseudo-supervision to guide the query model training. Extensive experiments on various large-scale datasets demonstrate the superiority of our two proposed methods.

Single-level Adversarial Data Synthesis based on Neural Tangent Kernels
Yu-Rong Zhang,Reddy Su,Sheng-Yen Chou,Shan-Hung Wu

Generative adversarial networks (GANs) have achieved impressive performance in data synthesis and have driven the development of many applications. How- ever, GANs are known to be hard to train due to their bilevel objective, which leads to the problems of convergence, mode collapse, and gradient vanishing. In this paper, we propose a new generative model called the generative adversarial NTK (GA-NTK) that has a single-level objective. The GA-NTK keeps the spirit of adversarial learning (which helps generate plausible data) while avoiding the training difficulties of GANs. This is done by modeling the discriminator as a Gaussian process with a neural tangent kernel (NTK-GP) whose training dynam- ics can be completely described by a closed-form formula. We analyze the conver- gence behavior of GA-NTK trained by gradient descent and give some sufficient conditions for convergence. We also conduct extensive experiments to study the advantages and limitations of GA-NTK and propose some techniques that make GA-NTK more practical.

Learning to Count Everything: Transformer-based Trackers are Strong Baselines for Class Agnostic Counting
Tsung-Han Chou,Brian Schweitzer Wang,Han Ru Chen,Jun-Cheng Chen

Class agnostic counting (CAC) is a vision task which can be used to count the total occurrence number of any given reference objects in the query image. The task is usually formulated as density map estimation problem through similarity computation among few image samples of the reference object and the query image. In this paper, we show the the popular and effective similarity computation operation, bilinear similarity, actually share high resemblance with self-attention and cross-attention operations which are widely used in the transformer architecture. Inspired by this observation, since the formulation of visual object tracking task is similar to CAC, we show the advanced attention modules of transformer-based trackers are actually powerful matching tools for the CAC task. These modules allow to learn more distinct features to capture the shared patterns among the query and reference images. In addition, we propose a transformer-based class agnostic counting framework by adapting transformer-based trackers for CAC. We demonstrate the effectiveness of the proposed framework with two state-of-the-art transformer-based trackers, MixFormer and TransT, with extensive experiments and ablation studies. The proposed methods outperform other state-of-the-art methods on the challenging FSC-147 and CARPK datasets and achieve new state-of-the-art performances. The code will be publicly available upon acceptance.

Unified Algorithms for RL with Decision-Estimation Coefficients: No-Regret, PAC, and Reward-Free Learning
Fan Chen,Song Mei,Yu Bai

Finding unified complexity measures and algorithms for sample-efficient learning is a central topic of research in reinforcement learning (RL). The Decision-Estimation Coefficient (DEC) is recently proposed by Foster et al. (2021) as a necessary and sufficient complexity measure for sample-efficient no-regret RL. This paper makes progress towards a unified theory for RL with the DEC framework. First, we propose two new DEC-type complexity measures: Explorative DEC (EDEC), and Reward-Free DEC (RFDEC). We show that they are necessary and sufficient for sample-efficient PAC learning and reward-free learning, thereby extending the original DEC which only captures no-regret learning. Next, we design new unified sample-efficient algorithms for all three learning goals. Our algorithms instantiate variants of the Estimation-To-Decisions (E2D) meta-algorithm with a strong and general model estimation subroutine. Even in the no-regret setting, our algorithm \textsc{E2D-TA} improves upon the algorithms of Foster et al. (2021) which require either bounding a variant of the DEC which may be prohibitively large, or designing problem-specific estimation subroutines. As applications, we recover existing and obtain new sample-efficient learning results for a wide range of tractable RL problems using essentially a single algorithm. Finally, as a connection, we re-analyze two existing optimistic model-based algorithms based on Posterior Sampling or Maximum Likelihood Estimation, showing that they enjoy similar reg

ret bounds as \textsc{E2D-TA} under similar structural conditions as the DEC.

Strength-Adaptive Adversarial Training
Chaojian Yu,Dawei Zhou,Li Shen,Jun Yu,Bo Han,Mingming Gong,Nannan Wang,Tongliang Liu
Adversarial training (AT) is proved to reliably improve network's robustness against adversarial data. However, current AT with a pre-specified perturbation budget has limitations in learning a robust network. Firstly, applying a pre-specified perturbation budget on networks of various model capacities will yield divergent degree of robustness disparity between natural and robust accuracies, which deviates from robust network's desideratum. Secondly, the attack strength of adversarial training data constrained by the pre-specified perturbation budget fails to upgrade as the growth of network robustness, which leads to robust overfitting and further degrades the adversarial robustness. To overcome these limitations, we propose Strength-Adaptive Adversarial Training (SAAT). Specifically, the adversary employs an adversarial loss constraint to generate adversarial training data. Under this constraint, the perturbation budget will be adaptively adjusted according to the training state of adversarial data, which can effectively avoid robust overfitting. Besides, SAAT explicitly constrains the attack strength of training data through the adversarial loss, which manipulates model capacity scheduling during training, and thereby can flexibly control the degree of robustness disparity and adjust the tradeoff between natural accuracy and robustness. Extensive experiments show that our proposal boosts the robustness of adversarial training.

Teach me how to Interpolate a Myriad of Embeddings
Shashanka Venkataramanan,Ewa Kijak,laurent amsaleg,Yannis Avrithis
Mixup refers to interpolation-based data augmentation, originally motivated as a way to go beyond empirical risk minimization (ERM). Yet, its extensions focus on the definition of interpolation and the space where it takes place, while the augmentation itself is less studied: For a mini-batch of size m, most methods interpolate between m pairs with a single scalar interpolation factor λ.

In this work, we make progress in this direction by introducing MultiMix, which interpolates an arbitrary number n of tuples, each of length m, with one vector λ per tuple. On sequence data, we further extend to dense interpolation and loss computation over all spatial positions. Overall, we increase the number of tuples per mini-batch by orders of magnitude at little additional cost. This is possible by interpolating at the very last layer before the classifier. Finally, to address inconsistencies due to linear target interpolation, we introduce a self-distillation approach to generate and interpolate synthetic targets.

We empirically show that our contributions result in significant improvement over state-of-the-art mixup methods on four benchmarks. By analyzing the embedding space, we observe that the classes are more tightly clustered and uniformly spread over the embedding space, thereby explaining the improved behavior.

Mega: Moving Average Equipped Gated Attention
Xuezhe Ma,Chunting Zhou,Xiang Kong,Junxian He,Liangke Gui,Graham Neubig,Jonathan May,Luke Zettlemoyer
The design choices in the Transformer attention mechanism, including weak inductive bias and quadratic computational complexity, have limited its application for modeling long sequences. In this paper, we introduce Mega, a simple, theoretically grounded, single-head gated attention mechanism equipped with (exponential) moving average to incorporate inductive bias of position-aware local dependencies into the position-agnostic attention mechanism. We further propose a variant of Mega that offers linear time and space complexity yet yields only minimal quality loss, by efficiently splitting the whole sequence into multiple chunks with fixed length. Extensive experiments on a wide range of sequence modeling bench

marks, including the Long Range Arena, neural machine translation, auto-regressive language modeling, and image and speech classification, show that Mega achieves significant improvements over other sequence models, including variants of Transformers and recent state space models.

IEDR: A Context-aware Intrinsic and Extrinsic Disentangled Recommender System

Yixin Su,Wei Jiang,Yunxiang Zhao,Fangquan Lin,Cheng Yang,Sarah Monazam Erfani,Junhao Gan

Intrinsic and extrinsic factors jointly affect users' decisions in item selection (e.g., click, purchase). Intrinsic factors reveal users' real interests and are invariant in different contexts (e.g., time, weather), whereas extrinsic factors can change w.r.t. different contexts. Analyzing these two factors is an essential yet challenging task in recommender systems. However, in existing studies, factor analysis is either largely neglected, or designed for a specific context (e.g., the time context in sequential recommendation), which limits the applicability of such models. In this paper, we propose a generic model, IEDR, to learn intrinsic and extrinsic factors from various contexts for recommendation. IEDR contains two key components: a contrastive learning component, and a disentangling component. The two components collaboratively enable our model to learn context-invariant intrinsic factors and context-based extrinsic factors from all available contexts. Experimental results on real-world datasets demonstrate the effectiveness of our model in factor learning and impart a significant improvement in recommendation accuracy over the state-of-the-art methods.

Deep Deformation Based on Feature-Constraint for 3D Human Mesh Correspondence

Na Gong

In this study, we address the challenges in mesh correspondence for various types of complete or single-view human body data. The parametric human model has been widely used in various human-related applications and in 3D human mesh correspondence because it provides sufficient scope to modify the resulting model. In contrast to prior methods that optimize both the correspondences and human model parameters (pose and shape), some of the recent methods directly deform each vertex of a parametric template by processing the point clouds that represent the input shapes. This allows the models to have more accurate representations of the details while maintaining the correspondence. However, we identified two limitations in these methods. First, it is difficult for the transformed template to completely restore the input shapes using only a pointwise reconstruction loss. Second, they cannot deform the template to a single-view human body from the depth camera observations or infer the correspondences between various forms of input human bodies. In representation learning, one of the main challenges is to design appropriate loss functions for supervising features with different abilities. To address this, we introduce the feature constraint deformation network (FCD-Net), which is an end-to-end deep learning approach that identifies 3D human mesh correspondences by learning various shape transformations from a predetermined template. The FCD-Net is implemented by an encoder–decoder architecture. A global feature encoded from the input shape and a decoder are used to deform the template based on the encoded global feature. We simultaneously input the complete shape and single-view shape into the encoder and closely constrain the features to enable the encoder to learn more robust features. Meanwhile, the decoder generates a completely transformed template with higher promise by using the complete shape as the ground truth, even if the input is single-view human body data. We conduct extensive experiments to validate the effectiveness of the proposed FCD-Net on four types of single-view human body data, both from qualitative and quantitative aspects. We also demonstrate that our approach improves the state-of-the-art results on the difficult "FAUST-inter" and "SHREC'19" challenges, with average correspondence errors of 2.54 cm and 6.62 cm, respectively . In addition, the proposed FCD-Net performs well on real and unclean point clouds from a depth camera.

Explaining Representation Bottlenecks of Convolutional Decoder Networks
Ling Tang,Wen Shen,Zhanpeng Zhou,YueFeng Chen,Quanshi Zhang

In this paper, we prove representation bottlenecks of a cascaded convolutional decoder network, considering the capacity of representing different frequency components of an input sample. We conduct the discrete Fourier transform on each channel of the feature map in an intermediate layer of the decoder network. Then, we introduce the rule of the forward propagation of such intermediate-layer spectrum maps, which is equivalent to the forward propagation of feature maps through a convolutional layer. Based on this, we find that each frequency component in the spectrum map is forward propagated independently with other frequency components. Furthermore, we prove two bottlenecks in representing feature spectrums. First, we prove that the convolution operation, the zero-padding operation, and a set of other settings all make a convolutional decoder network more likely to weaken high-frequency components. Second, we prove that the upsampling operation generates a feature spectrum, in which strong signals repetitively appears at certain frequencies. We will release all codes when this paper is accepted.

Dual Ensembled Multiagent Q-Learning with Hypernet Regularizer
Yaodong Yang,Guangyong Chen,Hongyao Tang,Furui Liu,Danruo DENG,Jianye HAO,Pheng-Ann Heng

Overestimation in the temporal-difference single-agent reinforcement learning has been widely studied, where the variance in value estimation causes overestimation of the maximal target value due to Jensen's inequality. Instead, overestimation in multiagent settings has received little attention though it can be even more severe. One kind of pioneer work extends ensemble methods from single-agent deep reinforcement learning to address the multiagent overestimation by discarding the large target values among the ensemble. However, its ability is limited by the ensemble diversity. Another kind of work softens the maximum operator in the Bellman equation to avoid large target values, but also leads to sub-optimal value functions. Unlike previous works, in this paper, we address the multiagent overestimation by analyzing its underlying causes in an estimation-optimization iteration manner. We show that the overestimation in multiagent value-mixing Q-learning not only comes from the overestimation of target Q-values but also accumulates in the online Q-network's optimization step. Therefore, first, we integrate the random ensemble and in-target minimization into the estimation of target Q-values to derive a lower update target. Second, we propose a novel hypernet regularizer on the learnable terms of the online global Q-network to further reduce overestimation. Experiments on various kinds of tasks demonstrate that the proposed method consistently addresses the overestimation problem while previous works fail.

Exploring Chemical Space with Score-based Out-of-distribution Generation
Seul Lee,Jaehyeong Jo,Sung Ju Hwang

A well-known limitation of existing works on molecule generation is that the generated molecules highly resemble those in the training set. To generate truly novel molecules with completely different structures that may have even better properties than known molecules for de novo drug discovery, more powerful exploration in the chemical space is necessary. To this end, we propose Molecular Out-Of-distribution Diffusion (MOOD), a novel score-based diffusion scheme that incorporates out-of-distribution (OOD) control in the generative stochastic differential equation (SDE) with simple control of a hyperparameter, thus requires no additional computational costs unlike existing methods (e.g., RL-based methods). However, some novel molecules may be chemically implausible, or may not meet the basic requirements of real-world drugs. Thus, MOOD performs conditional generation by utilizing the gradients from a property prediction network that guides the reverse-time diffusion process to high-scoring regions according to multiple target properties such as protein-ligand interactions, drug-likeness, and synthesizability. This allows MOOD to search for novel and meaningful molecules rather than generating unseen yet trivial ones. We experimentally validate that MOOD is able to explore the chemical space beyond the training distribution, generating mol ecules that outscore ones found with existing methods, and even the top 0.01% of the original training pool.

Node Number Awareness Representation for Graph Similarity Learning

JaX Lyu,Liang Zhang,Yi Huang,Shifeng Chen,Guangming Zhu,Mohammed Bennamoun,Syed Afaq Ali Shah

This work aims to address two important issues in the graph similarity computation, the first one is the Node Number Awareness Issue (N^{2}AI), and the second one is how to accelerate the inference speed of graph similarity computation in downstream tasks. We found that existing Graph Neural Network based graph similarity models have a large error in predicting the similarity scores of two graphs with similar number of nodes. Our analysis shows that this is because of the global pooling function in graph neural networks that maps graphs with similar number of nodes to similar embedding distributions, reducing the separability of their embeddings, which we refer to as the N^{2}AI. Our motivation is to enhance the difference between the two embeddings to improve their separability, thus we leverage our proposed Different Attention (DiffAtt) to construct Node Number Awareness Graph Similarity Model (N^{2}AGim). In addition, we propose the Graph Similarity Learning with Landmarks (GSL^2) to accelerate similarity computation. GSL^2 uses the trained N^{2}AGim to generate the individual embedding for each graph without any additional learning, and this individual embedding can effectively help GSL^2 to improve its inference speed. Experiments demonstrate that our N^{2}AGim outperforms the second best approach on Mean Square Error by 24.3\%(1.170 vs 1.546), 43.1\%(0.066 vs 0.116), and 44.3\%(0.308 vs 0.553), on AIDS700nef, LINUX, and IMDBMulti datasets, respectively. Our GSL^2 is at most 47.7 and 1.36 times faster than N^{2}AGim and the second faster model. Our code is publicly available on https://github.com/iclr231312/N2AGim.

Evaluating Fairness Without Sensitive Attributes: A Framework Using Only Auxiliary Models

Zhaowei Zhu,Yuanshun Yao,Jiankai Sun,Yang Liu,Hang Li

Although the volume of literature and public attention on machine learning fairness has been growing significantly in recent years, in practice some tasks as basic as measuring fairness, which is the first step in studying and promoting fairness, can be challenging. This is because the sensitive attributes are often unavailable in a machine learning system due to privacy regulations. The straightforward solution is to use auxiliary models to predict the missing sensitive attributes. However, our theoretical analyses show that the estimation error of the directly measured fairness metrics is proportional to the error rates of auxiliary models' predictions. Existing works that attempt to reduce the estimation error often require strong assumptions, e.g. access to the ground-truth sensitive attributes in a subset of samples, auxiliary models' training data and the target data are i.i.d, or some form of conditional independence. In this paper, we drop those assumptions and propose a framework that uses only off-the-shelf auxiliary models. The main challenge is how to reduce the negative impact of imperfectly predicted sensitive attributes on the fairness metrics without knowing the ground-truth sensitive attribute values. Inspired by the noisy label learning literature, we first derive a closed-form relationship between the directly measured fairness metrics and their corresponding ground-truth metrics. And then we estimate some key statistics (most importantly transition matrix in the noisy label literature), which we use, together with the derived relationship, to calibrate the fairness metrics. Our framework can be applied to all popular group fairness definitions as well as multi-class classifiers and multi-category sensitive attributes. In addition, we theoretically prove the upper bound of the estimation error in our calibrated metrics and show our method can substantially decrease the estimation error especially when auxiliary models are inaccurate or the target model is highly biased. Experiments on COMPAS and CelebA validate our theoretical analyses and show our method can measure fairness significantly more accurately than baselines under favorable circumstances.

Optimal Neural Network Approximation of Wasserstein Gradient Direction via Convex Optimization
Yifei Wang,Peng Chen,Mert Pilanci,Wuchen Li
The computation of Wasserstein gradient direction is essential for posterior sampling problems and scientific computing. The approximation of the Wasserstein gradient with finite samples requires solving a variational problem. We study the variational problem in the family of two-layer networks with squared-ReLU activations, towards which we derive a semi-definite programming (SDP) relaxation. This SDP can be viewed as an approximation of the Wasserstein gradient in a broader function family including two-layer networks. By solving the convex SDP, we obtain the optimal approximation of the Wasserstein gradient direction in this class of functions. Numerical experiments including PDE-constrained Bayesian inference and parameter estimation in COVID-19 modeling demonstrate the effectiveness of the proposed method.

Parallel Deep Neural Networks Have Zero Duality Gap
Yifei Wang,Tolga Ergen,Mert Pilanci
Training deep neural networks is a challenging non-convex optimization problem. Recent work has proven that the strong duality holds (which means zero duality gap) for regularized finite-width two-layer ReLU networks and consequently provided an equivalent convex training problem. However, extending this result to deeper networks remains to be an open problem. In this paper, we prove that the duality gap for deeper linear networks with vector outputs is non-zero. In contrast, we show that the zero duality gap can be obtained by stacking standard deep networks in parallel, which we call a parallel architecture, and modifying the regularization. Therefore, we prove the strong duality and existence of equivalent convex problems that enable globally optimal training of deep networks. As a by-product of our analysis, we demonstrate that the weight decay regularization on the network parameters explicitly encourages low-rank solutions via closed-form expressions. In addition, we show that strong duality holds for three-layer standard ReLU networks given rank-1 data matrices.
****
Multi-domain image generation and translation with identifiability guarantees
Shaoan Xie,Lingjing Kong,Mingming Gong,Kun Zhang
Multi-domain image generation and unpaired image-to-to-image translation are two important and related computer vision problems. The common technique for the two tasks is the learning of a joint distribution from multiple marginal distributions. However, it is well known that there can be infinitely many joint distributions that can derive the same marginals. Hence, it is necessary to formulate suitable constraints to address this highly ill-posed problem. Inspired by the recent advances in nonlinear Independent Component Analysis (ICA) theory, we propose a new method to learn the joint distribution from the marginals by enforcing a specific type of minimal change across domains. We report one of the first results connecting multi-domain generative models to identifiability and shows why identifiability is essential and how to achieve it theoretically and practically. We apply our method to five multi-domain image generation and six image-to-image translation tasks. The superior performance of our model supports our theory and demonstrates the effectiveness of our method. The training code are available at https://github.com/Mid-Push/i-stylegan.
****
Interventional Rationalization
Linan Yue,Qi Liu,Li Wang,Yanqing An,Yichao Du,Zhenya Huang
Selective rationalizations improve the explainability of neural networks by selecting a subsequence of the input (i.e., rationales) to explain the prediction results. Although existing methods have achieved promising results, they still suffer from adopting the spurious correlations in data (aka., shortcuts) to compose rationales and make predictions. Inspired by the causal theory, in this paper, we develop an interventional rationalization (Inter-RAT) to discover the causal rationales. Specifically, we first analyse the causalities among the input, rationales and results with a structural causal model. Then, we discover spurious co

rrelations between input and rationales, and between rationales and results, respectively, by identifying the confounder in the causalities. Next, based on the backdoor adjustment, we propose a causal intervention method to remove the spurious correlations in input and rationales. Further, we discuss reasons why spurious correlations between the selected rationales and results exist by analysing the limitations of the sparsity constraint in the rationalization, and employ the causal intervention method to remove these correlations. Extensive experimental results on three real-world datasets clearly validate the effectiveness of our proposed method.

Information-Theoretic Analysis of Unsupervised Domain Adaptation

Ziqiao Wang,Yongyi Mao

This paper uses information-theoretic tools to analyze the generalization error in unsupervised domain adaptation (UDA). We present novel upper bounds for two notions of generalization errors. The first notion measures the gap between the population risk in the target domain and that in the source domain, and the second measures the gap between the population risk in the target domain and the empirical risk in the source domain. While our bounds for the first kind of error are in line with the traditional analysis and give similar insights, our bounds on the second kind of error are algorithm-dependent, which also provide insights into algorithm designs. Specifically, we present two simple techniques for improving generalization in UDA and validate them experimentally.

Pessimism in the Face of Confounders: Provably Efficient Offline Reinforcement Learning in Partially Observable Markov Decision Processes

Miao Lu,Yifei Min,Zhaoran Wang,Zhuoran Yang

We study offline reinforcement learning (RL) in partially observable Markov decision processes. In particular, we aim to learn an optimal policy from a dataset collected by a behavior policy which possibly depends on the latent state. Such a dataset is confounded in the sense that the latent state simultaneously affects the action and the observation, which is prohibitive for existing offline RL algorithms. To this end, we propose the \underline{P}roxy variable \underline{P}essimistic \underline{P}olicy \underline{O}ptimization (\texttt{P3O}) algorithm, which addresses the confounding bias and the distributional shift between the optimal and behavior policies in the context of general function approximation. At the core of \texttt{P3O} is a coupled sequence of pessimistic confidence regions constructed via proximal causal inference, which is formulated as minimax estimation. Under a partial coverage assumption on the confounded dataset, we prove that \texttt{P3O} achieves a $n^{-1/2}$-suboptimality, where n is the number of trajectories in the dataset. To our best knowledge, \texttt{P3O} is the first provably efficient offline RL algorithm for POMDPs with a confounded dataset.

DELVING INTO THE HIERARCHICAL STRUCTURE FOR EFFICIENT LARGE-SCALE BI-LEVEL LEARNING

Xixi Jia,Renzhen Wang,Deyu Meng,Xiangchu Feng

Recent years have witnessed growing interest and emerging successes of bi-level learning in a wide range of applications, such as meta learning and hyper-parameter optimization. While current bi-level learning approaches suffer from high memory and computation costs especially for large-scale deep learning scenarios, which is due to the hierarchical optimization therein. {\textit {It is therefore interesting to know whether the hierarchical structure can be untied for efficient learning}.} To answer this question, we introduce NSGame that, transforming the hierarchical bi-level learning problem into a parallel Nash game, incorporates the tastes of hierarchy by a very small scale Stackelberg game.

We prove that strong differential Stackelberg equilibrium (SDSE) of the bi-level learning problem corresponds to local Nash equilibrium of the NSGame. To obtain such SDSE from NSGame, we introduce a two-time scale stochastic gradient descent (TTS-SGD) method, and provide theoretical guarantee that local Nash equilibrium obtained by the TTS-SGD method is SDSE of the bi-level learning problem. We co mpare NSGame with representative bi-level learning models, such as MWN and MLC, experimental results on class imbalance learning and noisy label learning have verified that the proposed NSGame achieves comparable and even better results than the corresponding meta learning models, while NSGame is computationally more efficient.

Can GNNs Learn Heuristic Information for Link Prediction?

Shuming Liang,Yu Ding,Zhidong Li,Bin Liang,siqi zhang,Yang Wang,Fang Chen

Graph Neural Networks (GNNs) have shown superior performance in Link Prediction (LP). Especially, SEAL and its successors address the LP problem by classifying the subgraphs extracted specifically for candidate links, gaining state-of-the-art results. Nevertheless, we question whether these methods can effectively learn the information equivalent to link heuristics such as Common Neighbors, Katz index, etc. (we refer to such information as heuristic information in this work). We show that link heuristics and GNNs capture different information. Link heuristics usually collect pair-specific information by counting the involved neighbors or paths between two nodes in a candidate link, while GNNs learn node-wise representations through a neighborhood aggregation algorithm in which two nodes in the candidate link do not pay special attention to each other. Our further analysis shows that SEAL-type methods only use a GNN to model the pair-specific subgraphs and also cannot effectively capture heuristic information. To verify our analysis, a straightforward way is to compare the LP performance between existing methods and a model that learns heuristic information independently of the GNN learning. To this end, we present a simple yet light framework ComHG by directly Combining the embeddings of link Heuristics and the representations produced by a GNN. Experiments on OGB LP benchmarks show that ComHG outperforms all top competitors by a large margin, empirically confirming our propositions. Our experimental study also indicates that the contributions of link heuristics and the GNN to LP are sensitive to the graph degree, where the former is powerful on sparse graphs while the latter becomes dominant on dense graphs.

****

Understanding Zero-shot Adversarial Robustness for Large-Scale Models

Chengzhi Mao,Scott Geng,Junfeng Yang,Xin Wang,Carl Vondrick

Pretrained large-scale vision-language models like CLIP have exhibited strong generalization over unseen tasks. Yet imperceptible adversarial perturbations can significantly reduce CLIP's performance on new tasks. In this work, we identify and explore the problem of adapting large-scale models for zero-shot adversarial robustness. We first identify two key factors during model adaption--training losses and adaptation methods--that affect the model's zero-shot adversarial robustness. We then propose a text-guided contrastive adversarial training loss, which aligns the text embeddings and the adversarial visual features with contrastive learning on a small set of training data. We apply this training loss to two adaption methods, model finetuning and visual prompt tuning. We find that visual prompt tuning is more effective in the absence of texts, while finetuning wins in the existence of text guidance. Overall, our approach significantly improves the zero-shot adversarial robustness over CLIP, seeing an average improvement of 31 points over ImageNet and 15 zero-shot datasets. We hope this work can shed light on understanding the zero-shot adversarial robustness of large-scale models.

****

HOYER REGULARIZER IS ALL YOU NEED FOR EXTREMELY SPARSE SPIKING NEURAL NETWORKS

Gourav Datta,Zeyu Liu,Peter Anthony Beerel

Spiking Neural networks (SNN) have emerged as an attractive spatio-temporal computing paradigm for a wide range of low-power vision tasks. However, state-of-the-art (SOTA) SNN models either incur multiple time steps which hinder their deployment in real-time use cases or increase the training complexity significantly.

To mitigate this concern, we present a training framework (from scratch) for one-time-step SNNs that uses a novel variant of the recently proposed Hoyer regulari

zer. We estimate the threshold of each SNN layer as the Hoyer extremum of a clipped version of its activation map, where the clipping threshold is trained using
gradient descent with our Hoyer regularizer. This approach not only downscales the value of the trainable threshold, thereby emitting a large number of spikes for
weight update with limited number of iterations (due to only one time step) but also shifts the pre-activation values away from the threshold, thereby mitigating
the effect of noise that can degrade the SNN accuracy. Our approach outperforms existing spiking, binary, and adder neural networks in terms of accuracy-FLOPs trade-off for complex image recognition tasks. Downstream experiments on object detection also demonstrate the efficacy of our approach.

Rademacher Complexity Over $\mathcal{H} \Delta \mathcal{H}$ Class for Adversarially Robust Domain Adaptation

Yuyang Deng,Nidham Gazagnadou,Junyuan Hong,Mehrdad Mahdavi,Lingjuan Lyu

In domain adaptation, a model is trained on a dataset generated from a source domain and its generalization is evaluated on a possibly different target domain. Understanding the generalization capability of the learned model is a longstanding question. Recent studies demonstrated that the adversarial robust learning under ℓ_∞ attack is even harder to generalize to different domains. To thoroughly study the fundamental difficulty behind adversarially robust domain adaptation, we propose to analyze a key complexity measure that controls the cross-domain generalization: the adversarial Rademacher complexity over $\mathcal{H} \Delta \mathcal{H}$ class. For linear models, we show that adversarial Rademacher complexity over $\mathcal{H} \Delta \mathcal{H}$ class is always greater than the non-adversarial one, which reveals the intrinsic hardness of adversarially robust domain adaptation. We also establish upper bounds on this complexity measure, and extend them to the ReLU neural network class as well. Finally, by properly extending our generalization bound for adversarially robust domain adaptation, we explain \emph{why adversarial training can help transferring the model performance to different domains}. We believe our results initiate the study of the generalization theory of adversarially robust domain adaptation, and could shed lights on distributed adversarially robust learning from heterogeneous sources -- a scenario typically encountered in federated learning applications.

Continual evaluation for lifelong learning: Identifying the stability gap

Matthias De Lange,Gido M van de Ven,Tinne Tuytelaars

Time-dependent data-generating distributions have proven to be difficult for gradient-based training of neural networks, as the greedy updates result in catastrophic forgetting of previously learned knowledge. Despite the progress in the field of continual learning to overcome this forgetting, we show that a set of common state-of-the-art methods still suffers from substantial forgetting upon starting to learn new tasks, except that this forgetting is temporary and followed by a phase of performance recovery. We refer to this intriguing but potentially problematic phenomenon as the stability gap. The stability gap had likely remained under the radar due to standard practice in the field of evaluating continual learning models only after each task. Instead, we establish a framework for continual evaluation that uses per-iteration evaluation and we define a new set of metrics to quantify worst-case performance. Empirically we show that experience replay, constraint-based replay, knowledge-distillation, and parameter regularization methods are all prone to the stability gap; and that the stability gap can be observed in class-, task-, and domain-incremental learning benchmarks. Additionally, a controlled experiment shows that the stability gap increases when tasks are more dissimilar. Finally, by disentangling gradients into plasticity and stability components, we propose a conceptual explanation for the stability gap.
****

On the Universal Approximation Property of Deep Fully Convolutional Neural Networks

Ting Lin,Zuowei Shen,Qianxiao Li

We study the approximation of shift-invariant or equivariant functions by deep fully convolutional networks from the dynamical systems perspective. We prove that deep residual fully convolutional networks and their continuous-layer counterpart can achieve universal approximation of these symmetric functions at constant channel width. Moreover, we show that the same can be achieved by non-residual variants with at least 2 channels in each layer and convolutional kernel size of at least 2. In addition, we show that these requirements are necessary, in the sense that networks with fewer channels or smaller kernels fail to be universal approximators.

****

Can We Faithfully Represent Absence States to Compute Shapley Values on a DNN?

Jie Ren,Zhanpeng Zhou,Qirui Chen,Quanshi Zhang

Masking some input variables of a deep neural network (DNN) and computing output changes on the masked input sample represent a typical way to compute attributions of input variables in the sample. People usually mask an input variable using its baseline value. However, there is no theory to examine whether baseline value faithfully represents the absence of an input variable, i.e., removing all signals from the input variable. Fortunately, recent studies (Ren et al., 2023a; Deng et al., 2022a) show that the inference score of a DNN can be strictly disentangled into a set of causal patterns (or concepts) encoded by the DNN. Therefore, we propose to use causal patterns to examine the faithfulness of baseline values. More crucially, it is proven that causal patterns can be explained as the elementary rationale of the Shapley value. Furthermore, we propose a method to learn optimal baseline values, and experimental results have demonstrated its effectiveness.

****

FedGSNR: Accelerating Federated Learning on Non-IID Data via Maximum Gradient Signal to Noise Ratio

Qi Tan,Yi Zhao,Ke Xu,Qi Li

Federated learning (FL) allows participants jointly training a model without direct data sharing. In such a process, participants rather than the central server perform local updates of stochastic gradient descent (SGD) and the central server aggregates the gradients from the participants to update the global model. However, the non-iid training data in participants significantly impact global model convergence.Most of existing studies addressed this issue by utilizing variance reduction or regularization. However, these studies focusing on specific datasets lack theoretical guarantee for efficient model training. In this paper, we provide a novel perspective on the non-iid issue by optimizing Gradient Signal to Noise Ratio (GSNR) during model training. In each participant, we decompose local gradients calculated on the non-iid training data into the signal and noise components and then speed up the model convergence by maximizing GSNR. We prove that GSNR can be maximized by using the optimal number of local updates. Subsequently, we develop FedGSNR to compute the optimal number of local updates for each participant, which can be applied to existing gradient calculation algorithms to accelerate the global model convergence. Moreover, according to the positive correlation between GSNR and the quality of shared information, FedGSNR allows the server to accurately evaluate contributions of different participants (i.e., the quality of local datasets) by utilizing GSNR. Extensive experimental evaluations demonstrate that FedGSNR achieves on average a 1.69× speedup with comparable accuracy.

Dataless Knowledge Fusion by Merging Weights of Language Models

Xisen Jin,Xiang Ren,Daniel Preotiuc-Pietro,Pengxiang Cheng

Fine-tuning pre-trained language models has become the prevalent paradigm for building downstream NLP models. Oftentimes fine-tuned models are readily available but their training data is not, due to data privacy or intellectual property concerns. This creates a barrier to fusing knowledge across individual models to yield a better single model. In this paper, we study the problem of merging individual models built on different training data sets to obtain a single model that

performs well both across all data set domains and can generalize on out-of-domain data. We propose a data-less knowledge fusion method that merges models in their parameter space, guided by weights that minimize prediction differences between the merged model and the individual models. Over a battery of evaluation settings, we show that the proposed method significantly outperforms baselines such as Fisher-weighted averaging or model ensembling. Further, we find that our method is a promising alternative to multi-task learning that can preserve or sometimes improve over the individual models without access to the training data. Finally, model merging is more efficient than training a multi-task model, thus making it applicable to a wider set of scenarios.
****

Domain-Indexing Variational Bayes: Interpretable Domain Index for Domain Adaptation

Zihao Xu,Guang-Yuan Hao,Hao He,Hao Wang

Previous studies have shown that leveraging "domain index" can significantly boost domain adaptation performance (Wang et al., 2020; Xu et al., 2022). However, such domain indices are not always available. To address this challenge, we first provide a formal definition of domain index from the probabilistic perspective, and then propose an adversarial variational Bayesian framework that infers domain indices from multi-domain data, thereby providing additional insight on domain relations and improving domain adaptation performance. Our theoretical analysis shows that our adversarial variational Bayesian framework finds the optimal domain index at equilibrium. Empirical results on both synthetic and real data verify that our model can produce interpretable domain indices which enable us to achieve superior performance compared to state-of-the-art domain adaptation methods. Code is available at https://github.com/Wang-ML-Lab/VDI.

Improving the Transferability of Adversarial Attacks through Experienced Precise Nesterov Momentum

Hao Wu,Jinwei Wang,Jiawei Zhang,Bin Ma,Xiangyang Luo,wang yu

Deep Neural Networks are vulnerable to adversarial attacks, which makes adversarial attacks serve as a method to evaluate the robustness of DNNs. However, adversarial attacks have high white-box attack success rates but poor transferability, making black-box attacks impracticable in the real world. Momentum-based attacks were proposed to accelerate optimization to improve transferability. Nevertheless, conventional momentum-based attacks accelerate optimization inefficiently during early iterations since the initial value of momentum is zero, which leads to unsatisfactory transferability. Therefore, we propose Experienced Momentum (EM), which is the pre-trained momentum. Initializing the momentum to EM can help accelerate optimization during the early iterations. Moreover, the pre-update of conventional Nesterov momentum based attacks is rough, prompting us to propose Precise Nesterov momentum (PN). PN refines the pre-update by considering the gradient of the current data point. Finally, we integrate EM with PN as Experienced Precise Nesterov momentum (EPN) to further improve transferability. Extensive experiments against normally trained and defense models demonstrate that our EPN is more effective than conventional momentum in the improvement of transferability. Specifically, the attack success rates of our EPN-based attacks are $\sim$11.9% and $\sim$13.1% higher than conventional momentum-based attacks on average against normally trained and defense models, respectively.

TaylorNet: A Taylor-Driven Generic Neural Architecture

Hongjue Zhao,Yizhuo Chen,Dachun Sun,Yingdong Hu,Kaizhao Liang,Yanbing Mao,Lui Sha,Huajie Shao

Physics-informed machine learning (PIML) aims to incorporate physics knowledge into deep neural networks (DNNs) to improve the model generalization. However, existing methods in PIML are either designed for specific problems or hard to interpret the results using black-box DNNs. In this work, we propose Taylor Neural Network (TaylorNet), a generic neural architecture that parameterizes Taylor polynomials using DNNs without using non-linear activation functions. The key challenges of developing TaylorNet lie in: (i) mitigating the curse of dimensionality caused by higher-order terms, and (ii) improving the stability of model training. To overcome these challenges, we first adopt Tucker decomposition to decompose the higher-order derivatives in Taylor expansion parameterized by DNNs into low-rank tensors. Then we propose a novel reducible TaylorNet to further reduce the computational complexity by removing more redundant parameters in the hidden layers. In order to improve training accuracy and stability, we develop a new Taylor initialization method. Finally, the proposed models are evaluated on a broad spectrum of applications, including image classification, natural language processing (NLP), and dynamical systems. The results demonstrate that our proposed Taylor-Mixer, which replaces MLP and activation layers in the MLP-Mixer with Taylor layer, can achieve comparable accuracy on image classification, and similarly on sentiment analysis in NLP, while significantly reducing the number of model parameters. More importantly, our method can interpret some dynamical systems with Taylor polynomials. Meanwhile, the results demonstrate that our Taylor initialization can significantly improve classification accuracy compared to Xavier and Kaiming initialization.

Semi-supervised learning of partial differential operators and dynamical flows

Michael Rotman,Amit Dekel,Ran Ilan Ber,Lior Wolf,Yaron Oz

The evolution of dynamical systems is generically governed by nonlinear partial differential equations (PDEs), whose solution, in a simulation framework, requires vast amounts of computational resources. In this work, we present a novel method that combines a hyper-network solver with a Fourier Neural Operator architecture. Our method treats time and space separately and as a result, it successfully propagates initial conditions in continuous time steps by employing the general composition properties of the partial differential operators. Following previous works, supervision is provided at a specific time point. We test our method on various time evolution PDEs, including nonlinear fluid flows in one, two, or three spatial dimensions. The results show that the new method improves the learning accuracy at the time of the supervision point, and can interpolate the solutions to any intermediate time.

View Synthesis with Sculpted Neural Points

Yiming Zuo,Jia Deng

We address the task of view synthesis, generating novel views of a scene given a set of images as input. In many recent works such as NeRF (Mildenhall et al., 2020), the scene geometry is parameterized using neural implicit representations (i.e., MLPs). Implicit neural representations have achieved impressive visual quality but have drawbacks in computational efficiency. In this work, we propose a new approach that performs view synthesis using point clouds. It is the first point-based method that achieves better visual quality than NeRF while being 100× faster in rendering speed. Our approach builds on existing works on differentiable point-based rendering but introduces a novel technique we call “Sculpted Neural Points (SNP)”, which significantly improves the robustness to errors and holes in the reconstructed point cloud. We further propose to use view-dependent point features based on spherical harmonics to capture non-Lambertian surfaces, and new designs in the point-based rendering pipeline that further boost the performance. Finally, we show that our system supports fine-grained scene editing. Code is available at https://github.com/princeton-vl/SNP.

Universal Vision-Language Dense Retrieval: Learning A Unified Representation Space for Multi-Modal Retrieval

Zhenghao Liu,Chenyan Xiong,Yuanhuiyi Lv,Zhiyuan Liu,Ge Yu

This paper presents Universal Vision-Language Dense Retrieval (UniVL-DR), which builds a unified model for multi-modal retrieval. UniVL-DR encodes queries and multi-modality resources in an embedding space for searching candidates from different modalities. To learn a unified embedding space for multi-modal retrieval, UniVL-DR proposes two techniques: 1) Universal embedding optimization strategy, which contrastively optimizes the embedding space using the modality-balanced hard negatives; 2) Image verbalization method, which bridges the modality gap betw een images and texts in the raw data space. UniVL-DR achieves the state-of-the-art on the multi-modal open-domain question answering benchmark, WebQA, and outperforms all retrieval models on the two subtasks, text-text retrieval and text-image retrieval. It demonstrates that universal multi-modal search is feasible to replace the divide-and-conquer pipeline with a united model and also benefits single/cross modality tasks. All source codes of this work are available at https://github.com/OpenMatch/UniVL-DR.

DFlow: Learning to Synthesize Better Optical Flow Datasets via a Differentiable Pipeline

Kwon Byung-Ki,Nam Hyeon-Woo,Ji-Yun Kim,Tae-Hyun Oh

Comprehensive studies of synthetic optical flow datasets have attempted to reveal what properties lead to accuracy improvement in learning-based optical flow estimation. However, manually identifying and verifying the properties that contribute to accurate optical flow estimation require large-scale trial-and-error experiments with iteratively generating whole synthetic datasets and training on them, \ie, impractical. To address this challenge, we propose a differentiable optical flow data generation pipeline and a loss function to drive the pipeline, called DFlow. DFlow efficiently synthesizes a dataset effective for a target domain without the need for cumbersome try-and-errors. This favorable property is achieved by proposing an efficient dataset comparison method that uses neural networks to approximately encode each dataset and compares the proxy networks instead of explicitly comparing datasets in a pairwise way. Our experiments show the competitive performance of our DFlow against the prior arts in pre-training. Furthermore, compared to competing datasets, DFlow achieves the best fine-tuning performance on the Sintel public benchmark with RAFT.

****

One-Pixel Shortcut: On the Learning Preference of Deep Neural Networks

Shutong Wu,Sizhe Chen,Cihang Xie,Xiaolin Huang

Unlearnable examples (ULEs) aim to protect data from unauthorized usage for training DNNs. Existing work adds ℓ_∞-bounded perturbations to the original sample so that the trained model generalizes poorly. Such perturbations, however, are easy to eliminate by adversarial training and data augmentations. In this paper, we resolve this problem from a novel perspective by perturbing only one pixel in each image. Interestingly, such a small modification could effectively degrade model accuracy to almost an untrained counterpart. Moreover, our produced \emph{One-Pixel Shortcut (OPS)} could not be erased by adversarial training and strong augmentations. To generate OPS, we perturb in-class images at the same position to the same target value that could mostly and stably deviate from all the original images. Since such generation is only based on images, OPS needs significantly less computation cost than the previous methods using DNN generators. Based on OPS, we introduce an unlearnable dataset called CIFAR-10-S, which is indistinguishable from CIFAR-10 by humans but induces the trained model to extremely low accuracy. Even under adversarial training, a ResNet-18 trained on CIFAR-10-S has only 10.61% accuracy, compared to 83.02% by the existing error-minimizing method.

Make Memory Buffer Stronger in Continual Learning: A Continuous Neural Transformation Approach

Zhenyi Wang,Li Shen,Qiuling Suo,Tiehang Duan,Yanjun Zhu,Tongliang Liu,Mingchen Gao

Continual learning (CL) focuses on learning non-stationary data distribution without forgetting previous knowledge. However, the most widely used memory-replay approach often suffers from memory overfitting. To mitigate the memory overfitting, we propose a continuous and reversible memory transformation method so that the memory data is hard to overfit, thus improving generalization. The transformation is achieved by optimizing a bi-level optimization objective that jointly learns the CL model and memory transformer. Specifically, we propose a deterministic continuous memory transformer (DCMT) modeled by an ordinary differential equation, allowing for infinite memory transformation and generating diverse and ha rd memory data. Furthermore, we inject uncertainty into the transformation function and propose a stochastic continuous memory transformer (SCMT) modeled by a stochastic differential equation, which substantially enhances the diversity of the transformed memory buffer. The proposed neural transformation approaches have significant advantages over existing ones: (1) we can obtain infinite many transformed data, thus significantly increasing the memory buffer diversity; (2) the proposed continuous transformations are reversible, i.e., the original raw memory data could be restored from the transformed memory data without the need to make a replica of the memory data. Extensive experiments on both task-aware and task-free CL show significant improvement with our approach compared to strong baselines.

Sparse Random Networks for Communication-Efficient Federated Learning
Berivan Isik,Francesco Pase,Deniz Gunduz,Tsachy Weissman,Zorzi Michele

One main challenge in federated learning is the large communication cost of exchanging weight updates from clients to the server at each round. While prior work has made great progress in compressing the weight updates through gradient compression methods, we propose a radically different approach that does not update the weights at all. Instead, our method freezes the weights at their initial \emph{random} values and learns how to sparsify the random network for the best performance. To this end, the clients collaborate in training a \emph{stochastic} binary mask to find the optimal sparse random network within the original one. At the end of the training, the final model is a sparse network with random weights -- or a subnetwork inside the dense random network. We show improvements in accuracy, communication (less than 1 bit per parameter (bpp)), convergence speed, and final model size (less than 1 bpp) over relevant baselines on MNIST, EMNIST, CIFAR-10, and CIFAR-100 datasets, in the low bitrate regime.

On the Impact of Adversarially Robust Models on Algorithmic Recourse
Satyapriya Krishna,Chirag Agarwal,Himabindu Lakkaraju

The widespread deployment of machine learning models in various high-stakes settings has underscored the need for ensuring that individuals who are adversely impacted by model predictions are provided with a means for recourse. To this end, several algorithms have been proposed in recent literature to generate recourses. Recent research has also demonstrated that the recourses generated by these algorithms often correspond to adversarial examples. This key finding emphasizes the need for a deeper understanding of the impact of adversarially robust models (which are designed to guard against adversarial examples) on algorithmic recourse. In this work, we make one of the first attempts at studying the impact of adversarially robust models on algorithmic recourse. We theoretically and empirically analyze the cost (ease of implementation) and validity (probability of obtaining a positive model prediction) of the recourses output by state-of-the-art algorithms when the underlying models are adversarially robust. More specifically, we construct theoretical bounds on the differences between the cost and the validity of the recourses generated by various state-of-the-art algorithms when the underlying models are adversarially robust vs. non-robust. We also carry out extensive empirical analysis with multiple real-world datasets to not only validate our theoretical results, but also analyze the impact of varying degrees of model robustness on the cost and validity of the resulting recourses. Our theoretical and empirical analyses demonstrate that adversarially robust models significantly increase the cost and reduce the validity of the resulting recourses, thereby shedding light on the inherent trade-offs between achieving adversarial robustness in predictive models and providing easy-to-implement and reliable algorithmic recourse.

Breaking Beyond COCO Object Detection
ali borji

COCO dataset has become the de facto standard for training and evaluating object detectors. According to the recent benchmarks, however, performance on this dataset is still far from perfect, which raises the following questions, a) how

far can
we improve the accuracy on this dataset using deep learning, b) what is holding us back in making progress in object detection, and c) what are the limitations of the COCO dataset and how can they be mitigated. To answer these questions, first, we propose a systematic approach to determine the empirical upper bound in AP over COCOval2017, and show that this upper bound is significantly higher than the state-of-the-art mAP (78.2% vs. 58.8%). Second, we introduce two complementary datasets to COCO: i) COCO_OI, composed of images from COCO and OpenImages (from 80 classes in common) with 1,418,978 training bounding boxes over 380,111 images, and 41,893 validation bounding boxes over 18,299 images, and ii) ObjectNet_D containing objects in daily life situations (originally created for object recognition known as ObjectNet; 29 categories in common with COCO). We evaluate models on these datasets and pinpoint the annotation errors on the COCO validation set. Third, we characterize the sources of errors in modern object detectors using a recently proposed error analysis tool (TIDE) and find that models behave differently on these datasets compared to COCO. For instance, missing objects are more frequent in the new datasets. We also find that models lack out of distribution generalization. Code and data will be shared.

NormSoftmax: Normalize the Input of Softmax to Accelerate and Stabilize Training
Zixuan Jiang,Jiaqi Gu,David Z. Pan

Softmax is a basic function that normalizes a vector to a probability distribution and is widely used in machine learning, most notably in cross-entropy loss function and dot product attention operations. However, optimization of softmax-based models is sensitive to the input statistics change. We observe that the input of softmax changes significantly during the initial training stage, causing slow and unstable convergence when training the model from scratch. To remedy the optimization difficulty of softmax, we propose a simple yet effective substitution, named NormSoftmax, where the input vector is first normalized to unit variance and then fed to the standard softmax function. Similar to other existing normalization layers in machine learning models, NormSoftmax can stabilize and accelerate the training process, and also increase the robustness of the training procedure against hyperparameters. Experiments on Transformer-based models and convolutional neural networks validate that our proposed NormSoftmax is an effective plug-and-play module to stabilize and speed up the optimization of neural networks with cross-entropy loss or dot-product attention operations.

Differentially Private Dataset Condensation
Tianhang Zheng,Baochun Li

Recent work in ICML'22 builds a theoretical connection between dataset condensation (DC) and differential privacy (DP) and claims that DC can provide privacy protection for free. However, the connection is problematic because of two controversial assumptions. In this paper, we revisit the ICML'22 work and elucidate the issues in the two controversial assumptions. To correctly connect DC and DP, we propose two differentially private dataset condensation (DPDC) algorithms---LDPDC and NDPDC. Through extensive evaluations on multiple datasets, we demonstrate that LDPDC has comparable performance to recent DP generative methods despite its simplicity. NDPDC provides acceptable DP guarantees with a mild utility loss, compared to the state-of-the-art DC method. Additionally, NDPDC allows a flexible trade-off between the synthetic data utility and DP budget.

A General Framework For Proving The Equivariant Strong Lottery Ticket Hypothesis
Damien Ferbach,Christos Tsirigotis,Gauthier Gidel,Joey Bose

The Strong Lottery Ticket Hypothesis (SLTH) stipulates the existence of a subnetwork within a sufficiently overparameterized (dense) neural network that---when initialized randomly and without any training---achieves the accuracy of a fully trained target network. Recent works by Da Cunha et. al 2022, Burkholz 2022 dem onstrate that the SLTH can be extended to translation equivariant networks---i.e. CNNs---with the same level of overparametrization as needed for the SLTs in dense networks. However, modern neural networks are capable of incorporating more than just translation symmetry, and developing general equivariant architectures such as rotation and permutation has been a powerful design principle. In this paper, we generalize the SLTH to functions that preserve the action of the group G---i.e. G-equivariant network---and prove, with high probability, that one can approximate any G-equivariant network of fixed width and depth by pruning a randomly initialized overparametrized G-equivariant network to a G-equivariant subnetwork. We further prove that our prescribed overparametrization scheme is optimal and provide a lower bound on the number of effective parameters as a function of the error tolerance. We develop our theory for a large range of groups, including subgroups of the Euclidean $\text{E}(2)$ and Symmetric group $G \leq \mathcal{S}_n$---allowing us to find SLTs for MLPs, CNNs, $\text{E}(2)$-steerable CNNs, and permutation equivariant networks as specific instantiations of our unified framework. Empirically, we verify our theory by pruning overparametrized $\text{E}(2)$-steerable CNNs, k-order GNNs, and message passing GNNs to match the performance of trained target networks.

Robust Fair Clustering: A Novel Fairness Attack and Defense Framework

Anshuman Chhabra,Peizhao Li,Prasant Mohapatra,Hongfu Liu

Clustering algorithms are widely used in many societal resource allocation applications, such as loan approvals and candidate recruitment, among others, and hence, biased or unfair model outputs can adversely impact individuals that rely on these applications. To this end, many $\textit{fair}$ clustering approaches have been recently proposed to counteract this issue. Due to the potential for significant harm, it is essential to ensure that fair clustering algorithms provide consistently fair outputs even under adversarial influence. However, fair clustering algorithms have not been studied from an adversarial attack perspective. In contrast to previous research, we seek to bridge this gap and conduct a robustness analysis against fair clustering by proposing a novel $\textit{black-box fairness attack}$. Through comprehensive experiments, we find that state-of-the-art models are highly susceptible to our attack as it can reduce their fairness performance significantly. Finally, we propose Consensus Fair Clustering (CFC), the first $\textit{robust fair clustering}$ approach that transforms consensus clustering into a fair graph partitioning problem, and iteratively learns to generate fair cluster outputs. Experimentally, we observe that CFC is highly robust to the proposed attack and is thus a truly robust fair clustering alternative.

Learning to Jointly Share and Prune Weights for Grounding Based Vision and Language Models

Shangqian Gao,Burak Uzkent,Yilin Shen,Heng Huang,Hongxia Jin

Transformers have seen growing interest in processing different modalities, including language and image data. As a result, we can process vision and language data using transformers that are architecturally similar. Leveraging this feature of transformers, we propose weight sharing across two transformer backbones and within the same transformer backbone and pruning across two backbones in a unified framework. More specifically, we investigate weight sharing and pruning for two components of the transformers: (1) Multi-Head Attention (MSA) and (2) Feed-Forward Network (FFN) layers. To jointly perform weight sharing and pruning, we propose to use a regularization term to align model weights and the desired structure during the multimodal pre-training step. The structure vectors of sharing and pruning are generated by using a hypernetwork, which can capture complex interactions between pruning and sharing across layers and modalities. We train the hypernetwork and model weights iteratively so that the learned structure evolves along with model weights. After minimizing the proposed objective in the pre-training step, we perform weight sharing and pruning and fine-tune the compressed model on downstream tasks. Finally, we perform experiments on vision and language tasks, including Referring Expression Comprehension (REC), Visual Question Answering (VQA), and Object Detection using the state-of-the-art grounding based models: MDETR and GLIP. Our experiments show that we can compress these models by $35-40\%$ by sharing and pruning MSA and FFN weights without almost any loss in accuracy.

****

Spatial Attention Kinetic Networks with E(n)-Equivariance

Yuanqing Wang,John Chodera

Neural networks that are equivariant to rotations, translations, reflections, and permutations on n-dimensional geometric space have shown promise in physical modeling for tasks such as accurately but inexpensively modeling complex potential energy surfaces to guiding the sampling of complex dynamical systems or forecasting their time evolution.

Current state-of-the-art methods employ spherical harmonics to encode higher-order interactions among particles, which are computationally expensive.

In this paper, we propose a simple alternative functional form that uses neurally parametrized linear combinations of edge vectors to achieve equivariance while still universally approximating node environments.

Incorporating this insight, we design \emph{spatial attention kinetic networks} with E(n)-equivariance, or SAKE, which are competitive in many-body system modeling tasks while being significantly faster.

****

Light-weight probing of unsupervised representations for Reinforcement Learning

Wancong Zhang,Anthony GX-Chen,Vlad Sobal,Yann LeCun,Nicolas Carion

Unsupervised visual representation learning offers the opportunity to leverage large corpora of unlabeled trajectories to form useful visual representations, which can benefit the training of reinforcement learning (RL) algorithms. However, evaluating the fitness of such representations requires training RL algorithms which is both computationally intensive and has high variance outcomes. To alleviate this issue, we design an evaluation protocol for unsupervised RL representations with lower variance and up to 600x lower computational cost. Inspired by the vision community, we propose two linear probing tasks: predicting the reward observed in a given state, and predicting the action of an expert in a given state. These two tasks are generally applicable to many RL domains, and we show through rigorous experimentation that they correlate strongly with the actual downstream control performance on the Atari100k Benchmark. This provides a better method for exploring the space of pretraining algorithms without the need of running RL evaluations for every setting. Leveraging this framework, we further improve existing self-supervised learning (SSL) recipes for RL, highlighting the importance of the forward model, the size of the visual backbone, and the precise formulation of the unsupervised objective.

****

Understanding Rare Spurious Correlations in Neural Networks

Yao-Yuan Yang,Chi-Ning Chou,Kamalika Chaudhuri

Neural networks are known to use spurious correlations such as background information for classification. While prior work has looked at spurious correlations that are widespread in the training data, in this work, we investigate how sensitive neural networks are to $rare$ spurious correlations, which may be harder to detect and correct, and may lead to privacy leaks. We introduce spurious patterns correlated with a fixed class to a few training examples and find that it takes only a handful of such examples for the network to learn the correlation. Furthermore, these rare spurious correlations also impact accuracy and privacy. We empirically and theoretically analyze different factors involved in rare spurious correlations and propose mitigation methods accordingly. Specifically, we observe that ℓ_2 regularization and adding Gaussian noise to inputs can reduce the undesirable effects.

****

Graph Domain Adaptation via Theory-Grounded Spectral Regularization

Yuning You,Tianlong Chen,Zhangyang Wang,Yang Shen

Transfer learning on graphs drawn from varied distributions (domains) is in great demand across many applications. Emerging methods attempt to learn domain-invariant representations using graph neural networks (GNNs), yet the empirical perf ormances vary and the theoretical foundation is limited. This paper aims at designing theory-grounded algorithms for graph domain adaptation (GDA). (i) As the first attempt, we derive a model-based GDA bound closely related to two GNN spectral properties: spectral smoothness (SS) and maximum frequency response (MFR). This is achieved by cross-pollinating between the OT-based (optimal transport) DA and graph filter theories. (ii) Inspired by the theoretical results, we propose algorithms regularizing spectral properties of SS and MFR to improve GNN transferability. We further extend the GDA theory into the more challenging scenario of conditional shift, where spectral regularization still applies. (iii) More importantly, our analyses of the theory reveal which regularization would improve performance of what transfer learning scenario, (iv) with numerical agreement with extensive real-world experiments: SS and MFR regularizations bring more benefits to the scenarios of node transfer and link transfer, respectively. In a nutshell, our study paves the way toward explicitly constructing and training GNNs that can capture more transferable representations across graph domains. Codes are released at https://github.com/Shen-Lab/GDA-SpecReg.

Effective dimension of machine learning models

Amira Abbas,David Sutter,Alessio Figalli,Stefan Woerner

Making statements about the performance of trained models on tasks involving new data is one of the primary goals of machine learning, i.e., to understand the generalization power of a model. Various capacity measures try to capture this ability, but usually fall short in explaining important characteristics of models that we observe in practice. In this study, we propose the local effective dimension as a capacity measure which seems to correlate well with generalization error on standard data sets. Importantly, we prove that the local effective dimension bounds the generalization error and discuss the aptness of this capacity measure for machine learning models.

****

CLARE: Conservative Model-Based Reward Learning for Offline Inverse Reinforcement Learning

Sheng Yue,Guanbo Wang,Wei Shao,Zhaofeng Zhang,Sen Lin,Ju Ren,Junshan Zhang

This work aims to tackle a major challenge in offline Inverse Reinforcement Learning (IRL), namely the reward extrapolation error, where the learned reward function may fail to explain the task correctly and misguide the agent in unseen environments due to the intrinsic covariate shift. Leveraging both expert data and lower-quality diverse data, we devise a principled algorithm (namely CLARE) that solves offline IRL efficiently via integrating "conservatism" into a learned reward function and utilizing an estimated dynamics model. Our theoretical analysis provides an upper bound on the return gap between the learned policy and the expert policy, based on which we characterize the impact of covariate shift by examining subtle two-tier tradeoffs between the exploitation (on both expert and diverse data) and exploration (on the estimated dynamics model). We show that CLARE can provably alleviate the reward extrapolation error by striking the right exploitation-exploration balance therein. Extensive experiments corroborate the significant performance gains of CLARE over existing state-of-the-art algorithms on MuJoCo continuous control tasks (especially with a small offline dataset), and the learned reward is highly instructive for further learning.

****

Data-Free One-Shot Federated Learning Under Very High Statistical Heterogeneity

Clare Elizabeth Heinbaugh,Emilio Luz-Ricca,Huajie Shao

Federated learning (FL) is an emerging distributed learning framework that collaboratively trains a shared model without transferring the local clients' data to a centralized server. Motivated by concerns stemming from extended communication and potential attacks, one-shot FL limits communication to a single round while attempting to retain performance. However, one-shot FL methods often degrade under high statistical heterogeneity, fail to promote pipeline security, or require an auxiliary public dataset. To address these limitations, we propose two novel data-free one-shot FL methods: FedCVAE-Ens and its extension FedCVAE-KD. Both approaches reframe the local learning task using a conditional variational auto

encoder (CVAE) to address high statistical heterogeneity. Furthermore, FedCVAE-KD leverages knowledge distillation to compress the ensemble of client decoders into a single decoder. We propose a method that shifts the center of the CVAE prior distribution and experimentally demonstrate that this promotes security, and show how either method can incorporate heterogeneous local models. We confirm the efficacy of the proposed methods over baselines under high statistical heterogeneity using multiple benchmark datasets. In particular, at the highest levels of statistical heterogeneity, both FedCVAE-Ens and FedCVAE-KD typically more than double the accuracy of the baselines.
****

Personalized Subgraph Federated Learning
Jinheon Baek,Wonyong Jeong,Jiongdao Jin,Jaehong Yoon,Sung Ju Hwang
In real-world scenarios, subgraphs of a larger global graph may be distributed across multiple devices or institutions, and only locally accessible due to privacy restrictions, although there may be links between them. Recently proposed subgraph Federated Learning (FL) methods deal with those missing links across private local subgraphs while distributively training Graph Neural Networks (GNNs) on them. However, they have overlooked the inevitable heterogeneity among subgraphs, caused by subgraphs comprising different communities of a global graph, therefore, consequently collapsing the incompatible knowledge from local GNN models trained on heterogeneous graph distributions. To overcome such a limitation, we introduce a new subgraph FL problem, personalized subgraph FL, which focuses on the joint improvement of the interrelated local GNN models rather than learning a single global GNN model, and propose a novel framework, FEDerated Personalized sUBgraph learning (FED-PUB), to tackle it. A crucial challenge in personalized subgraph FL is that the server does not know which subgraph each client has. FED-PUB thus utilizes functional embeddings of the local GNNs using random graphs as inputs to compute similarities between them, and use them to perform weighted averaging for server-side aggregation. Further, it learns a personalized sparse mask at each client to select and update only the subgraph-relevant subset of the aggregated parameters. We validate FED-PUB for its subgraph FL performance on six datasets, considering both non-overlapping and overlapping subgraphs, on which ours largely outperforms relevant baselines.

Domain-Adjusted Regression or: ERM May Already Learn Features Sufficient for Out-of-Distribution Generalization
Elan Rosenfeld,Pradeep Kumar Ravikumar,Andrej Risteski
A common explanation for the failure of deep networks to generalize out-of-distribution is that they fail to recover the "correct" features. We challenge this notion with a simple experiment which suggests that ERM already learns sufficient features and that the current bottleneck is not feature learning, but robust regression. We therefore argue that devising simpler methods for learning predictors on existing features is a promising direction for future research. Towards this end, we introduce Domain-Adjusted Regression (DARE), a convex objective for learning a linear predictor that is provably robust under a new model of distribution shift. Rather than learning one function, DARE performs a domain-specific adjustment to unify the domains in a canonical latent space and learns to predict in this space. Under a natural model, we prove that the DARE solution is the minimax-optimal predictor for a constrained set of test distributions. Further, we provide the first finite-environment convergence guarantee to the minimax risk, improving over existing analyses which only yield minimax predictors after an environment threshold. Evaluated on finetuned features, we find that DARE compares favorably to prior methods, consistently achieving equal or better performance.

Initial Value Problem Enhanced Sampling for Closed-Loop Optimal Control Design with Deep Neural Networks
Xuanxi Zhang,Jihao Long,Wei Hu,Weinan E,Jiequn Han
Closed-loop optimal control design for high-dimensional nonlinear systems has been a long-standing challenge. Traditional methods, such as solving the associate

d Hamilton-Jacobi-Bellman equation, suffer from the curse of dimensionality. Recent literature proposed a new promising approach based on supervised learning, by leveraging powerful open-loop optimal control solvers to generate training data and neural networks as efficient high-dimensional function approximators to fit the closed-loop optimal control. This approach successfully handles certain high-dimensional optimal control problems but still performs poorly on more challenging problems. One of the crucial reasons for the failure is the so-called distribution mismatch phenomenon brought by the controlled dynamics. In this paper, we investigate this phenomenon and propose the initial value problem enhanced sampling method to mitigate this problem. We theoretically prove that this sampling strategy improves over the vanilla strategy on the classical linear-quadratic regulator by a factor proportional to the total time duration. We further numerically demonstrate that the proposed sampling strategy significantly improves the performance on tested control problems, including the optimal landing problem of a quadrotor and the optimal reaching problem of a 7 DoF manipulator.

C3PO: Learning to Achieve Arbitrary Goals via Massively Entropic Pretraining
Alexis D. Jacq,Manu Orsini,Gabriel Dulac-Arnold,Olivier Pietquin,Matthieu Geist,Olivier Bachem

Given a particular embodiment, we propose a novel method (C3PO) that learns policies able to achieve any arbitrary position and pose. Such a policy would allow for easier control, and would be re-useable as a key building block for downstream tasks. The method is two-fold: First, we introduce a novel exploration algorithm that optimizes for uniform coverage, is able to discover a set of achievable states, and investigates its abilities in attaining both high coverage, and hard-to-discover states; Second, we leverage this set of achievable states as training data for a universal goal-achievement policy, a goal-based SAC variant. We demonstrate the trained policy's performance in achieving a large number of novel states. Finally, we showcase the influence of massive unsupervised training of a goal-achievement policy with state-of-the-art pose-based control of the Hopper, Walker, Halfcheetah, Humanoid and Ant embodiments.

****

ProtoVAE: Using Prototypical Networks for Unsupervised Disentanglement
Vaishnavi S Patil,Matthew Evanusa,Joseph JaJa

Generative modeling and self-supervised learning have in recent years made great strides towards learning from data in a completely \emph{unsupervised} way. There is still, however, an open area of investigation into guiding the neural network to learn useful or good representations. The problem of unsupervised \textit{Disentanglement} is of particular importance as it offers to learn interpretable representations, with disjoint subsets of the representation encoding different, meaningful factors of variation. Recent work has theoretically grounded the factors of variation, via the lens of group theory, as disentangled actions of the symmetry subgroups which transform only the correspond subspaces of the disentangled representation. We use this mathematical formalism instead to impose constraints on the representations learned by a unsupervised generative neural network, such that transformations of the representation correspond to the actions of a unique symmetry subgroup. To this end, we introduce a novel model, ProtoVAE, that leverages a deep metric learning Prototypical network trained via self-supervision to constrain the latent space of a Variational Autoencoder to decompose into independent subspaces. Further, we actively change or \textit{intervene} in the latent space during training to enforce each dimension of the representation to uniquely and consistently transform the data corresponding to some symmetry subgroup. We demonstrate and evaluate our proposed model on the benchmark DSprites and 3DShapes datasets and compare with other state of the art disentanglement methods via qualitative traversals in the latent space, as well as quantitative disentanglement metrics. We further qualitatively demonstrate the effectiveness of our model on the real-world datasets CelebA which consistently encodes the different factors.

Neural Diffusion Processes

Vincent Dutordoir,Alan Saul,Zoubin Ghahramani,Fergus Simpson

Gaussian processes provide an elegant framework for specifying prior and posterior distributions over functions. They are, however, also computationally expensive, and limited by the expressivity of their covariance function. We propose Neural Diffusion Processes (NDPs), a novel approach based upon diffusion models, that learns to sample from distributions over functions. Using a novel attention block we are able to incorporate properties of stochastic processes, such as exchangeability, directly into the NDP's architecture. We empirically show that NDPs are able to capture functional distributions that are close to the true Bayesian posterior. This enables a variety of downstream tasks, including hyperparameter marginalisation, non-Gaussian posteriors and global optimisation.

****

Global Context Vision Transformers

Ali Hatamizadeh,Hongxu Yin,Jan Kautz,Pavlo Molchanov

We propose global context vision transformer (GC ViT), a novel architecture that enhances parameter and compute utilization for computer vision tasks. The core of the novel model are global context self-attention modules, joint with standard local self-attention, to effectively yet efficiently model both long and short-range spatial interactions, as an alternative to complex operations such as an attention masks or local windows shifting. While the local self-attention modules are responsible for modeling short-range information, the global query tokens are shared across all global self-attention modules to interact with local key and values. In addition, we address the lack of inductive bias in ViTs and improve the modeling of inter-channel dependencies by proposing a novel downsampler which leverages a parameter-efficient fused inverted residual block. The proposed GC ViT achieves new state-of-the-art performance across image classification, object detection and semantic segmentation tasks. On ImageNet-1K dataset for classification, the tiny, small and base variants of GC ViT with 28M, 51M and 90M parameters achieve 83.4%, 83.9% and 84.4% Top-1 accuracy, respectively, surpassing comparably-sized prior art such as CNN-based ConvNeXt and ViT-based Swin Transformer. Pre-trained GC ViT backbones in downstream tasks of object detection, instance segmentation, and semantic segmentation on MS COCO and ADE20K datasets outperform prior work consistently, sometimes by large margins.

Adversarial Learned Fair Representations using Dampening and Stacking

Max Knobbout

As more decisions in our daily life become automated, the need to have machine learning algorithms that make fair decisions increases. In fair representation learning we are tasked with finding a suitable representation of the data in which a sensitive variable is censored. Recent work aims to learn fair representations through adversarial learning. This paper builds upon this work by introducing a novel algorithm which uses dampening and stacking to learn adversarial fair representations. Results show that that our algorithm improves upon earlier work in both censoring and reconstruction.

Watch What You Pretrain For: Targeted, Transferable Adversarial Examples on Self-Supervised Speech Recognition models

Raphael Olivier,Hadi Abdullah,Bhiksha Raj

A targeted adversarial attack produces audio samples that can force an Automatic Speech Recognition (ASR) system to output attacker-chosen text. To exploit ASR models in real-world, black-box settings, an adversary can leverage the transferability property, i.e. that an adversarial sample produced for a proxy ASR can also fool a different remote ASR. However recent work has shown that transferability against large ASR models is very difficult. In this work, we show that modern ASR architectures, specifically ones based on Self-Supervised Learning, are in fact vulnerable to transferability. We successfully demonstrate this phenomenon by evaluating state-of-the-art self-supervised ASR models like Wav2Vec2, HuBERT, Data2Vec and WavLM. We show that with low-level additive noise achieving a 30dB Signal-Noise Ratio, we can achieve target transferability with up to 80\% accuracy. Next, we 1) use an ablation study to show that Self-Supervised learning i s the main cause of that phenomenon, and 2) we provide an explanation for this phenomenon. Through this we show that modern ASR architectures are uniquely vulnerable to adversarial security threats.

Imposing conservation properties in deep dynamics modeling via contrastive learning

Wang Zhang,Subhro Das,Tsui-Wei Weng,Alexandre Megretski,Luca Daniel,Lam M. Nguyen

Deep neural networks (DNN) has shown great capacity of modeling a dynamical system, but these DNN-based dynamical models usually do not obey conservation laws. To impose the learned DNN dynamical models with key physical properties such as conservation laws, this paper proposes a two-step approach to endow the invariant priors into the simulations. We first establish a contrastive learning framework to capture the system invariants along the trajectory observations. During the dynamics modeling, we design a projection layer of DNNs to preserve the system invariance. Through experiments, we show our method consistently outperforms the baseline in both coordinate error and conservation metrics and can be further extended to complex and large dynamics by leveraging autoencoder. Notably, a byproduct of our framework is the automated conservation law discovery for dynamical systems with single conservation property.

GReTo: Remedying dynamic graph topology-task discordance via target homophily

Zhengyang Zhou,qihe huang,Gengyu Lin,Kuo Yang,LEI BAI,Yang Wang

Dynamic graphs are ubiquitous across disciplines where observations usually change over time. Regressions on dynamic graphs often contribute to diverse critical tasks, such as climate early-warning and traffic controlling. Existing homophily Graph Neural Networks (GNNs) adopt physical connections or feature similarity as adjacent matrix to perform node-level aggregations. However, on dynamic graphs with diverse node-wise relations, exploiting a pre-defined fixed topology for message passing inevitably leads to the aggregations of target-deviated neighbors. We designate such phenomenon as the topology-task discordance, which naturally challenges the homophily assumption. In this work, we revisit node-wise relationships and explore novel homophily measurements on dynamic graphs with both signs and distances, capturing multiple node-level spatial relations and temporal evolutions. We discover that advancing homophily aggregations to signed target-oriented message passing can effectively resolve the discordance and promote aggregation capacity. Therefore, a GReTo is proposed, which performs signed message passing in immediate neighborhood, and exploits both local environments and target awareness to realize high-order message propagation. Empirically, our solution achieves significant improvements against best baselines, notably improving 24.79% on KnowAir and 3.60% on Metr-LA.

Towards predicting dynamic stability of power grids with Graph Neural Networks

Christian Nauck,Michael Lindner,Konstantin Schürholt,Frank Hellmann

To mitigate climate change, the share of renewable energies in power production needs to be increased. Renewables introduce new challenges to power grids regarding the dynamic stability due to decentralization, reduced inertia and volatility in production. However, dynamic stability simulations are intractable and exceedingly expensive for large grids. Graph Neural Networks (GNNs) are a promising method to reduce the computational effort of analyzing dynamic stability of power grids. We provide new datasets of dynamic stability of synthetic power grids and find that GNNs are surprisingly effective at predicting highly non-linear targets from topological information only. We show that large GNNs outperform GNNs from previous work as well as as handcrafted graph features and semi-analytic approximations. Further, we demonstrate GNNs can accurately identify \emph{trouble maker}-nodes in the power grids. Lastly, we show that GNNs trained on small grids can perform accurately on a large synthetic Texan power grid model, which illustrates the potential of our approach.

Deep Reinforcement Learning for Cost-Effective Medical Diagnosis

Zheng Yu,Yikuan Li,Joseph Chahn Kim,Kaixuan Huang,Yuan Luo,Mengdi Wang

Dynamic diagnosis is desirable when medical tests are costly or time-consuming. In this work, we use reinforcement learning (RL) to find a dynamic policy that selects lab test panels sequentially based on previous observations, ensuring accurate testing at a low cost. Clinical diagnostic data are often highly imbalanced; therefore, we aim to maximize the F1 score instead of the error rate. However, optimizing the non-concave F_1 score is not a classic RL problem, thus invalidating standard RL methods. To remedy this issue, we develop a reward shaping approach, leveraging properties of the F_1 score and duality of policy optimization, to provably find the set of all Pareto-optimal policies for budget-constrained F_1 score maximization. To handle the combinatorially complex state space, we propose a Semi-Model-based Deep Diagnosis Policy Optimization (SM-DDPO) framework that is compatible with end-to-end training and online learning. SM-DDPO is tested on diverse clinical tasks: ferritin abnormality detection, sepsis mortality prediction, and acute kidney injury diagnosis. Experiments with real-world data validate that SM-DDPO trains efficiently and identify all Pareto-front solutions. Across all tasks, SM-DDPO is able to achieve state-of-the-art diagnosis accuracy (in some cases higher than conventional methods) with up to 85% reduction in testing cost. Core codes are available at https://github.com/Zheng321/Deep-Reinforcement-Learning-for-Cost-Effective-Medical-Diagnosis.

Deterministic training of generative autoencoders using invertible layers

Gianluigi Silvestri,Daan Roos,Luca Ambrogioni

In this work, we provide a deterministic alternative to the stochastic variational training of generative autoencoders. We refer to these new generative autoencoders as AutoEncoders within Flows (AEF), since the encoder and decoder are defined as affine layers of an overall invertible architecture. This results in a deterministic encoding of the data, as opposed to the stochastic encoding of VAEs. The paper introduces two related families of AEFs. The first family relies on a partition of the ambient space and is trained by exact maximum-likelihood. The second family exploits a deterministic expansion of the ambient space and is trained by maximizing the log-probability in this extended space. This latter case leaves complete freedom in the choice of encoder, decoder and prior architectures, making it a drop-in replacement for the training of existing VAEs and VAE-style models. We show that these AEFs can have strikingly higher performance than architecturally identical VAEs in terms of log-likelihood and sample quality, especially for low dimensional latent spaces. Importantly, we show that AEF samples are substantially sharper than VAE samples.

ACAT: Adversarial Counterfactual Attention for Classification and Detection in Medical Imaging

Alessandro Fontanella,Antreas Antoniou,Wenwen Li,Joanna Wardlaw,Grant Mair,Emanuele Trucco,Amos Storkey

In some medical imaging tasks and other settings where only small parts of the image are informative for the classification task, traditional CNNs can sometimes struggle to generalise. Manually annotated Regions of Interest (ROI) are sometimes used to isolate the most informative parts of the image. However, these are expensive to collect and may vary significantly across annotators. To overcome these issues, we propose a method to generate saliency maps, obtained from adversarially generated counterfactual images. With this method, we are able to isolate the area of interest in brain and lung CT scans without using any manual annotations. Our saliency maps, in the task of localising the lesion location out of 6 possible regions, obtain a score of 65.05% on brain CT scans, improving the score of 61.29% obtained with the best competing method. We also employ the saliency maps in a framework that refines a classifier pipeline. In particular, the saliency maps are used to obtain soft spatial attention masks that modulate the image features at different scales. We refer to our method as \emph{Adversarial Counterfactual Attention} (ACAT). ACAT increases the baseline classification accuracy of lesions in brain CT scans from 71.39% to 72.55% and of COVID-19 related findings in lung CT scans from 67.71% to 70.84% and excee

ds the performance of competing methods.

Abstract Visual Reasoning by Self-supervised Contrastive Learning

Weiwen Lu,Aihua Yin,Sidong Wang,Hongzhi You,Ru-Yuan Zhang,Dahui Wang,Zonglei Zhen,Xiaohong Wan

Neuro-symbolic models of artificial intelligence (AI) have been recently developed to perform tasks involving abstract visual reasoning that is a hallmark of human intelligence but remains challenging for deep neural network methods. However, most of the current neuro-symbolic models also rely on supervised learning and auxiliary annotations, different from human cognitive processes that are much dependent on the general cognitive abilities of entity and rule recognitions, rather than learning how to solve the specific tasks from examples. In this work, we propose a neuro-symbolic model by self-supervised contrastive learning (NS-SSCL) with unique and invariant representations of entities and rules in the perception and reasoning modules, respectively, to solve Raven’s Progressive Matrices (RPMs) and its variant, a typical type of visual reasoning task used to test human intelligence. The perception module parses each object into invariant representations of attributes. The reasoning module grounds the representations of object attributes to form the latent rule representations also through SSCL. Further, the relationships between the neural representations of object attributes and symbols used for rule reasoning are coherently mapped. Finally, the scene generation engine aggregates all attribute and rule representation distributions to produce a probabilistic representation of the target. NS-SSCL obtains state-of-the-art performance in unsupervised models to solve the RAVEN and V-PROM benchmarks, even better than most of the supervised models. The success of the proposed model suggests that construction of general cognitive abilities like humans may render the AI algorithms to solve complex tasks involving higher-level cognition such as abstract reasoning in a human-like manner.

POPGym: Benchmarking Partially Observable Reinforcement Learning

Steven Morad,Ryan Kortvelesy,Matteo Bettini,Stephan Liwicki,Amanda Prorok

Real world applications of Reinforcement Learning (RL) are often partially observable, thus requiring memory. Despite this, partial observability is still largely ignored by contemporary RL benchmarks and libraries. We introduce Partially Observable Process Gym (POPGym), a two-part library containing (1) a diverse collection of 15 partially observable environments, each with multiple difficulties and (2) implementations of 13 memory model baselines -- the most in a single RL library. Existing partially observable benchmarks tend to fixate on 3D visual navigation, which is computationally expensive and only one type of POMDP. In contrast, POPGym environments are diverse, produce smaller observations, use less memory, and often converge within two hours of training on a consumer-grade GPU. We implement our high-level memory API and memory baselines on top of the popular RLlib framework, providing plug-and-play compatibility with various training algorithms, exploration strategies, and distributed training paradigms. Using POPGym, we execute the largest comparison across RL memory models to date. POPGym is available at https://github.com/proroklab/popgym.

HierBatching: Locality-Aware Out-of-Core Training of Graph Neural Networks

Tianhao Huang,Xuhao Chen,Muhua Xu,Arvind Arvind,Jie Chen

As graph neural networks (GNNs) become increasingly more popular for analyzing data organized as massive graphs, how these models can be efficiently trained under economic computing resources becomes a critical subject that influences the widespread adoption of GNNs in practice. We consider the use of a single commodity machine restrained by limited memory but otherwise is attached with ample external storage. In such an under-explored scenario, not only the feature data often exceeds the memory capacity, but also the graph structure may not fit in memory as well. Then, with data stored on disk, gathering features and constructing neighborhood subgraphs in a usual mini-batch training incur inefficient random access and expensive data movement.

To overcome this bottleneck, we propose a locality-aware training scheme, coined HierBatching, to significantly increase sequential disk access, while maintaining the random nature of stochastic training and its quality. HierBatching exploits the memory hierarchy of a modern GPU machine and constructs batches in an analogously hierarchical manner. Therein, graph nodes are organized in many partitions, each of which is laid out contiguously in disk for maximal spatial locality; while the main memory stores random partitions and is treated as the cache of the disk. Its content is reused multiple times for improving temporal locality. We conduct comprehensive experiments, including locality ablation, to demonstrate that HierBatching is economic, fast, and accurate.

Everybody Needs Good Neighbours: An Unsupervised Locality-based Method for Bias Mitigation
Xudong Han,Timothy Baldwin,Trevor Cohn
Learning models from human behavioural data often leads to outputs that are biased with respect to user demographics, such as gender or race. This effect can be controlled by explicit mitigation methods, but this typically presupposes access to demographically-labelled training data. Such data is often not available, motivating the need for unsupervised debiasing methods. To this end, we propose a new meta-algorithm for debiasing representation learning models, which combines the notions of data locality and accuracy of model fit, such that a supervised debiasing method can optimise fairness between neighbourhoods of poorly vs. well modelled instances as identified by our method. Results over five datasets, spanning natural language processing and structured data classification tasks, show that our technique recovers proxy labels that correlate with unknown demographic data, and that our method outperforms all unsupervised baselines, while also achieving competitive performance with state-of-the-art supervised methods which are given access to demographic labels.

Continual Learning In Low-coherence Subspace: A Strategy To Mitigate Learning Capacity Degradation
Zihao Xu,Zhengyu Li,Yufei Shi,Xihao Wang,Yingjie Liu,Kexin Ke,Xian Wei
Methods using gradient orthogonal projection, an efficient strategy in continual learning, have achieved promising success in mitigating catastrophic forgetting. However, these methods often suffer from the learning capacity degradation problem following the increasing number of tasks. To address this problem, we propose to learn new tasks in low-coherence subspaces rather than orthogonal subspaces. Specifically, we construct a unified cost function involving regular DNN parameters and gradient projections on the Oblique manifold. We finally develop a gradient descent algorithm on a smooth manifold to jointly minimize the cost function and minimize both the inter-task and the intra-task coherence. Numerical experimental results show that the proposed method has prominent advantages in maintaining the learning capacity when tasks are increased, especially on a large number of tasks, compared with baselines.

Particle-based Variational Inference with Preconditioned Functional Gradient Flow
Hanze Dong,Xi Wang,LIN Yong,Tong Zhang
Particle-based variational inference (VI) minimizes the KL divergence between model samples and the target posterior with gradient flow estimates. With the popularity of Stein variational gradient descent (SVGD), the focus of particle-based VI algorithms has been on the properties of functions in Reproducing Kernel Hilbert Space (RKHS) to approximate the gradient flow. However, the requirement of RKHS restricts the function class and algorithmic flexibility. This paper offers a general solution to this problem by introducing a functional regularization term that encompasses the RKHS norm as a special case. This allows us to propose a new particle-based VI algorithm called preconditioned functional gradient flow (PFG). Compared to SVGD, PFG has several advantages. It has a larger function class, improved scalability in large particle-size scenarios, better adaptation to ill-conditioned distributions, and provable continuous-time convergence in K

L divergence. Additionally, non-linear function classes such as neural networks can be incorporated to estimate the gradient flow. Our theory and experiments demonstrate the effectiveness of the proposed framework.

****

An Efficient Mean-field Approach to High-Order Markov Logic

Weidi Xu,Jianshan He,Jingwei Wang,Hongting Zhou,Xiaopei Wan,Taifeng Wang,Ruopeng Li,Wei Chu

Markov logic networks (MLNs) are powerful models for symbolic reasoning, which combine probabilistic modeling with relational logic. Inference algorithms for MLNs often perform at the level of propositional logic or require building a first-order probabilistic graph, and the computational efficiency remains a challenge. The mean-field algorithm generalizes message passing for approximate inference in many intractable probabilistic graphical models, but in MLNs it still suffers from the high-order dependencies among the massive groundings, resulting in time complexity exponential in both the length and the arity of logic rules. We propose a novel method, LogicMP, to simplify the logic message passing especially. In most practical cases, it can reduce the complexity significantly to polynomial for the formulae in conjunctive normal form (CNF). We exploit the property of CNF logic rules to sidestep the expectation computation of high-order dependency, and then formulate the logic message passing by Einstein summation to facilitate parallel computation, which can be optimized by sequentially contracting the rule arguments. With LogicMP, we achieve evident improvements on several reasoning benchmark datasets in both performance and efficiency over competitor methods. Specifically, the AUC-PR of the UW-CSE and Cora datasets is improved by more than 11\% absolutely and the speed is about ten times faster.

A theory of representation learning in neural networks gives a deep generalisation of kernel methods

Adam X. Yang,Maxime Robeyns,Edward Milsom,Nandi Schoots,Laurence Aitchison

The successes of modern deep neural networks (DNNs) are founded on their ability to transform inputs across multiple layers to build good high-level representations. It is therefore critical to understand this process of representation learning. However, standard theoretical approaches (formally NNGPs) involving infinite width limits eliminate representation learning. We therefore develop a new infinite width limit, the representation learning limit, that exhibits representation learning mirroring that in finite-width networks, yet at the same time, remains extremely theoretically tractable. In particular, we derive an elegant objective that describes how each network layer learns representations that interpolate between input and output, and we confirm that the modes of the objective match the behaviour of finite but wide networks. Moreover, we use this limit and objective to develop a flexible, deep generalisation of kernel methods, that we call deep kernel machines (DKMs). We show that DKMs can be scaled to large datasets using inducing point methods from the Gaussian process literature, and we show that DKMs exhibit superior performance to other kernel-based approaches.

A spatiotemporal graph neural network with multi granularity for air quality prediction

Haibin Liao,Yuan Li,Mou Wu,Hongsheng Chen

Air quality prediction is a complex system engineering. How to fully consider the impact of meteorological, spatial and temporal factors on air quality is the core problem. To address this central conundrum, in an elaborate encoder-decoder architecture, we propose a new air quality prediction method based on multi-granularity spatiotemporal graph network. At the encoder, firstly, we use multi granularity graph and the well-known HYSPLIT model to build spatial relationship and dynamic edge relationship between nodes, respectively, while meteorological, temporal and topographic characteristics are used to build node features and LSTM (Long Short Term Memory) is used to learn the time-series relationship of pollutant concentration. At the decoder, secondly, we use the attention mechanism LSTM for decoding and forecasting of pollutant concentration. The proposed model is capable of tracking different influences on prediction resulting from the changes of air quality. On a project-based dataset, we validate the effectiveness of the proposed model and examine its abilities of capturing both fine-grained and long-term influences in pollutant process. We also compare the proposed model with the state-of-the-art air quality forecasting methods on the dataset of Yangtze River Delta city group, the experimental results show the appealing performance of our model over competitive baselines.

****

Highway Reinforcement Learning

Yuhui Wang,Haozhe Liu,Miroslav Strupl,Francesco Faccio,Qingyuan Wu,Xiaoyang Tan,Jürgen Schmidhuber

Traditional Dynamic Programming (DP) approaches suffer from slow backward credit-assignment (CA): only a one-step search is performed at each update. A popular solution for multi-step CA is to use multi-step Bellman operators. Unfortunately, in the control settings, existing methods typically suffer from the large variance of multi-step off-policy corrections or are biased, preventing convergence. To overcome these problems, we introduce a novel multi-step Bellman optimality equation with adaptive lookahead steps. We first derive a new multi-step Value Iteration (VI) method that converges to the optimal Value Function (VF) with an exponential contraction rate but linear computational complexity. Given some trial, our so-called Highway RL performs rapid CA, by picking a policy and a possible lookahead (up to the trial end) that maximize the near-term reward during lookahead plus a DP-based estimate of the cumulative reward for the remaining part of the trial. Highway RL does not require off-policy corrections. Under mild assumptions, it achieves better convergence rates than the traditional one-step Bellman Optimality Operator. We then derive Highway Q-Learning, a convergent multi-step off-policy variant of Q-learning. We show that our Highway algorithms significantly outperform DP approaches on toy tasks. Finally, we propose a deep function approximation variant called Highway DQN. We evaluate it on visual MinAtar Games, outperforming similar multi-step methods.

****

Learning Locality and Isotropy in Dialogue Modeling

Han Wu,Haochen Tan,Mingjie Zhan,Gangming Zhao,Shaoqing Lu,Ding Liang,Linqi Song

Existing dialogue modeling methods have achieved promising performance on various dialogue tasks with the aid of Transformer and the large-scale pre-trained language models. However, some recent studies revealed that the context representations produced by these methods suffer the problem of anisotropy. In this paper, we find that the generated representations are also not conversational, losing the conversation structure information during the context modeling stage. To this end, we identify two properties in dialogue modeling, i.e., locality and isotropy, and present a simple method for dialogue representation calibration, namely SimDRC, to build isotropic and conversational feature spaces. Experimental results show that our approach significantly outperforms current state-of-the-art models on three open-domain dialogue tasks with eight benchmarks. More in-depth analyses further confirm the effectiveness of our proposed approach. We release the code at https://github.com/hahahawu/SimDRC.

****

Dynamic Historical Adaptation for Continual Image-Text Modeling

Yutian Luo,Yizhao Gao,Zhiwu Lu

In realistic application scenarios, existing methods for image-text modeling have limitations in dealing with data stream: training on all data needs too much computation/storage resources, and even the full access to previous data is invalid. In this work, we thus propose a new continual image-text modeling (CITM) setting that requires a model to be trained sequentially on a number of diverse image-text datasets. Although recent continual learning methods can be directly applied to the CITM setting, most of them only consider reusing part of previous data or aligning the output distributions of previous and new models, which is a partial or indirect way to acquire the old knowledge. In contrast, we propose a novel dynamic historical adaptation (DHA) method which can holistically and directly review the old knowledge from a historical model. Concretely, the historical model transfers its total parameters to the main/current model to utilize the holistic old knowledge. In turn, the main model dynamically transfers its parameters to the historical model at every five training steps to ensure that the knowledge gap between them is not too large. Extensive experiments show that our DHA outperforms other representative/latest continual learning methods under the CITM setting.

AutoGT: Automated Graph Transformer Architecture Search

Zizhao Zhang,Xin Wang,Chaoyu Guan,Ziwei Zhang,Haoyang Li,Wenwu Zhu

Although Transformer architectures have been successfully applied to graph data with the advent of Graph Transformer, current design of Graph Transformer still heavily relies on human labor and expertise knowledge to decide proper neural architectures and suitable graph encoding strategies at each Transformer layer. In literature, there have been some works on automated design of Transformers focusing on non-graph data such as texts and images without considering graph encoding strategies, which fail to handle the non-euclidean graph data. In this paper, we study the problem of automated graph Transformer, for the first time. However, solving these problems poses the following challenges: i) how can we design a unified search space for graph Transformer, and ii) how to deal with the coupling relations between Transformer architectures and the graph encodings of each Transformer layer. To address these challenges, we propose Automated Graph Transformer (AutoGT), a neural architecture search framework that can automatically discover the optimal graph Transformer architectures by joint optimization of Transformer architecture and graph encoding strategies. Specifically, we first propose a unified graph Transformer formulation that can represent most of state-of-the-art graph Transformer architectures. Based upon the unified formulation, we further design the graph Transformer search space that includes both candidate architectures and various graph encodings. To handle the coupling relations, we propose a novel encoding-aware performance estimation strategy by gradually training and splitting the supernets according to the correlations between graph encodings and architectures. The proposed strategy can provide a more consistent and fine-grained performance prediction when evaluating the jointly optimized graph encodings and architectures. Extensive experiments and ablation studies show that our proposed AutoGT gains sufficient improvement over state-of-the-art hand-crafted baselines on all datasets, demonstrating its effectiveness and wide applicability.

Cross Modal Domain Generalization for Query-based Video Segmentation

Yan Xia,Zhou Zhao,Jieming Zhu

Domain generalization (DG) aims to increase a model's generalization ability against the performance degradation when transferring to the target domains, which has been successfully applied in various visual and natural language tasks. However, DG on multi-modal tasks is still an untouched field. Compared with traditional single-modal DG, the biggest challenge of multi-modal DG is that each modality has to cope with its own domain shift. Directly applying the previous methods will make the generalization direction of the model in each modality inconsistent, resulting in negative effects when the model is migrated to the target domains. Thus in this paper, we explore the scenario of query-based video segmentation to study how to better advance the generalization ability of the model in the multi-modal situation. Considering the information from different modalities often shows consistency, we propose query-guided feature augmentation (QFA) and attention map adaptive instance normalization (AM-AdaIN) modules. Compared with traditional DG models, our method can combine visual and textual modalities together to guide each other for data augmentation and learn a domain-agnostic cross-modal relationship, which is more suitable for multi-modal transfer tasks. Extensive experiments on three query-based video segmentation generalization tasks demonstrate the effectiveness of our method.

****

Combating Exacerbated Heterogeneity for Robust Models in Federated Learning

Jianing Zhu,Jiangchao Yao,Tongliang Liu,quanming yao,Jianliang Xu,Bo Han

Privacy and security concerns in real-world applications have led to the development of adversarially robust federated models. However, the straightforward combination between adversarial training and federated learning in one framework can lead to the undesired robustness deterioration. We discover that the attribution behind this phenomenon is that the generated adversarial data could exacerbate the data heterogeneity among local clients, making the wrapped federated learning perform poorly. To deal with this problem, we propose a novel framework called Slack Federated Adversarial Training (SFAT), assigning the client-wise slack during aggregation to combat the intensified heterogeneity. Theoretically, we analyze the convergence of the proposed method to properly relax the objective when combining federated learning and adversarial training. Experimentally, we verify the rationality and effectiveness of SFAT on various benchmarked and real-world datasets with different adversarial training and federated optimization methods. The code is publicly available at: https://github.com/ZFancy/SFAT.

Pruning with Output Error Minimization for Producing Efficient Neural Networks

Koji Kamma,Toshikazu Wada

DNNs are known to have excessive parameters and thus are computationally expensive, which poses a challenge for implementations in various applications. Structured pruning is a technique of compressing a trained DNN model by removing redundant neurons (or channels). How well a pruned model maintains its accuracy depends on two factors. The first is compression ratio optimization, in other words, how many neurons are reduced in each layer. The other is layer-wise optimization, in other words, which neurons to be preserved in each layer. In this paper, we propose Pruning with Output Error Minimization (POEM), a layer-wise pruning method that conducts pruning and then performs reconstruction to compensate the error caused by pruning. The strength of POEM lies in its reconstruction using the weighted least squares method so as to minimize the output error of the activation function, while the previous methods minimize the error of the value before applying the activation function. The experiments with well-known DNN models and a large scale image recognition dataset show that POEM is better than the previous methods in maintaining the accuracy of those models.

Orientation-Aware Graph Neural Networks for Protein Structure Representation Learning

Jiahan Li,Shitong Luo,Congyue Deng,Chaoran Cheng,Jiaqi Guan,Leonidas Guibas,Jianzhu Ma,Jian Peng

By folding to particular 3D structures, proteins play a key role in living beings. To learn meaningful representation from a protein structure for downstream tasks, not only the global backbone topology but the local fine-grained orientational relations between amino acids should also be considered. In this work, we propose the Orientation-Aware Graph Neural Networks (OAGNNs) to better sense the geometric characteristics in protein structure (e.g. inner-residue torsion angles, inter-residue orientations). Extending a single weight from a scalar to a 3D vector, we construct a rich set of geometric-meaningful operations to process both the classical and SO(3) representations of a given structure. To plug our designed perceptron unit into existing Graph Neural Networks, we further introduce an equivariant message passing paradigm, showing superior versatility in maintaining SO(3)-equivariance at the global scale. Experiments have shown that our OAGNNs have a remarkable ability to sense geometric orientational features compared to classical networks. OAGNNs have also achieved state-of-the-art performance on various computational biology applications related to protein 3D structures.

****

Adaptive Update Direction Rectification for Unsupervised Continual Learning

Yizhao Gao,Nanyi Fei,Zhiwu Lu

Recent works on continual learning have shown that unsupervised continual learning (UCL) methods rival or even beat supervised continual learning methods. Howev

er, most UCL methods typically adopt fixed learning strategies with pre-defined objectives and ignore the influence of the constant shift of data distributions on the newer training process. This non-adaptive paradigm tends to achieve sub-optimal performance, since the optimal update direction (to ensure the trade-off between old and new tasks) keeps changing during training over sequential tasks. In this work, we thus propose a novel UCL framework termed AUDR to adaptively rectify the update direction by a policy network (i.e., the Actor) at each training step based on the reward predicted by a value network (i.e., the Critic). Concretely, different from existing Actor-Critic based reinforcement learning works, there are three vital designs that make our AUDR applicable to the UCL setting: (1) A reward function to measure the score/value of the currently selected action, which provides the ground-truth reward to guide the Critic's predictions; (2) An action space for the Actor to select actions (i.e., update directions) according to the reward predicted by the Critic; (3) A multinomial sampling strategy with a lower-bound on the sampling probability of each action, which is designed to improve the variance of the Actor's selected actions for more diversified exploration. Extensive experiments show that our AUDR achieves state-of-the-art results under both the in-dataset and cross-dataset UCL settings. Importantly, our AUDR also shows superior performance when combined with other UCL methods, which suggests that our AUDR is highly extensible and versatile.

Language Model Pre-training with Linguistically Motivated Curriculum Learning
Yile Wang,Yue Zhang,Peng Li,Yang Liu

Pre-training serves as a foundation of recent NLP models, where language modeling task is performed over large texts. It has been shown that data affects the quality of pre-training, and curriculum has been investigated regarding sequence length. We consider a linguistic perspective in the curriculum, where frequent words are learned first and rare words last. This is achieved by substituting syntactic constituents for rare words with their constituent labels. By such syntactic substitutions, a curriculum can be made by gradually introducing words with decreasing frequency levels. Without modifying model architectures or introducing external computational overhead, our data-centric method gives better performances over vanilla BERT on various downstream benchmarks.

Offline Reinforcement Learning with Closed-Form Policy Improvement Operators
Jiachen Li,Edwin Zhang,Ming Yin,Qinxun Bai,Yu-Xiang Wang,William Yang Wang

Behavior constrained policy optimization has been demonstrated to be a successful paradigm for tackling Offline Reinforcement Learning. By exploiting historical transitions, a policy is trained to maximize a learned value function while constrained by the behavior policy to avoid a significant distributional shift. In this paper, we propose our closed-form policy improvement operators. We make a novel observation that the behavior constraint naturally motivates the use of first-order Taylor approximation, leading to a linear approximation of the policy objective. Additionally, as practical datasets are usually collected by heterogeneous policies, we model the behavior policies as a Gaussian Mixture and overcome the induced optimization difficulties by leveraging the LogSumExp's lower bound and Jensen's Inequality, giving rise to a closed-form policy improvement operator. We instantiate an offline RL algorithm with our novel policy improvement operator and empirically demonstrate its effectiveness over state-of-the-art algorithms on the standard D4RL benchmark.

Sensitivity-aware Visual Parameter-efficient Tuning
Haoyu He,Jianfei Cai,Jing Zhang,Dacheng Tao,Bohan Zhuang

Visual Parameter-efficient Tuning (VPT) has become a powerful alternative for full fine-tuning, which only updates a small number of parameters while freezing the remaining vast majority of parameters to significantly reduce the storage costs for adapting the pre-trained vision models to downstream tasks. Although the storage burden is largely alleviated, VPT approaches still face many challenges, e.g., lower inference speed and lacking effective configurations for trainable parameters tailored for each task. In this paper, we present a simple yet effect ive approach termed Sensitivity-aware visual Parameter-efficient Tuning (SPT) to tackle these challenges. Given a desired tunable parameter budget, SPT quickly identifies the important parameters to the given task in a data-dependent way before fine-tuning, without the complex selection schedule. To increase the representational capacity at a negligible cost within the same parameter budget, we employ low-rank reparameterization to achieve a better trade-off between parameter efficiency and accuracy. Through extensive experiments on a wide range of downstream recognition tasks, our SPT achieves better overall transfer performance than the full fine-tuning and the other VPT approaches, with no additional computational or memory overhead during inference. For instance, SPT saves 99.35% of the trainable parameters than the full fine-tuning while achieving a 7.3% higher average top-1 accuracy on VTAB-1k benchmark with the supervised pre-trained ViT-B backbone. Notably, SPT is also the first work that bridges the gap between full fine-tuning and VPT approaches for backbones under self-supervised pre-training strategies MAE and MoCo v3 on the challenging VTAB-1k benchmark.

Towards Robust Object Detection Invariant to Real-World Domain Shifts

Qi Fan,Mattia Segu,Yu-Wing Tai,Fisher Yu,Chi-Keung Tang,Bernt Schiele,Dengxin Dai

Safety-critical applications such as autonomous driving require robust object detection invariant to real-world domain shifts. Such shifts can be regarded as different domain styles, which can vary substantially due to environment changes and sensor noises, but deep models only know the training domain style. Such domain style gap impedes object detection generalization on diverse real-world domains. Existing classification domain generalization (DG) methods cannot effectively solve the robust object detection problem, because they either rely on multiple source domains with large style variance or destroy the content structures of the original images. In this paper, we analyze and investigate effective solutions to overcome domain style overfitting for robust object detection without the above shortcomings. Our method, dubbed as Normalization Perturbation (NP), perturbs the channel statistics of source domain low-level features to synthesize various latent styles, so that the trained deep model can perceive diverse potential domains and generalizes well even without observations of target domain data in training. This approach is motivated by the observation that feature channel statistics of the target domain images deviate around the source domain statistics. We further explore the style-sensitive channels for effective style synthesis. Normalization Perturbation only relies on a single source domain and is surprisingly simple and effective, contributing a practical solution by effectively adapting or generalizing classification DG methods to robust object detection. Extensive experiments demonstrate the effectiveness of our method for generalizing object detectors under real-world domain shifts.

Light Sampling Field and BRDF Representation for Physically-based Neural Rendering

Jing Yang,Hanyuan Xiao,Wenbin Teng,Yunxuan Cai,Yajie Zhao

Physically-based rendering (PBR) is key for immersive rendering effects used widely in the industry to showcase detailed realistic scenes from computer graphics assets. A well-known caveat is that producing the same is computationally heavy and relies on complex capture devices. Inspired by the success in quality and efficiency of recent volumetric neural rendering, we want to develop a physically-based neural shader to eliminate device dependency and significantly boost performance. However, no existing lighting and material models in the current neural rendering approaches can accurately represent the comprehensive lighting models and BRDFs properties required by the PBR process. Thus, this paper proposes a novel lighting representation that models direct and indirect light locally through a light sampling strategy in a learned light sampling field. We also propose BRDF models to separately represent surface/subsurface scattering details to enable complex objects such as translucent material (i.e., skin, jade). We then implement our proposed representations with an end-to-end physically-based neural face skin shader, which takes a standard face asset (i.e., geometry, albedo map, and normal map) and an HDRI for illumination as inputs and generates a photo-realistic rendering as output. Extensive experiments showcase the quality and efficiency of our PBR face skin shader, indicating the effectiveness of our proposed lighting and material representations.

DREAM: Domain-free Reverse Engineering Attributes of Black-box Model

Rongqing Li,Jiaqi Yu,Changsheng Li,Wenhan Luo,Ye Yuan,Guoren Wang

Deep learning models are usually black boxes when deployed on machine learning platforms. Prior works have shown that the attributes (e.g., the number of convolutional layers) of a target black-box neural network can be exposed through a sequence of queries. There is a crucial limitation that these works assume the dataset used for training the target model to be known beforehand, and leverage this dataset for model attribute attack. However, it is difficult to access the training dataset of the target black-box model in reality. Therefore, whether the attributes of a target black-box model could be still revealed in this case is doubtful. In this paper, we investigate a new problem of Domain-free Reverse Engineering the Attributes of a black-box target Model, called DREAM, without requiring the model's training dataset available, and put forward a general and principled framework by casting this problem as an out of distribution (OOD) generalization problem. At the heart of our framework, we devise a multi-discriminator generative adversarial network (MDGAN) to learn domain invariant features. Based on these features, we can learn a domain-free model to inversely infer the attributes of a target black-box model with unknown training data. This makes our method one of the kinds that can gracefully apply to an arbitrary domain for model attribute reverse engineering with good generalization ability. Extensive experimental studies are conducted and the results validate the superiority of our proposed method over the baselines.

Structural Generalization of Visual Imitation Learning with Position-Invariant Regularization

Zhao-Heng Yin,Yang Gao,Qifeng Chen

How the visual imitation learning models can generalize to novel unseen visual observations is a highly challenging problem. Such a generalization ability is very crucial for their real-world applications. Since this generalization problem has many different aspects, we focus on one case called structural generalization, which refers to generalization to unseen task setup, such as a novel setup of object locations in the robotic manipulation problem. In this case, previous works observe that the visual imitation learning models will overfit to the absolute information (e.g., coordinates) rather than the relational information between objects, which is more important for decision making. As a result, the models will perform poorly in novel scenarios. Nevertheless, so far, it remains unclear how we can solve this problem effectively. Our insight into this problem is to explicitly remove the absolute information from the features learned by imitation learning models so that the models can use robust, relational information to make decisions. To this end, we propose a novel, position-invariant regularizer for generalization. The proposed regularizer will penalize the imitation learning model when its features contain absolute, positional information of objects. We carry out experiments on the MAGICAL and ProcGen benchmark, as well as a real-world robot manipulation problem. We find that our regularizer can effectively boost the structural generalization performance of imitation learning models. Through both qualitative and quantitative analysis, we verify that our method does learn robust relational representations.

Dealing with missing data using attention and latent space regularization

Jahan Che Penny-Dimri,Christoph Bergmeir,Julian Smith

Most practical data science problems encounter missing data. A wide variety of solutions exist, each with strengths and weaknesses that depend upon the missingness-generating process. Here we develop a theoretical framework for training and inference using only observed variables enabling modeling of incomplete dataset s without imputation. Using an information and measure-theoretic argument we construct models with latent space representations that regularize against the potential bias introduced by missing data. The theoretical properties of this approach are demonstrated empirically using a synthetic dataset. The performance of this approach is tested on 11 benchmarking datasets with missingness and 18 datasets corrupted across three missingness patterns with comparison against a state-of-the-art model and industry-standard imputation. We show that our proposed method outperforms common imputation methods and the current state-of-the-art with statistical significance.

****

Bidirectional Propagation for Cross-Modal 3D Object Detection

Yifan Zhang,Qijian Zhang,Junhui Hou,Yixuan Yuan,Guoliang Xing

Recent works have revealed the superiority of feature-level fusion for cross-modal 3D object detection, where fine-grained feature propagation from 2D image pixels to 3D LiDAR points has been widely adopted for performance improvement. Still, the potential of heterogeneous feature propagation between 2D and 3D domains has not been fully explored. In this paper, in contrast to existing pixel-to-point feature propagation, we investigate an opposite point-to-pixel direction, allowing point-wise features to flow inversely into the 2D image branch. Thus, when jointly optimizing the 2D and 3D streams, the gradients back-propagated from the 2D image branch can boost the representation ability of the 3D back-bone network working on LiDAR point clouds. Then, combining pixel-to-point and point-to-pixel information flow mechanisms, we further construct an interactive bidirectional feature propagation framework, dubbed BiProDet. In addition to the architectural design, we also propose normalized local coordinates map estimation, a new 2D auxiliary task for the training of the 2D image branch, which facilitates learning local spatial-aware features from the image modality and implicitly enhances the overall 3D detection performance. Extensive experiments and ablation studies validate the effectiveness of our method. Notably, we rank 1st on the highly competitive KITTI benchmark on the cyclist class by the time of submission. We also uploaded the source code in the supplementary material, which will be publicly available.

Policy Pre-training for Autonomous Driving via Self-supervised Geometric Modeling

Penghao Wu,Li Chen,Hongyang Li,Xiaosong Jia,Junchi Yan,Yu Qiao

Witnessing the impressive achievements of pre-training techniques on large-scale data in the field of computer vision and natural language processing, we wonder whether this idea could be adapted in a grab-and-go spirit, and mitigate the sample inefficiency problem for visuomotor driving. Given the highly dynamic and variant nature of the input, the visuomotor driving task inherently lacks the view and translation invariance, and the visual input contains massive irrelevant information for decision making, resulting in predominant pre-training approaches from general vision less suitable for the autonomous driving task. To this end, we propose PPGeo (Policy Pre-training via Geometric modeling), an intuitive and straightforward fully self-supervised framework curated for the policy pre-training in visuomotor driving. We aim at learning policy representations as a powerful abstraction by modeling 3D geometric scenes on large-scale unlabeled and uncalibrated YouTube driving videos. The proposed PPGeo is performed in two stages to support effective self-supervised training. In the first stage, the geometric modeling framework generates pose and depth predictions simultaneously, with two consecutive frames as input. In the second stage, the visual encoder learns driving policy representation by predicting the future ego-motion and optimizing with the photometric error based on current visual observation only. As such, the pre-trained visual encoder is equipped with rich driving policy related representations and thereby competent for multiple visuomotor driving tasks. As a side product, the pre-trained geometric modeling networks could bring further improvement to the depth and odometry estimation tasks. Extensive experiments covering a wide span of challenging scenarios have demonstrated the superiority of our pr oposed approach, where improvements range from 2% to even over 100% with very limited data.

****

Towards Expressive Graph Representations for Graph Neural Networks

Chengsheng Mao,Liang Yao,Yuan Luo

Graph Neural Network (GNN) shows its powerful capability for graph representation learning in various application areas. However, most existing GNN variants learn the graph representations in a non-injective or non-continuous fashion, both reducing the model expressive power. In this paper, we present a theoretical framework to improve the expressive power of GNN by taking both injectivity and continuity into account. Accordingly, we develop \textit{Injective Continuous Graph Neural Network} (ICGNN) that learns the graph and node representations in an injective and continuous fashion, so that it can map similar nodes or graphs to similar embeddings, and non-equivalent nodes or non-isomorphic graphs to different embeddings. We validate the proposed ICGNN model for graph classification and node classification on multiple benchmark datasets including both simple graphs and attributed graphs. The experimental results demonstrate that our model achieves state-of-the-art performances on most of the benchmarks.

EurNet: Efficient Multi-Range Relational Modeling of Spatial Multi-Relational Data

Minghao Xu,Yuanfan Guo,Yi Xu,Jian Tang,Xinlei Chen,Yuandong Tian

Modeling spatial relationship in the data remains critical across many different tasks, such as image classification, semantic segmentation and protein structure understanding. Previous works often use a unified solution like relative positional encoding. However, there exists different kinds of spatial relations, including short-range, medium-range and long-range relations, and modeling them separately can better capture the focus of different tasks on the multi-range relations (e.g., short-range relations can be important in instance segmentation, while long-range relations should be upweighted for semantic segmentation). In this work, we introduce the EurNet for Efficient multi-range relational modeling. EurNet constructs the multi-relational graph, where each type of edge corresponds to short-, medium- or long-range spatial interactions. In the constructed graph, EurNet adopts a novel modeling layer, called gated relational message passing (GRMP), to propagate multi-relational information across the data. GRMP captures multiple relations within the data with little extra computational cost. We study EurNets in two important domains for image and protein structure modeling. Extensive experiments on ImageNet classification, COCO object detection and ADE20K semantic segmentation verify the gains of EurNet over the previous SoTA FocalNet. On the EC and GO protein function prediction benchmarks, EurNet consistently surpasses the previous SoTA GearNet. Our results demonstrate the strength of EurNets on modeling spatial multi-relational data from various domains.

TimesNet: Temporal 2D-Variation Modeling for General Time Series Analysis

Haixu Wu,Tengge Hu,Yong Liu,Hang Zhou,Jianmin Wang,Mingsheng Long

Time series analysis is of immense importance in extensive applications, such as weather forecasting, anomaly detection, and action recognition. This paper focuses on temporal variation modeling, which is the common key problem of extensive analysis tasks. Previous methods attempt to accomplish this directly from the 1D time series, which is extremely challenging due to the intricate temporal patterns. Based on the observation of multi-periodicity in time series, we ravel out the complex temporal variations into the multiple intraperiod- and interperiod-variations. To tackle the limitations of 1D time series in representation capability, we extend the analysis of temporal variations into the 2D space by transforming the 1D time series into a set of 2D tensors based on multiple periods. This transformation can embed the intraperiod- and interperiod-variations into the columns and rows of the 2D tensors respectively, making the 2D-variations to be easily modeled by 2D kernels. Technically, we propose the TimesNet with TimesBlock as a task-general backbone for time series analysis. TimesBlock can discover the multi-periodicity adaptively and extract the complex temporal variations fro m transformed 2D tensors by a parameter-efficient inception block. Our proposed TimesNet achieves consistent state-of-the-art in five mainstream time series analysis tasks, including short- and long-term forecasting, imputation, classification, and anomaly detection. Code is available at this repository: https://github.com/thuml/TimesNet.

Learning without Prejudices: Continual Unbiased Learning via Benign and Malignant Forgetting

Myeongho Jeon,Hyoje Lee,Yedarm Seong,Myungjoo Kang

Although machine learning algorithms have achieved state-of-the-art status in image classification, recent studies have substantiated that the ability of the models to learn several tasks in sequence, termed continual learning (CL), often suffers from abrupt degradation of performance from previous tasks. A large body of CL frameworks has been devoted to alleviating this issue. However, we observe that forgetting phenomena in CL are not always unfavorable, especially when there is bias (spurious correlation) in training data. We term such type of forgetting benign forgetting, and categorize detrimental forgetting as malignant forgetting. Based on this finding, our objective in this study is twofold: (a) to discourage malignant forgetting by generating previous representations, and (b) encourage benign forgetting by employing contrastive learning in conjunction with feature-level augmentation. Extensive evaluations of biased experimental setups demonstrate that our proposed method, Learning without Prejudices, is effective for continual unbiased learning.

FINDE: Neural Differential Equations for Finding and Preserving Invariant Quantities

Takashi Matsubara,Takaharu Yaguchi

Many real-world dynamical systems are associated with first integrals (a.k.a. invariant quantities), which are quantities that remain unchanged over time. The discovery and understanding of first integrals are fundamental and important topics both in the natural sciences and in industrial applications. First integrals arise from the conservation laws of system energy, momentum, and mass, and from constraints on states; these are typically related to specific geometric structures of the governing equations. Existing neural networks designed to ensure such first integrals have shown excellent accuracy in modeling from data. However, these models incorporate the underlying structures, and in most situations where neural networks learn unknown systems, these structures are also unknown. This limitation needs to be overcome for scientific discovery and modeling of unknown systems. To this end, we propose first integral-preserving neural differential equation (FINDE). By leveraging the projection method and the discrete gradient method, FINDE finds and preserves first integrals from data, even in the absence of prior knowledge about underlying structures. Experimental results demonstrate that FINDE can predict future states of target systems much longer and find various quantities consistent with well-known first integrals in a unified manner.

Approximate Vanishing Ideal Computations at Scale

Elias Samuel Wirth,Hiroshi Kera,Sebastian Pokutta

The vanishing ideal of a set of points $X = \{\mathbf{x}_1, \ldots, \mathbf{x}_m\}\subseteq \mathbb{R}^n$ is the set of polynomials that evaluate to 0 over all points $\mathbf{x} \in X$ and admits an efficient representation by a finite subset of generators. In practice, to accommodate noise in the data, algorithms that construct generators of the approximate vanishing ideal are widely studied but their computational complexities remain expensive. In this paper, we scale up the oracle approximate vanishing ideal algorithm (OAVI), the only generator-constructing algorithm with known learning guarantees. We prove that the computational complexity of OAVI is not superlinear, as previously claimed, but linear in the number of samples m. In addition, we propose two modifications that accelerate OAVI's training time: Our analysis reveals that replacing the pairwise conditional gradients algorithm, one of the solvers used in OAVI, with the faster blended pairwise conditional gradients algorithm leads to an exponential speed-up in the number of features n. Finally, using a new inverse Hessian boosting approach, intermediate convex optimization problems can be solved almost instantly, improving OAVI's training time by multiple orders of magnitude in a variety of numerical experiments.

****

Understanding Incremental Learning of Gradient Descent: A Fine-grained analysis of Matrix Sensing

Jikai Jin,Zhiyuan Li,Kaifeng Lyu,Simon Shaolei Du,Jason D. Lee

The implicit bias of optimization algorithms such as gradient descent (GD) is believed to play an important role in generalization of modern machine learning methods such as deep learning. This paper provides a fine-grained analysis of the dynamics of GD for the matrix sensing problem, whose goal is to recover a low-rank ground-truth matrix from near-isotropic linear measurements. With small initialization, we that GD behaves similarly to the greedy low-rank learning heuristics~\citep{li2020towards} and follows an incremental learning procedure~\citep{gissin2019implicit}. That is, GD sequentially learns solutions with increasing ranks until it recovers the ground-truth matrix. Compared to existing works which only analyze the first learning phase for rank-1 solutions, our result is stronger because it characterizes the whole learning process. Moreover, our analysis of the incremental learning procedure applies to the
under-parameterized regime as well. As a key ingredient of our analysis, we observe that GD always follows an approximately low-rank trajectory and develops novel landscape properties for matrix sensing with low-rank parameterization. Finally, we conduct numerical experiments which confirm our theoretical findings.

Selective Annotation Makes Language Models Better Few-Shot Learners

Hongjin SU,Jungo Kasai,Chen Henry Wu,Weijia Shi,Tianlu Wang,Jiayi Xin,Rui Zhang,Mari Ostendorf,Luke Zettlemoyer,Noah A. Smith,Tao Yu

Many recent approaches to natural language tasks are built on the remarkable abilities of large language models. Large language models can perform in-context learning, where they learn a new task from a few task demonstrations, without any parameter updates. This work examines the implications of in-context learning for the creation of datasets for new natural language tasks. Departing from recent in-context learning methods, we formulate an annotation-efficient, two-step framework: selective annotation that chooses a pool of examples to annotate from unlabeled data in advance, followed by prompt retrieval that retrieves task examples from the annotated pool at test time. Based on this framework, we propose an unsupervised, graph-based selective annotation method, voke-k, to select diverse, representative examples to annotate. Extensive experiments on 10 datasets (covering classification, commonsense reasoning, dialogue, and text/code generation) demonstrate that our selective annotation method improves the task performance by a large margin. On average, vote-k achieves a 12.9%/11.4% relative gain under an annotation budget of 18/100, as compared to randomly selecting examples to annotate. Compared to state-of-the-art supervised finetuning approaches, it yields similar performance with 10-100x less annotation cost across 10 tasks. We further analyze the effectiveness of our framework in various scenarios: language models with varying sizes, alternative selective annotation methods, and cases where there is a test data domain shift. We hope that our studies will serve as a basis for data annotations as large language models are increasingly applied to new tasks.

Switch-NeRF: Learning Scene Decomposition with Mixture of Experts for Large-scale Neural Radiance Fields

Zhenxing MI,Dan Xu

The Neural Radiance Fields (NeRF) have been recently applied to reconstruct building-scale and even city-scale scenes. To model a large-scale scene efficiently, a dominant strategy is to employ a divide-and-conquer paradigm via performing scene decomposition, which decomposes a complex scene into parts that are further processed by different sub-networks. Existing large-scale NeRFs mainly use heuristic hand-crafted scene decomposition, with regular 3D-distance-based or physic al-street-block-based schemes. Although achieving promising results, the hand-crafted schemes limit the capabilities of NeRF in large-scale scene modeling in several aspects. Manually designing a universal scene decomposition rule for different complex scenes is challenging, leading to adaptation issues for different scenarios. The decomposition procedure is not learnable, hindering the network from jointly optimizing the scene decomposition and the radiance fields in an end-to-end manner. The different sub-networks are typically optimized independently, and thus hand-crafted rules are required to composite them to achieve a better consistency. To tackle these issues, we propose Switch-NeRF, a novel end-to-end large-scale NeRF with learning-based scene decomposition. We design a gating network to dispatch 3D points to different NeRF sub-networks. The gating network can be optimized together with the NeRF sub-networks for different scene partitions, by a design with the Sparsely Gated Mixture of Experts (MoE). The outputs from different sub-networks can also be fused in a learnable way in the unified framework to effectively guarantee the consistency of the whole scene. Furthermore, the proposed MoE-based Switch-NeRF model is carefully implemented and optimized to achieve both high-fidelity scene reconstruction and efficient computation. Our method establishes clear state-of-the-art performances on several large-scale datasets. To the best of our knowledge, we are the first to propose an applicable end-to-end sparse NeRF network with learning-based decomposition for large-scale scenes. Codes are released at https://github.com/MiZhenxing/Switch-NeRF.

Efficient, Stable, and Analytic Differentiation of the Sinkhorn Loss
Yixuan Qiu,Haoyun Yin,Xiao Wang

Optimal transport and the Wasserstein distance have become indispensable building blocks of modern deep generative models, but their computional costs greatly prohibit their applications in statistical machine learning models. Recently, the Sinkhorn loss, as an approximation to the Wasserstein distance, has gained massive popularity, and much work has been done for its theoretical properties. To embed the Sinkhorn loss into gradient-based learning frameworks, efficient algorithms for both the forward and backward passes of the Sinkhorn loss are required. In this article, we first demonstrate issues of the widely-used Sinkhorn's algorithm, and show that the L-BFGS algorithm is a potentially better candidate for the forward pass. Then we derive an analytic form of the derivative of the Sinkhorn loss with respect to the input cost matrix, which results in a very efficient backward algorithm. We rigorously analyze the convergence and stability properties of the advocated algorithms, and use various numerical experiments to validate the superior performance of the proposed methods.

****

A Holistic View of Label Noise Transition Matrix in Deep Learning and Beyond
LIN Yong,Renjie Pi,WEIZHONG ZHANG,Xiaobo Xia,Jiahui Gao,Xiao Zhou,Tongliang Liu,Bo Han

In this paper, we explore learning statistically consistent classifiers under label noise by estimating the noise transition matrix T. We first provide a holistic view of existing T-estimation methods including those with or without anchor point assumptions. We unified them into the Minimum Geometric Envelope Operator (MGEO) framework, which tries to find the smallest T (in terms of a certain metric) that elicits a convex hull to enclose the posteriors of all the training data. Although MGEO methods show appealing theoretical properties and empirical results, we find them prone to failing when the noisy posterior estimation is imperfect, which is inevitable in practice. Specifically, we show that MGEO methods are in-consistent even with infinite samples if the noisy posterior is not estimated accurately. In view of this, we make the first effort to address this issue by proposing a novel T-estimation framework via the lens of bilevel optimization, and term it RObust Bilevel OpTimzation (ROBOT). ROBOT paves a new road beyond MGEO framework, which enjoys strong theoretical properties: identifibility, consistency and finite-sample generalization guarantees. Notably, ROBOT neither requires the perfect posterior estimation nor assumes the existence of anchor points. We further theoretically demonstrate that ROBOT is more robust in the case where MGEO methods fail. Experimentally, our framework also shows superior perform ance across multiple benchmarks.

Active Learning in Bayesian Neural Networks with Balanced Entropy Learning Principle

Jae Oh Woo

Acquiring labeled data is challenging in many machine learning applications with limited budgets. Active learning gives a procedure to select the most informative data points and improve data efficiency by reducing the cost of labeling. The info-max learning principle maximizing mutual information such as BALD has been successful and widely adapted in various active learning applications. However, this pool-based specific objective inherently introduces a redundant selection and further requires a high computational cost for batch selection. In this paper, we design and propose a new uncertainty measure, Balanced Entropy Acquisition (BalEntAcq), which captures the information balance between the uncertainty of underlying softmax probability and the label variable. To do this, we approximate each marginal distribution by Beta distribution. Beta approximation enables us to formulate BalEntAcq as a ratio between an augmented entropy and the marginalized joint entropy. The closed-form expression of BalEntAcq facilitates parallelization by estimating two parameters in each marginal Beta distribution. BalEntAcq is a purely standalone measure without requiring any relational computations with other data points. Nevertheless, BalEntAcq captures a well-diversified selection near the decision boundary with a margin, unlike other existing uncertainty measures such as BALD, Entropy, or Mean Standard Deviation (MeanSD). Finally, we demonstrate that our balanced entropy learning principle with BalEntAcq consistently outperforms well-known linearly scalable active learning methods, including a recently proposed PowerBALD, a simple but diversified version of BALD, by showing experimental results obtained from MNIST, CIFAR-100, SVHN, and TinyImageNet datasets.

****

Near-Optimal Adversarial Reinforcement Learning with Switching Costs

Ming Shi,Yingbin Liang,Ness Shroff

Switching costs, which capture the costs for changing policies, are regarded as a critical metric in reinforcement learning (RL), in addition to the standard metric of losses (or rewards). However, existing studies on switching costs (with a coefficient that is strictly positive and is independent of the time horizon) have mainly focused on static RL, where the loss distribution is assumed to be fixed during the learning process, and thus practical scenarios where the loss distribution could be non-stationary or even adversarial are not considered. While adversarial RL better models this type of practical scenarios, an open problem remains: how to develop a provably efficient algorithm for adversarial RL with switching costs? This paper makes the first effort towards solving this problem. First, we provide a regret lower-bound that shows that the regret of any algorithm must be larger than $\tilde{\Omega}((H S A)^{1/3} T^{2/3})$, where $T$, $S$, $A$ and $H$ are the number of episodes, states, actions and layers in each episode, respectively. Our lower bound indicates that, due to the fundamental challenge of switching costs in adversarial RL, the best achieved regret (whose dependency on $T$ is $\tilde{O}(\sqrt{T})$) in static RL with switching costs (as well as adversarial RL without switching costs) is no longer achievable. Moreover, we propose two novel switching-reduced algorithms with regrets that match our lower bound when the transition function is known, and match our lower bound within a small factor of $\tilde{O}(H^{1/3})$ when the transition function is unknown. Our regret analysis demonstrates the near-optimal performance of them.

NORM: Knowledge Distillation via N-to-One Representation Matching

Xiaolong Liu,Lujun Li,Chao Li,Anbang Yao

Existing feature distillation methods commonly adopt the One-to-one Representation Matching between any pre-selected teacher-student layer pair. In this paper, we present $N$-to-$O$ne $R$epresentation $M$atching (NORM), a new two-stage knowledge distillation method, which relies on a simpleFeature Transform (FT) module consisting of two linear layers. In view of preserving the intact information l earnt by the teacher network, during training, our FT module is merely inserted after the last convolutional layer of the student network. The first linear layer projects the student representation to a feature space having N times feature channels than the teacher representation from the last convolutional layer, and the second linear layer contracts the expanded output back to the original feature space. By sequentially splitting the expanded student representation into N non-overlapping feature segments having the same number of feature channels as the teacher's, they can be readily forced to approximate the intact teacher representation simultaneously, formulating a novel many-to-one representation matching mechanism conditioned on a single teacher-student layer pair. After training, such an FT module will be naturally merged into the subsequent fully connected layer thanks to its linear property, introducing no extra parameters or architectural modifications to the student network at inference. Extensive experiments on different visual recognition benchmarks demonstrate the leading performance of our method. For instance, the ResNet18|MobileNet|ResNet50-1/4 model trained by NORM reaches 72.14%|74.26%|68.03% top-1 accuracy on the ImageNet dataset when using a pre-trained ResNet34|ResNet50|ResNet50 model as the teacher, achieving an absolute improvement of 2.01%|4.63%|3.03% against the individually trained counterpart. Code is available at https://github.com/OSVAI/NORM.

Downstream Datasets Make Surprisingly Good Pretraining Corpora

Kundan Krishna,Saurabh Garg,Jeffrey P. Bigham,Zachary Chase Lipton

For most natural language processing tasks, the dominant practice is to finetune large pretrained transformer models (e.g., BERT) using smaller downstream datasets. Despite the success of this approach, it remains unclear to what extent these gains are attributable to the massive background corpora employed for pretraining versus to the pretraining objectives themselves. This paper introduces a large-scale study of self-pretraining, where the same (downstream) training data is used for both pretraining and finetuning. In experiments addressing both ELECTRA and RoBERTa models and 10 distinct downstream datasets, we observe that self-pretraining rivals standard pretraining on the BookWiki corpus (despite using around $10\times$--$500\times$ less data), outperforming the latter on 7 and 5 datasets, respectively. Surprisingly, these task-specific pretrained models often perform well on other tasks, including the GLUE benchmark. Our results suggest that in many scenarios, performance gains attributable to pretraining are driven primarily by the pretraining objective itself and are not always attributable to the incorporation of massive datasets. These findings are especially relevant in light of concerns about intellectual property and offensive content in web-scale pretraining data.

Revisiting Embeddings for Graph Neural Networks

Skye Purchase,Yiren Zhao,Robert D. Mullins

Current graph representation learning techniques use Graph Neural Networks (GNNs) to extract features from dataset embeddings. In this work, we examine the quality of these embeddings and assess how changing them can affect the accuracy of GNNs. We explore different embedding extraction techniques for both images and texts; and find that the choice of embedding biases the performance of different GNN architectures and thus the choice of embedding influences the selection of GNNs regardless of the underlying dataset. In addition, we only see an improvement in accuracy from some GNN models compared to the accuracy of models trained from scratch or fine-tuned on the underlying data without utilising the graph connections. As an alternative, we propose Graph-connected Network (GraNet) layers to better leverage existing unconnected models within a GNN. Existing language and vision models are thus improved by allowing neighbourhood aggregation. This gives a chance for the model to use pre-trained weights, if possible, and we demonstrate that this approach improves the accuracy compared to traditional GNNs: on Flickr v2, GraNet beats GAT2 and GraphSAGE by 7.7% and 1.7% respectively.

Empirical analysis of representation learning and exploration in neural kernel bandits

Michal Lisicki,Arash Afkanpour,Graham W. Taylor

Neural bandits have been shown to provide an efficient solution to practical sequential decision tasks that have nonlinear reward functions. The main contributor to that success is approximate Bayesian inference, which enables neural network (NN) training with uncertainty estimates. However, Bayesian NNs often suffer from a prohibitive computational overhead or operate on a subset of parameters. Alternatively, certain classes of infinite neural networks were shown to directly correspond to Gausian processes (GP) with neural kernels (NK). NK-GPs provide accurate uncertainty estimates and can be trained faster than most Bayesian NNs. We propose to guide common bandit policies with NK distributions and show that NK bandits achieve state-of-the-art performance on nonlinear structured data. Moreover, we propose a framework for measuring independently the ability of a bandit algorithm to learn representations and explore, and use it to analyze the impact of NK distributions w.r.t. those two aspects. We consider policies based on a GP and a Student's t-process (TP). Furthermore, we study practical considerations, such as training frequency and model partitioning. We believe our work will help better understand the impact of utilizing NKs in applied settings.

Exploiting Spatial Separability for Deep Learning Multichannel Speech Enhancement with an Align-and-Filter Network

Ching-Hua Lee,Chouchang Yang,Yilin Shen,Hongxia Jin

Multichannel speech enhancement (SE) systems separate the target speech from background noise by performing spatial and spectral filtering. The development of multichannel SE has a long history in the signal processing field, where one crucial step is to exploit spatial separability of sound sources by aligning the microphone signals in response to the target speech source prior to further filtering processes. However, most existing deep learning based multichannel SE works have yet to effectively incorporate or emphasize this spatial alignment aspect in the network design – we postulate that it is owing to the lack of suitable datasets with sufficient spatial diversity of the speech sources. In this paper, we highlight this important but often overlooked step in deep learning based multichannel SE, i.e., signal alignment, by introducing an Align-and-Filter network (AFnet) featuring a two-stage sequential masking design. The AFnet estimates two sets of masks, the alignment masks and filtering masks, and multiplies the estimated masks with the respective input signals to each stage sequentially, while leveraging the relative transfer functions (RTFs) for guiding the model to align signals with various speech source locations during training. For exploration purposes, we argue that the popular CHiME-3 multichannel dataset has its own limitation in representing spatially diverse speech data as the speakers were mostly located at the front side, and thereby adopt simulated and real-world measured room impulse responses to generate multichannel recordings where the target speech sources might come from arbitrary directions. Our findings suggest that for spatially diverse speaker scenarios, careful consideration of exploiting spatial characteristics is of great importance for deep learning based multichannel SE especially when the number of microphone gets increased. We show that utilizing the RTFs for signal alignment purposes in the two-stage, sequential masking framework consistently improves the capability of the network to separate the target speech from the noise signals, supporting that spatial separability is being effectively exploited by the proposed model. Our studies advocate for the advantages and significance of considering the signal alignment aspect, a wisdom coming from conventional signal processing, for developing future deep based multichannel SE algorithms to improve enhancement outcomes with positional diverse target speech scenarios.

CroMA: Cross-Modality Adaptation for Monocular BEV Perception

Yunze Man,Liangyan Gui,Yu-Xiong Wang

Incorporating multiple sensor modalities, and closing the domain gaps between tr aining and deployment are two challenging yet critical topics for self-driving. Existing adaption works only focus on visual-level domain gaps, overlooking the sensor-type gaps which exist in reality. A model trained with a collection of sensor modalities may need to run on another setting with less types of sensors available. In this work, we propose a Cross-Modality Adaptation (CroMA) framework to facilitate the learning of a more robust monocular BEV perception model, which transfer the point clouds knowledge from LiDAR sensor during training phase to the camera-only testing scenario. The absence of LiDAR during testing negates the usage of it as model input. Hence, our key idea lies in the design of a LiDAR-teacher and Camera-student knowledge distillation model, as well as a multi-level adversarial learning mechanism, which adapt and align the features learned from different sensors and domains. This work results in the first open analysis of cross-domain perception and cross-sensor adaptation model for monocular 3D tasks in the wild. We benchmark our approach on large-scale datasets under various domain shifts and show state-of-the-art results against various baselines.

CausalAgents: A Robustness Benchmark for Motion Forecasting Using Causal Relationships

Rebecca Roelofs,Liting Sun,Benjamin Caine,Khaled S. Refaat,Benjamin Sapp,Scott Ettinger,Wei Chai

As machine learning models become increasingly prevalent in motion forecasting systems for autonomous vehicles (AVs), it is critical that we ensure that model predictions are safe and reliable. However, exhaustively collecting and labeling the data necessary to fully test the long tail of rare and challenging scenarios is difficult and expensive. In this work, we construct a new benchmark for evaluating and improving model robustness by applying perturbations to existing data. Specifically, we conduct an extensive labeling effort to identify causal agents, or agents whose presence influences human driver behavior in any way, in the Waymo Open Motion Dataset (WOMD), and we use these labels to perturb the data by deleting non-causal agents from the scene. We then evaluate a diverse set of state-of-the-art deep-learning model architectures on our proposed benchmark and find that all models exhibit large shifts under perturbation. Under non-causal perturbations, we observe a 25-38% relative change in minADE as compared to the original. We then investigate techniques to improve model robustness, including increasing the training dataset size and using targeted data augmentations that drop agents throughout training. We provide the causal agent labels as an additional attribute to WOMD and release the robustness benchmarks to aid the community in building more reliable and safe deep-learning models for motion forecasting.

Adaptive Client Sampling in Federated Learning via Online Learning with Bandit Feedback

Boxin Zhao,Ziqi Liu,Chaochao Chen,mladen kolar,Zhiqiang Zhang,JUN ZHOU

Due to the high cost of communication, federated learning (FL) systems need to sample a subset of clients that are involved in each round of training. As a result, client sampling plays an important role in FL systems as it affects the convergence rate of optimization algorithms used to train machine learning models. Despite its importance, there is limited work on how to sample clients effectively. In this paper, we cast client sampling as an online learning task with bandit feedback, which we solve with an online stochastic mirror descent (OSMD) algorithm designed to minimize the sampling variance. We then theoretically show how our sampling method can improve the convergence speed of optimization algorithms. To handle the tuning parameters in OSMD that depend on the unknown problem parameters, we use the online ensemble method and doubling trick. We prove a dynamic regret bound relative to any sampling sequence. The regret bound depends on the total variation of the comparator sequence, which naturally captures the intrinsic difficulty of the problem. To the best of our knowledge, these theoretical contributions are new and the proof technique is of independent interest. Through both synthetic and real data experiments, we illustrate advantages of the proposed client sampling algorithm over the widely used uniform sampling and existing online learning based sampling strategies. The proposed adaptive sampling procedure is applicable beyond the FL problem studied here and can be used to improve the performance of stochastic optimization procedures such as stochastic gradient descent and stochastic coordinate descent.

Dynamical Isometry for Residual Networks

Advait Harshal Gadhikar,Rebekka Burkholz

The training success, training speed and generalization ability of neural networks rely crucially on the choice of random parameter initialization. It has been shown for multiple architectures that initial dynamical isometry is particularly advantageous. Known initialization schemes for residual blocks, however, miss this property and suffer from degrading separability of different inputs for increasing depth and instability without Batch Normalization or lack feature diversity. We propose a random initialization scheme, Risotto, that achieves perfect dynamical isometry for residual networks with ReLU activation functions even for finite depth and width. It balances the contributions of the residual and skip branches unlike other schemes, which initially bias towards the skip connections. In experiments, we demonstrate that in most cases our approach outperforms initialization schemes proposed to make Batch Normalization obsolete, including Fixup and SkipInit, and facilitates stable training. Also in combination with Batch Normalization, we find that Risotto often achieves the overall best result.

How Erdös and Rényi Win the Lottery

Advait Harshal Gadhikar,Sohom Mukherjee,Rebekka Burkholz

Random masks define surprisingly effective sparse neural network models, as has been shown empirically. The resulting Erd\"os-R\'enyi (ER) random graphs can often compete with dense architectures and state-of-the-art lottery ticket pruning algorithms struggle to outperform them, even though the random baselines do not rely on computationally expensive pruning-training iterations but can be drawn initially without significant computational overhead. We offer a theoretical explanation of how such ER masks can approximate arbitrary target networks if they are wider by a logarithmic factor in the inverse sparsity $1 / \log(1/\text{sparsity})$. While we are the first to show theoretically and experimentally that random ER source networks contain strong lottery tickets, we also prove the existence of weak lottery tickets that require a lower degree of overparametrization than strong lottery tickets. These unusual results are based on the observation that ER masks are well trainable in practice, which we verify in experiments with varied choices of random masks. Some of these data-free choices outperform previously proposed random approaches on standard image classification benchmark datasets.

GPViT: A High Resolution Non-Hierarchical Vision Transformer with Group Propagation

Chenhongyi Yang,Jiarui Xu,Shalini De Mello,Elliot J. Crowley,Xiaolong Wang

We present the Group Propagation Vision Transformer (GPViT): a novel non- hierarchical (i.e. non-pyramidal) transformer model designed for general visual recognition with high-resolution features. High-resolution features (or tokens) are a natural fit for tasks that involve perceiving fine-grained details such as detection and segmentation, but exchanging global information between these features is expensive in memory and computation because of the way self-attention scales. We provide a highly efficient alternative Group Propagation Block (GP Block) to exchange global information. In each GP Block, features are first grouped to- gether by a fixed number of learnable group tokens; we then perform Group Propagation where global information is exchanged between the grouped fea- tures; finally, global information in the updated grouped features is returned back to the image features through a transformer decoder. We evaluate GPViT on a variety of visual recognition tasks including image classification, semantic seg- mentation, object detection, and instance segmentation. Our method achieves significant performance gains over previous works across all tasks, especially on tasks that require high-resolution outputs, for example, our GPViT-L3 out- performs Swin Tra nsformer-B by 2.0 mIoU on ADE20K semantic segmentation with only half as many parameters. Code and pre-trained models are available at https://github.com/ChenhongyiYang/GPViT.

Variational Imbalanced Regression

Ziyan Wang,Hao Wang

Existing regression models tend to fall short in both accuracy and uncertainty estimation when the label distribution is imbalanced. In this paper, we propose a probabilistic deep learning model, dubbed variational imbalanced regression (VIR), which not only performs well in imbalanced regression but naturally produces reasonable uncertainty estimation as a byproduct. Different from typical variational autoencoders assuming I.I.D. representation (a data point's representation is not directly affected by other data points), our VIR borrows data with similar regression labels to compute the latent representation's variational distribution; furthermore, different from deterministic regression models producing point estimates, VIR predicts the entire normal-inverse-gamma distributions and modulates the associated conjugate distributions to impose probabilistic reweighting on the imbalanced data, thereby providing better uncertainty estimation. Experiments in several real-world datasets show that our VIR can outperform state-of-the-art imbalanced regression models in terms of both accuracy and uncertainty estimation.

Critic Sequential Monte Carlo

Vasileios Lioutas,Jonathan Wilder Lavington,Justice Sefas,Matthew Niedoba,Yunpeng Liu,Berend Zwartsenberg,Setareh Dabiri,Frank Wood,Adam Scibior

We introduce CriticSMC, a new algorithm for planning as inference built from a composition of sequential Monte Carlo with learned Soft-Q function heuristic factors. These heuristic factors, obtained from parametric approximations of the marginal likelihood ahead, more effectively guide SMC towards the desired target distribution, which is particularly helpful for planning in environments with hard constraints placed sparsely in time. Compared with previous work, we modify the placement of such heuristic factors, which allows us to cheaply propose and evaluate large numbers of putative action particles, greatly increasing inference and planning efficiency. CriticSMC is compatible with informative priors, whose density function need not be known, and can be used as a model-free control algorithm. Our experiments on collision avoidance in a high-dimensional simulated driving task show that CriticSMC significantly reduces collision rates at a low computational cost while maintaining realism and diversity of driving behaviors across vehicles and environment scenarios.

Radial Spike and Slab Bayesian Neural Networks for Sparse Data in Ransomware Attacks

Jurijs Nazarovs,Jack W Stokes,Melissa Turcotte,Justin Carroll,Itai Grady

Ransomware attacks are increasing at an alarming rate, leading to large financial losses, unrecov- erable encrypted data, data leakage, and privacy concerns. The prompt detection of ransomware attacks is required to minimize further damage, particularly during the encryption stage. However, the frequency and structure of the observed ransomware attack data makes this task difficult to accomplish in practice. The data corresponding to ransomware attacks represents temporal, high- dimensional sparse signals, with limited records and very imbalanced classes. While traditional deep learning models have been able to achieve state-of-the-art results in a wide variety of domains, Bayesian Neural Networks, which are a class of probabilistic models, are better suited to the issues of the ransomware data. These models combine ideas from Bayesian statistics with the rich expres- sive power of neural networks. In this paper, we propose the Radial Spike and Slab Bayesian Neural Network, which is a new type of Bayesian Neural network that includes a new form of the approx- imate posterior distribution. The model scales well to large architectures and recovers the sparse structure of target functions. We provide a theoretical justification for using this type of distribution, as well as a computationally efficient method to perform variational inference

. We demonstrate the performance of our model on a real dataset of ransomware attacks and show improvement over a large number of baselines, including state-of-the-art models such as Neural ODEs (ordinary dif- ferential equations). In addition, we propose to represent low-level events as MITRE ATT&CK tactics, techniques, and procedures (TTPs) which allows the model to better generalize to unseen ransomware attacks.

Autoencoders as Cross-Modal Teachers: Can Pretrained 2D Image Transformers Help 3D Representation Learning?

Runpei Dong,Zekun Qi,Linfeng Zhang,Junbo Zhang,Jianjian Sun,Zheng Ge,Li Yi,Kaisheng Ma

The success of deep learning heavily relies on large-scale data with comprehensive labels, which is more expensive and time-consuming to fetch in 3D compared to 2D images or natural languages. This promotes the potential of utilizing models pretrained with data more than 3D as teachers for cross-modal knowledge transferring. In this paper, we revisit masked modeling in a unified fashion of knowledge distillation, and we show that foundational Transformers pretrained with 2D images or natural languages can help self-supervised 3D representation learning through training Autoencoders as Cross-Modal Teachers (ACT). The pretrained Transformers are transferred as cross-modal 3D teachers using discrete variational autoencoding self-supervision, during which the Transformers are frozen with prompt tuning for better knowledge inheritance. The latent features encoded by the 3D teachers are used as the target of masked point modeling, wherein the dark knowledge is distilled to the 3D Transformer students as foundational geometry understanding. Our ACT pretrained 3D learner achieves state-of-the-art generalization capacity across various downstream benchmarks, e.g., 88.21% overall accuracy on ScanObjectNN. Codes have been released at https://github.com/RunpeiDong/ACT.

Explainability of deep reinforcement learning algorithms in robotic domains by using Layer-wise Relevance Propagation

Mehran Taghian Jazi,Shotaro Miwa,Yoshihiro Mitsuka,Johannes Günther,Osmar Zaiane

A key component to the recent success of reinforcement learning is the introduction of neural networks for representation learning. Doing so allows for solving challenging problems in several domains, one of which is robotics. However, a major criticism of deep reinforcement learning (DRL) algorithms is their lack of explainability and interpretability. This problem is even exacerbated in robotics as they oftentimes cohabitate space with humans, making it imperative to be able to reason about their behaviour.

In this paper, we propose to analyze the learned representation in a robotic setting by utilizing graph neural networks. Using the graphical neural networks and Layer-wise Relevance Propagation (LRP), we represent the observations as an entity-relationship to allow us to interpret the learned policy. We evaluate our approach in two environments in MuJoCo. These two environments were delicately designed to effectively measure the value of knowledge gained by our approach to analyzing learned representations. This approach allows us to analyze not only how different parts of the observation space contribute to the decision-making process but also differentiate between policies and their differences in performance. This difference in performance also allows for reasoning about the agent's recovery from faults. These insights are key contributions to explainable deep reinforcement learning in robotic settings.

Learning to Take a Break: Sustainable Optimization of Long-Term User Engagement

Eden Saig,Nir Rosenfeld

Optimizing user engagement is a key goal for modern recommendation systems, but blindly pushing users towards increased consumption risks burn-out, churn, or even addictive habits. To promote digital well-being, most platforms now offer a service that periodically prompts users to take a break. These, however, must be set up manually, and so may be suboptimal for both users and the system.

In this paper, we propose a framework for optimizing long-term engagement by learning individualized breaking policies. Using Lotka-Volterra dynamics, we model users as acting based on two balancing latent states: drive, and interest---which must be conserved. We then give an efficient learning algorithm, provide theoretical guarantees, and empirically evaluate its performance on semi-synthetic data.

HyperQuery: A Framework for Higher Order Link Prediction

Sepideh Maleki,Josh Vekhter,Keshav Pingali

Groups with complex set intersection relations are a natural way to model a wide array of data, from the formation of social groups to the complex protein interactions which form the basis of biological life. While graphs are a natural way to represent complex networks and are well studied, typical approaches to modeling group membership using graphs are lossy. Hypergraphs are a more natural way to represent such ``higher order'' relationships, but efforts to apply machine learning techniques to hypergraph structured datasets have been limited thus far. In this paper, we address the problem of link prediction in knowledge hypergraphs as well as regular hypergraphs and develop a novel, simple, and effective optimization architecture to solve this task. Additionally, we study how integrating data from node-level labels can improve the results of our system. Our self-supervised approach achieves significant improvement over state of the art results on several hyperedge prediction and knowledge hypergraph completeion benchmarks.

****

Generative Model Based Noise Robust Training for Unsupervised Domain Adaptation

Zhongying Deng,Da Li,Junjun He,Yi-Zhe Song,Tao Xiang

Target domain pseudo-labeling has shown effectiveness in unsupervised domain adaptation (UDA). However, pseudo-labels of unlabeled target domain data are inevitably noisy due to the distribution shift between source and target domains. In this paper, we propose a generative model-based noise-robust training method (GeMo-NoRT), serving for domain shift elimination and label noise robustness simultaneously. GeMo-NoRT incorporates a distribution-based class-wise feature augmentation (D-CFA) and a generative-discriminative classifier consistency (GDC), both based on the class-wise target distributions modeled by generative models. D-CFA minimizes the domain gap by augmenting the source data with distribution-sampled target features, and trains a noise-robust discriminative classifier by using target domain knowledge from the generative models. GDC regards all the class-wise generative models as a generative classifier and enforces a consistency regularization between the generative and discriminative classifiers. It exploits an ensemble of target knowledge from all the generative models to train a noise-robust discriminative classifier, and eventually gets theoretically linked to the Ben-David domain adaptation theorem for reducing domain gap. Extensive experiments on Office-Home, PACS, and Digit-Five show that our GeMo-NoRT achieves state of the art under single-source and multi-source UDA settings.

Deep Learning meets Nonparametric Regression: Are Weight-Decayed DNNs Locally Adaptive?

Kaiqi Zhang,Yu-Xiang Wang

We study the theory of neural network (NN) from the lens of classical nonparametric regression problems with a focus on NN’s ability to adaptively estimate functions with heterogeneous smoothness — a property of functions in Besov or Bounded Variation (BV) classes. Existing work on this problem requires tuning the NN architecture based on the function spaces and sample sizes. We consider a “Parallel NN” variant of deep ReLU networks and show that the standard weight decay is equivalent to promoting the ■p -sparsity (0 < p < 1) of the coefficient vector of an end-to-end learned function bases, i.e., a dictionary. Using this equivalence, we further establish that by tuning only the weight decay, such Parallel NN achieves an estimation error arbitrarily close to the minimax rates for both the Besov and BV classes. Notably, it gets exponentially closer to minimax optimal as the NN gets deeper. Our research sheds new lights on why depth matters and how NNs are more powerful than kernel methods

****

Sparse Token Transformer with Attention Back Tracking

Heejun Lee,Minki Kang,Youngwan Lee,Sung Ju Hwang

Despite the success of Transformers in various applications from text, vision, and speech domains, they are yet to become standard architectures for mobile and edge device applications due to their heavy memory and computational requirements. While there exist many different approaches to reduce the complexities of the Transformers, such as the pruning of the weights/attentions/tokens, quantization, and distillation, we focus on token pruning, which reduces not only the complexity of the attention operations, but also the linear layers, which have non-negligible computational costs. However, previous token pruning approaches often remove tokens during the feed-forward stage without consideration of their impact on later layers' attentions, which has a potential risk of dropping out important tokens for the given task. To tackle this issue, we propose an attention back-tracking method that tracks the importance of each attention in a Transformer architecture from the outputs to the inputs, to preserve the tokens that have a large impact on the final predictions. We experimentally validate the effectiveness of the method on both NLP and CV benchmarks, using Transformer architectures for both domains, and the results show that the proposed attention back-tracking allows the model to better retain the full models' performance even at high sparsity rates, significantly outperforming all baselines. Qualitative analysis of the examples further shows that our method does preserve semantically meaningful tokens.

A Deep Conjugate Direction Method for Iteratively Solving Linear Systems

Ayano Kaneda,Osman Akar,Jingyu Chen,Victoria Alicia Trevino Kala,David Hyde,Joseph Teran

We present a novel deep learning approach to approximate the solution of large, sparse, symmetric, positive-definite linear systems of equations.These systems arise from many problems in applied science, e.g., in numerical methods for partial differential equations. Algorithms for approximating the solution to these systems are often the bottleneck in problems that require their solution, particularly for modern applications that require many millions of unknowns. Indeed, numerical linear algebra techniques have been investigated for many decades to alleviate this computational burden. Recently, data-driven techniques have also shown promise for these problems. Motivated by the conjugate gradients algorithm that iteratively selects search directions for minimizing the matrix norm of the approximation error, we design an approach that utilizes a deep neural network to accelerate convergence via data-driven improvement of the search directions.

Our method leverages a carefully chosen convolutional network to approximate the action of the inverse of the linear operator up to an arbitrary constant. We train the network using unsupervised learning with a loss function equal to the L^2 difference between an input and the system matrix times the network evaluation, where the unspecified constant in the approximate inverse is accounted for.

We demonstrate the efficacy of our approach on spatially discretized Poisson equations with millions of degrees of freedom arising in computational fluid dynamics applications.Unlike state-of-the-art learning approaches, our algorithm is capable of reducing the linear system residual to a given tolerance in a small number of iterations, independent of the problem size.Moreover, our method generalizes effectively to various systems beyond those encountered during training.

****

Smart Multi-tenant Federated Learning

Weiming Zhuang,Yonggang Wen,Shuai Zhang

Federated learning (FL) is an emerging distributed machine learning method that empowers in-situ model training on decentralized edge devices. However, multiple simultaneous training activities could overload resource-constrained devices. In this work, we propose a smart multi-tenant FL system, MuFL, to effectively coordinate and execute simultaneous training activities. We first formalize the problem of multi-tenant FL, define multi-tenant FL scenarios, and introduce a vanilla multi-tenant FL system that trains activities sequentially to form baselines. Then, we propose two approaches to optimize multi-tenant FL: 1) activity consol

idation merges training activities into one activity with a multi-task architecture; 2) after training it for rounds, activity splitting divides it into groups by employing affinities among activities such that activities within a group have better synergy. Extensive experiments demonstrate that MuFL outperforms other methods while consuming 40% less energy. We hope this work will inspire the community to further study and optimize multi-tenant FL.

Robust Active Distillation
Cenk Baykal,Khoa Trinh,Fotis Iliopoulos,Gaurav Menghani,Erik Vee
Distilling knowledge from a large teacher model to a lightweight one is a widely successful approach for generating compact, powerful models in the semi-supervised learning setting where a limited amount of labeled data is available. In large-scale applications, however, the teacher tends to provide a large number of incorrect soft-labels that impairs student performance. The sheer size of the teacher additionally constrains the number of soft-labels that can be queried due to prohibitive computational and/or financial costs. The difficulty in achieving simultaneous \emph{efficiency} (i.e., minimizing soft-label queries) and \emph{robustness} (i.e., avoiding student inaccuracies due to incorrect labels) hurts the widespread application of knowledge distillation to many modern tasks. In this paper, we present a parameter-free approach with provable guarantees to query the soft-labels of points that are simultaneously informative and correctly labeled by the teacher. At the core of our work lies a game-theoretic formulation that explicitly considers the inherent trade-off between the informativeness and correctness of input instances. We establish bounds on the expected performance of our approach that hold even in worst-case distillation instances. We present empirical evaluations on popular benchmarks that demonstrate the improved distillation performance enabled by our work relative to that of state-of-the-art active learning and active distillation methods.
****
Controllable Image Generation via Collage Representations
Arantxa Casanova,Marlene Careil,Adriana Romero-Soriano,Christopher Pal,Jakob Verbeek,Michal Drozdzal
Recent advances in conditional generative image models have enabled impressive results. On the one hand, text-based conditional models have achieved remarkable generation quality, by leveraging large-scale datasets of image-text pairs. To enable fine-grained controllability, however, text-based models require long prompts, whose details may be ignored by the model. On the other hand, layout-based conditional models have also witnessed significant advances. These models rely on bounding boxes or segmentation maps for precise spatial conditioning in combination with coarse semantic labels. The semantic labels, however, cannot be used to express detailed appearance characteristics. In this paper, we approach fine-grained scene controllability through image collages which allow a rich visual description of the desired scene as well as the appearance and location of the objects therein, without the need of class nor attribute labels. We introduce "mixing and matching scenes" (M&Ms), an approach that consists of an adversarially trained generative image model which is conditioned on appearance features and spatial positions of the different elements in a collage, and integrates these into a coherent image. We train our model on the OpenImages (OI) dataset and evaluate it on collages derived from OI and MS-COCO datasets. Our experiments on the OI dataset show that M&Ms outperforms baselines in terms of fine-grained scene controllability while being very competitive in terms of image quality and sample diversity. On the MS-COCO dataset, we highlight the generalization ability of our model by outperforming DALL-E in terms of the zero-shot FID metric, despite using two magnitudes fewer parameters and data. Collage based generative models have the potential to advance content creation in an efficient and effective way as they are intuitive to use and yield high quality generations.

Robust Multi-Agent Reinforcement Learning with State Uncertainties
Sihong He,Songyang Han,Sanbao Su,Shuo Han,Shaofeng Zou,Fei Miao
In real-world multi-agent reinforcement learning (MARL) applications, agents may

not have perfect state information (e.g., due to inaccurate measurement or malicious attacks), which challenges the robustness of agents' policies. Though robustness is getting important in MARL deployment, little prior work has studied state uncertainties in MARL, neither in problem formulation nor algorithm design. Motivated by this robustness issue, we study the problem of MARL with state uncertainty in this work. We provide the first attempt to the theoretical and empirical analysis of this challenging problem. We first model the problem as a Markov Game with state perturbation adversaries (MG-SPA), and introduce Robust Equilibrium as the solution concept. We conduct fundamental analysis regarding MG-SPA and give conditions under which such an equilibrium exists. Then we propose a robust multi-agent Q-learning (RMAQ) algorithm to find such an equilibrium, with convergence guarantees. To handle high-dimensional state-action space, we design a robust multi-agent actor-critic (RMAAC) algorithm based on an analytical expression of the policy gradient derived in the paper. Our experiments show that the proposed RMAQ algorithm converges to the optimal value function; our RMAAC algorithm outperforms several MARL methods that do not consider the state uncertainty in several multi-agent environments.

Tiny Adapters for Vision Transformers

Imad Eddine MAROUF,Enzo Tartaglione,Stéphane Lathuilière

Vision Transformers (ViTs) have become one of the dominant architectures in computer vision and pretrained ViT models are commonly adapted to new tasks via fine-tuning of its parameters. Recent works in NLP proposed a variety of parameter-efficient transfer learning methods such as adapters to avoid the prohibitive storage cost of fine-tuning.

In this work, we start from the observation that adapters perform poorly when the dimension of adapters is small and we propose a training algorithm that addresses this issue. We start from large adapters which can be trained easily and iteratively reduce the size of every adapter. We introduce a scoring function that can compare neuron importance across layers and consequently allow automatic estimation of the hidden dimension of every adapter. Our method outperforms existing approaches in terms of the trade-off between accuracy and trained parameters across domain adaptation benchmarks. We will release our code publicly upon acceptance.

Accelerating Inverse Reinforcement Learning with Expert Bootstrapping

David Wu,Sanjiban Choudhury

Existing inverse reinforcement learning methods (e.g. MaxEntIRL, f-IRL) search over candidate reward functions and solve a reinforcement learning problem in the inner loop. This creates a rather strange inversion where a harder problem, reinforcement learning, is in the inner loop of a presumably easier problem, imitation learning. In this work, we show that better utilization of expert demonstrations can reduce the need for hard exploration in the inner RL loop, hence accelerating learning. Specifically, we propose two simple recipes: (1) placing expert transitions into the replay buffer of the inner RL algorithm (e.g. Soft-Actor Critic) which directly informs the learner about high reward states instead of forcing the learner to discover them through extensive exploration, and (2) using expert actions in Q value bootstrapping in order to improve the target Q value estimates and more accurately describe high value expert states. Our methods show significant gains over a MaxEntIRL baseline on the benchmark MuJoCo suite of tasks, speeding up recovery to 70\% of deterministic expert performance by 2.13x on HalfCheetah-v2, 2.6x on Ant-v2, 18x on Hopper-v2, and 3.36x on Walker2d-v2.

****

Kernel Neural Optimal Transport

Alexander Korotin,Daniil Selikhanovych,Evgeny Burnaev

We study the Neural Optimal Transport (NOT) algorithm which uses the general optimal transport formulation and learns stochastic transport plans. We show that NOT with the weak quadratic cost may learn fake plans which are not optimal. To resolve this issue, we introduce kernel weak quadratic costs. We show that they p

rovide improved theoretical guarantees and practical performance. We test NOT with kernel costs on the unpaired image-to-image translation task.

Neural Optimal Transport
Alexander Korotin,Daniil Selikhanovych,Evgeny Burnaev
We present a novel neural-networks-based algorithm to compute optimal transport maps and plans for strong and weak transport costs. To justify the usage of neural networks, we prove that they are universal approximators of transport plans between probability distributions. We evaluate the performance of our optimal transport algorithm on toy examples and on the unpaired image-to-image translation.

SeaFormer: Squeeze-enhanced Axial Transformer for Mobile Semantic Segmentation
Qiang Wan,Zilong Huang,Jiachen Lu,Gang YU,Li Zhang
Since the introduction of Vision Transformers, the landscape of many computer vision tasks (e.g., semantic segmentation), which has been overwhelmingly dominated by CNNs, recently has significantly revolutionized. However, the computational cost and memory requirement render these methods unsuitable on the mobile device, especially for the high resolution per-pixel semantic segmentation task. In this paper, we introduce a new method squeeze-enhanced Axial Transformer (SeaFormer) for mobile semantic segmentation. Specifically, we design a generic attention block characterized by the formulation of squeeze Axial and spatial enhancement. It can be further used to create a family of backbone architectures with superior cost-effectiveness. Coupled with a light segmentation head, we demonstrate state-of-the-art results on the ADE20K, Pascal Context and COCO-stuff datasets. Critically, we beat both the mobile-friendly rivals and Transformer-based counterparts with better performance and lower latency without bells and whistles. Beyond semantic segmentation, we further apply the proposed SeaFormer architecture to image classification problem, demonstrating the potentials of serving as a versatile mobile-friendly backbone.

Joint Edge-Model Sparse Learning is Provably Efficient for Graph Neural Networks
Shuai Zhang,Meng Wang,Pin-Yu Chen,Sijia Liu,Songtao Lu,Miao Liu
Due to the significant computational challenge of training large-scale graph neural networks (GNNs), various sparse learning techniques have been exploited to reduce memory and storage costs. Examples include graph sparsification that samples a subgraph to reduce the amount of data aggregation and model sparsification that prunes the neural network to reduce the number of trainable weights. Despite the empirical successes in reducing the training cost while maintaining the test accuracy, the theoretical generalization analysis of sparse learning for GNNs remains elusive. To the best of our knowledge, this paper provides the first theoretical characterization of joint edge-model sparse learning from the perspective of sample complexity and convergence rate in achieving zero generalization error. It proves analytically that both sampling important nodes and pruning neurons with lowest-magnitude can reduce the sample complexity and improve convergence without compromising the test accuracy. Although the analysis is centered on two-layer GNNs with structural constraints on data, the insights are applicable to more general setups and justified by both synthetic and practical citation datasets.

Harnessing spectral representations for subgraph alignment
Marco Pegoraro,Riccardo Marin,Arianna Rampini,Simone Melzi,Luca Cosmo,Emanuele Rodolà
With the rise and advent of graph learning techniques, graph data has become ubiquitous in the machine learning field. However, while several efforts have been devoted to the design of new convolutional architectures, pooling or positional encoding schemes, relatively little focus has been spent on modeling pairwise problems such as signal transfer, graph isomorphism and subgraph correspondence tasks. With this paper, we anticipate the need for a convenient framework to deal with problems that revolve around the notion of a map among graphs, and focus in particular on the challenging subgraph alignment scenario. We claim that, first

and foremost, the representation of a map plays a central role in how these problems should be modeled -- be it a map inference problem or a simpler signal transport task. Taking the hint from recent work in geometry processing, we propose the adoption of a spectral representation for maps that is compact, easy to compute, permutation-equivariant, easy to plug into learning pipelines, and especially effective for a wide range of situations, most notably when dealing with subgraph alignment problems. We further report for the first time a surprising phenomenon where the partiality arising in subgraph alignment is manifested in the structure of the map coefficients, even in the absence of exact isomorphism, and which is consistently observed over different families of graphs.

MotifExplainer: a Motif-based Graph Neural Network Explainer

Zhaoning Yu,Hongyang Gao

We consider the explanation problem of Graph Neural Networks (GNNs). Most existing GNN explanation methods identify the most important edges or nodes but fail to consider substructures, which are more important for graph data. One method considering subgraphs tries to search all possible subgraphs and identifies the most significant ones. However, the subgraphs identified may not be recurrent or statistically important for interpretation. This work proposes a novel method, named MotifExplainer, to explain GNNs by identifying important motifs, which are recurrent and statistically significant patterns in graphs. Our proposed motif-based methods can provide better human-understandable explanations than methods based on nodes, edges, and regular subgraphs. Given an instance graph and a pre-trained GNN model, our method first extracts motifs in the graph using domain-specific motif extraction rules. Then, a motif embedding is encoded by feeding motifs into the pre-trained GNN. Finally, we employ an attention-based method to identify the most influential motifs as explanations for the prediction results. The empirical studies on both synthetic and real-world datasets demonstrate the effectiveness of our method.

Receding Neuron Importances for Structured Pruning

Mihai Suteu,Yike Guo

Structured pruning efficiently compresses networks by identifying and removing unimportant neurons. While this can be elegantly achieved by applying sparsity-inducing regularisation on BatchNorm parameters, an L1 penalty would shrink all scaling factors rather than just those of superfluous neurons. To tackle this issue, we introduce a simple BatchNorm variation with bounded scaling parameters, based on which we design a novel regularisation term that suppresses only neurons with low importance. Under our method, the weights of unnecessary neurons effectively recede, producing a polarised bimodal distribution of importances. We show that neural networks trained this way can be pruned to a larger extent and with less deterioration. We one-shot prune VGG and ResNet architectures at different ratios on CIFAR and ImagenNet datasets. In the case of VGG-style networks, our method significantly outperforms existing approaches particularly under severe pruning.

Learning Sparse and Low-Rank Priors for Image Recovery via Iterative Reweighted Least Squares Minimization

Stamatios Lefkimmiatis,Iaroslav Sergeevich Koshelev

In this work we introduce a novel optimization algorithm for image recovery under learned sparse and low-rank constraints, which are parameterized with weighted extensions of the ℓ_p^p-vector and $\mathcal{S}_p^p$ Schatten-matrix quasi-norms for $0\!<p\!\le1$, respectively. Our proposed algorithm generalizes the Iteratively Reweighted Least Squares (IRLS) method, used for signal recovery under ℓ_1 and nuclear-norm constrained minimization. Further, we interpret our overall minimization approach as a recurrent network that we then employ to deal with inverse low-level computer vision problems. Thanks to the convergence guarantees that our IRLS strategy offers, we are able to train the derived reconstruction networks using a memory-efficient implicit back-propagation scheme, which does not pose any restrictions on their effective depth. To assess our networks'

performance, we compare them against other existing reconstruction methods on several inverse problems, namely image deblurring, super-resolution, demosaicking and sparse recovery. Our reconstruction results are shown to be very competitive and in many cases outperform those of existing unrolled networks, whose number of parameters is orders of magnitude higher than that of our learned models.

Unifying Diffusion Models' Latent Space, with Applications to CycleDiffusion and Guidance

Chen Henry Wu,Fernando De la Torre

Diffusion models have achieved unprecedented performance in generative modeling. The commonly-adopted formulation of the latent code of diffusion models is a sequence of gradually denoised samples, as opposed to the simpler (e.g., Gaussian) latent space of GANs, VAEs, and normalizing flows. This paper provides an alternative, Gaussian formulation of the latent space of various diffusion models, as well as an invertible DPM-Encoder that maps images into the latent space. While our formulation is purely based on the definition of diffusion models, we demonstrate several intriguing consequences. (1) Empirically, we observe that a common latent space emerges from two diffusion models trained independently on related domains. In light of this finding, we propose CycleDiffusion, which uses DPM-Encoder for unpaired image-to-image translation. Furthermore, applying CycleDiffusion to text-to-image diffusion models, we show that large-scale text-to-image diffusion models can be used as zero-shot image-to-image editors. (2) One can guide pre-trained diffusion models and GANs by controlling the latent codes in a unified, plug-and-play formulation based on energy-based models. Using the CLIP model and a face recognition model as guidance, we demonstrate that diffusion models have better coverage of low-density sub-populations and individuals than GANs.

Spherical Sliced-Wasserstein

Clément Bonet,Paul Berg,Nicolas Courty,François Septier,Lucas Drumetz,Minh Tan Pham

Many variants of the Wasserstein distance have been introduced to reduce its original computational burden. In particular the Sliced-Wasserstein distance (SW), which leverages one-dimensional projections for which a closed-form solution of the Wasserstein distance is available, has received a lot of interest. Yet, it is restricted to data living in Euclidean spaces, while the Wasserstein distance has been studied and used recently on manifolds. We focus more specifically on the sphere, for which we define a novel SW discrepancy, which we call spherical Sliced-Wasserstein, making a first step towards defining SW discrepancies on manifolds. Our construction is notably based on closed-form solutions of the Wasserstein distance on the circle, together with a new spherical Radon transform. Along with efficient algorithms and the corresponding implementations, we illustrate its properties in several machine learning use cases where spherical representations of data are at stake: sampling on the sphere, density estimation on real eath data or hyperspherical auto-encoders.

Intepreting & Improving Pretrained Language Models: A Probabilistic Conceptual Approach

Hengyi Wang,Zhiqing Hong,Desheng Zhang,Hao Wang

Pretrained Language Models (PLMs) such as BERT and its variants have achieved remarkable success in natural language processing. To date, the interpretability of PLMs has primarily relied on the attention weights in their self-attention layers. However, these attention weights only provide word-level interpretations, failing to capture higher-level structures, and are therefore lacking in readability and intuitiveness. In this paper, we propose a hierarchical Bayesian deep learning model, dubbed continuous latent Dirichlet allocation (CLDA), to go beyond word-level interpretations and provide concept-level interpretations. Our CLDA is compatible with any attention-based PLMs and can work as either (1) an interpreter which interprets model predictions at the concept level without any performance sacrifice or (2) a regulator which is jointly trained with PLMs during fin

etuning to further improve performance. Experimental results on various benchmark datasets show that our approach can successfully provide conceptual interpretation and performance improvement for state-of-the-art PLMs.

Does Dataset Lottery Ticket Hypothesis Exist?

Zhiqiang Shen,Eric Xing

Tuning hyperparameters and exploring the suitable training schemes for the self-supervised models are usually expensive and resource-consuming, especially on large-scale datasets like ImageNet-1K. Critically, this means only a few establishments (e.g., Google, Meta, etc.) have the ability to afford the heavy experiments on this task, which seriously hinders more engagement and better development of this area. An ideal situation is that there exists a subset from the full large-scale dataset, the subset can correctly reflect the performance distinction when performing different training frameworks, hyper-parameters, etc. This new training manner will substantially decrease resource requirements and improve the computational performance of ablations without compromising accuracy on the full dataset. We formulate this interesting problem as the dataset lottery ticket hypothesis and the target subsets as the winning tickets.

In this work, we analyze this problem through finding out partial empirical data on the class dimension that has a consistent {\em Empirical Risk Trend} as the full observed dataset. We also examine multiple solutions, including (i) a uniform selection scheme that has been widely used in literature; (ii) subsets by involving prior knowledge, for instance, using the sorted per-class performance of the strong supervised model to identify the desired subset, WordNet Tree on hierarchical semantic classes, etc., for generating the target winning tickets.

We verify this hypothesis on the self-supervised learning task across a variety of recent mainstream methods, such as MAE, DINO, MoCo-V1/V2, etc., with different backbones like ResNet and Vision Transformers. The supervised classification task is also examined as an extension. We conduct extensive experiments for training more than 2K self-supervised models on the large-scale ImageNet-1K and its subsets by 1.5M GPU hours, to scrupulously deliver our discoveries and demonstrate our conclusions. According to our experimental results, the winning tickets (subsets) that we find behave consistently to the original dataset, which generally can benefit many experimental studies and ablations, saving 10x of training time and resources for the hyperparameter tuning and other ablation studies.

Random Weight Factorization improves the training of Continuous Neural Representations

Sifan Wang,Hanwen Wang,Jacob H Seidman,Paris Perdikaris

Continuous neural representations have recently emerged as a powerful and flexible alternative to classical discretized representations of signals. However, training them to capture fine details in multi-scale signals is difficult and computationally expensive. Here we propose random weight factorization as a simple drop-in replacement for parameterizing and initializing conventional linear layers in coordinate-based multi-layer perceptrons (MLPs) that significantly accelerates and improves their training. We show how this factorization alters the underlying loss landscape and effectively enables each neuron in the network to learn using its own self-adaptive learning rate. This not only helps with mitigating spectral bias, but also allows networks to quickly recover from poor initializations and reach better local minima. We demonstrate how random weight factorizatio n can be leveraged to improve the training of neural representations on a variety of tasks, including image regression, shape representation, computed tomography, inverse rendering, solving partial differential equations, and learning operators between function spaces.

InPL: Pseudo-labeling the Inliers First for Imbalanced Semi-supervised Learning

Zhuoran Yu,Yin Li,Yong Jae Lee

Recent state-of-the-art methods in imbalanced semi-supervised learning (SSL) rely on confidence-based pseudo-labeling with consistency regularization. To obtain high-quality pseudo-labels, a high confidence threshold is typically adopted. However, it has been shown that softmax-based confidence scores in deep networks can be arbitrarily high for samples far from the training data, and thus, the pseudo-labels for even high-confidence unlabeled samples may still be unreliable. In this work, we present a new perspective of pseudo-labeling for imbalanced SSL. Without relying on model confidence, we propose to measure whether an unlabeled sample is likely to be "in-distribution''; i.e., close to the current training data. To decide whether an unlabeled sample is "in-distribution'' or "out-of-distribution'', we adopt the energy score from out-of-distribution detection literature. As training progresses and more unlabeled samples become in-distribution and contribute to training, the combined labeled and pseudo-labeled data can better approximate the true class distribution to improve the model. Experiments demonstrate that our energy-based pseudo-labeling method, InPL, albeit conceptually simple, significantly outperforms confidence-based methods on imbalanced SSL benchmarks. For example, it produces a 4-6% absolute accuracy improvement on CIFAR10-LT when the imbalance ratio is higher than 50. When combined with state-of-the-art long-tailed SSL methods, further improvements are attained. In particular, in one of the most challenging scenarios, InPL achieves a 6.9% accuracy improvement over the best competitor.

Mixed-Precision Inference Quantization: Problem Resetting, Mapping math concept and Branch\&bound methods

Daning Cheng

Based on the model's resilience to computational noise, model quantization is important for compressing models and improving computing speed. Existing quantization techniques rely heavily on experience and "fine-tuning" skills.   This study shows that in inference process, the mixed-precision quantization is a NP-hard problem and we designed a set of method to map mathematical method into pratical method. And our problem setting can be solved by branch and bound method with less computing resouces. We also show that how to set the quantization parameters in theorical method.

Latent Offline Distributional Actor-Critic

Félicien Hêche,BARAKAT Oussama,Thibaut P Desmettre,Tania Marx,Stephan Robert-Nicoud

Offline reinforcement learning (RL) has emerged as a promising paradigm for real world applications, since it aims to train policies directly from datasets of past interactions with the environment. The past few years, algorithms have been introduced to learn policies from high-dimensional observational states in an offline settings. The general idea of these methods is to encode the environment into a smaller latent space and train policies on the top of this smaller representation. In this paper, we extend this general method to stochastic environments (i.e. where the reward function is stochastic) and considering a risk measure instead of the classical expected return. First, we show that under some assumptions it is equivalent to minimize a risk measure in the latent space and in the natural space. Based on this result, we present Latent Offline Distributional Actor-Critic (LODAC), an algorithm which is able to train policies in high-dimensional stochastic and offline settings to minimize a given risk measure. Empirically, we show that using LODAC to minimize Conditional Value-at-Risk (CVaR), outperforms previous methods in term of CVaR and return on stochastic environments.

****

Mixed-Precision Inference Quantization: Radically Towards Faster inference speed, Lower Storage requirement, and Lower Loss

Daning Cheng

Model quantization is important for compressing models and improving computing speed. However, current researchers think that the loss function of quantizated model is usually higher than full precision model. This study provides a methodology for acquiring a mixed-precise quantization model with a lower loss than the full precision model. In addition, the analysis demonstrates that, throughout the inference process, the loss function is mostly affected by the noise of the layer inputs. In particular, we will demonstrate that neural networks with massive identity mappings are resistant to the quantization method. It is also difficult to improve the performance of these networks using quantization.

****

Leveraging Double Descent for Scientific Data Analysis: Face-Based Social Behavior as a Case Study

Christine H Lind,Angela J. Yu

Scientific data analysis often involves making use of a large number of correlated predictor variables to predict multiple response variables. Understanding how the predictor and response variables relate to one another, especially in the presence of relatively scarce data, is a common and challenging problem. Here, we leverage the recently popular concept of ``double descent'' to develop a particular treatment of the problem, including a set of key theoretical results. We also apply the proposed method to a novel experimental dataset consisting of human ratings of social traits and social decision making tendencies based on the facial features of strangers, and resolve a scientific debate regarding the existence of a ``beauty premium'' or ``attractiveness halo,'' which refers to a (presumed) advantage attractive people enjoy in social situations. We demonstrate that more attractive faces indeed enjoy a social advantage, but this is indirectly due to the facial features that contribute to both perceived attractiveness and trustworthiness, and that the component of attractiveness perception due to facial features (unrelated to trustworthiness) actually elicit a ``beauty penalty'', which has also been reported in the literature. Conversely, the facial features that contribute to trustworthiness and not to attractiveness still contribute positively to pro-social trait perception and decision making. Thus, what was previously thought to be an ``attractiveness halo'' is actually a ``trustworthiness halo'' plus a ``beauty penalty.'' Moreover, we see that the facial features that contribute to the ``trustworthiness halo' primarily have to do with how smiley a face is, while the facial features that contribute to attractiveness but actually acts as a ``beauty penalty'' is anti-correlated with age. In other words, youthfulness and smiley-ness both contribute to attractiveness, but only smiley-ness positively contributes to pro-social perception and decision making, while youthfulness actually negatively contribute to them. A further interesting wrinkle is that youthfulness as a whole does not negatively contribute to social traits/decision-making, only the component of youthfulness contributing to attractiveness does.

Maximizing Communication Efficiency for Large-scale Training via 0/1 Adam

Yucheng Lu,Conglong Li,Minjia Zhang,Christopher De Sa,Yuxiong He

1-bit gradient compression and local steps are two representative techniques that enable drastic communication reduction in distributed SGD. Their benefits, however, remain an open question on Adam-based large model pre-training (e.g. BERT and GPT). In this paper, we demonstrate the non-linearity in Adam causes slow convergence even when 1-bit compression or local steps are individually applied. To alleviate this limitation, we propose \textbf{0/1 Adam} that linearizes each Adam step via approximating its optimizer states using their stale estimates and linear correlation. \textbf{0/1 Adam} performs an Adam-like step to preserve the adaptivity, while its linearity allows utilizing 1-bit compression and local steps simultaneously for wall-clock time speed up. We provide convergence guarantee for \textbf{0/1 Adam} on smooth non-convex objectives. On various large-scale benchmarks such as BERT-Base, BERT-Large, GPT-2 pre-training and ImageNet, we demonstrate on up to 128 GPUs that \textbf{0/1 Adam} is able to reduce up to 87\% of data volume, 54\% of communication rounds, and achieve up to 2$\times$ higher training throughput and end-to-end training time reduction compared to the state-of-the-art baseline 1-bit Adam; while enjoying the same statistical convergence speed and end task model accuracy on GLUE dataset and ImageNet validation set.

****

Truthful Self-Play

Shohei Ohsawa

We present a general framework for evolutionary learning to emergent unbiased state representation without any supervision. Evolutionary frameworks such as self-play converge to bad local optima in case of multi-agent reinforcement learning in non-cooperative partially observable environments with communication due to information asymmetry. Our proposed framework is a simple modification of self-play inspired by mechanism design, also known as {\em reverse game theory}, to elicit truthful signals and make the agents cooperative. The key idea is to add imaginary rewards using the peer prediction method, i.e., a mechanism for evaluating the validity of information exchanged between agents in a decentralized environment. Numerical experiments with predator prey, traffic junction and StarCraft tasks demonstrate that the state-of-the-art performance of our framework.

****

Iterative α-(de)Blending: Learning a Deterministic Mapping Between Arbitrary Densities

Eric Heitz,Laurent Belcour,Thomas Chambon

We present a learning method that produces a mapping between arbitrary densities, such that random samples of a density can be mapped to random samples of another. In practice, our method is similar to deterministic diffusion processes where samples of the target density are blended with Gaussian noise. The originality of our approach is that, in contrast to several recent works, we do not rely on Langevin dynamics or score-matching concepts. We propose a simpler take on the topic, which is based solely on Bayes' theorem. By studying blended samples and their posteriors, we show that iteratively blending and deblending samples produces random paths between arbitrary densities. We prove that, for finite-variance densities, these paths converge towards a deterministic mapping that can be learnt with a neural network trained to deblend samples. Our method can thus be seen as a generalization of deterministic denoising diffusion where, instead of learning to denoise Gaussian noise, we learn to deblend arbitrary data.

****

Strategic Classification with Graph Neural Networks

Itay Eilat,Ben Finkelshtein,Chaim Baskin,Nir Rosenfeld

Strategic classification studies learning in settings where users can modify their features to obtain favorable predictions. Most current works focus on simple classifiers that trigger independent user responses. Here we examine the implications of learning with more elaborate models that break the independence assumption. Motivated by the idea that applications of strategic classification are often social in nature, we focus on graph neural networks, which make use of social relations between users to improve predictions. Using a graph for learning introduces inter-user dependencies in prediction; our key point is that strategic users can exploit these to promote their goals. As we show through analysis and simulation, this can work either against the system---or for it. Based on this, we propose a differentiable framework for strategically-robust learning of graph-based classifiers. Experiments on several real networked datasets demonstrate the utility of our approach.

****

Continual Transformers: Redundancy-Free Attention for Online Inference

Lukas Hedegaard,Arian Bakhtiarnia,Alexandros Iosifidis

Transformers in their common form are inherently limited to operate on whole token sequences rather than on one token at a time. Consequently, their use during online inference on time-series data entails considerable redundancy due to the overlap in successive token sequences. In this work, we propose novel formulations of the Scaled Dot-Product Attention, which enable Transformers to perform efficient online token-by-token inference on a continual input stream. Importantly, our modifications are purely to the order of computations, while the outputs and learned weights are identical to those of the original Transformer Encoder. We validate our Continual Transformer Encoder with experiments on the THUMOS14, TVSeries and GTZAN datasets with remarkable results: Our Continual one- and two-block architectures reduce the floating point operations per prediction by up to 63x and 2.6x, respectively, while retaining predictive performance.

****

FedPSE: Personalized Sparsification with Element-wise Aggregation for Federated Learning

Longfei Zheng,Yingting Liu,Xiaolong Xu,Chaochao Chen,Weipeng Sun,Xiaolong Hu,Lei Wang,Li Wang

Federated learning (FL) is a popular distributed machine learning framework in which clients aggregate models' parameters instead of sharing their individual data. In FL, clients communicate with the server under limited network bandwidth frequently, which arises the communication challenge. To resolve this challenge, multiple compression methods have been proposed to reduce the transmitted parameters. However, these techniques show that the federated performance degrades significantly with Non-IID (non-identically independently distributed) datasets. To address this issue, we propose an effective method, called FedPSE, which solves the efficiency challenge of FL with heterogeneous data. FedPSE compresses the local updates on clients using Top-K sparsification and aggregates these updates on the server by element-wise average. Then clients download the personalized sparse updates from the server to update their individual local models. We then theoretically analyze the convergence of FedPSE under the non-convex setting. Moreover, extensive experiments on four benchmark tasks demonstrate that our FedPSE outperforms the state-of-the-art methods on Non-IID datasets in terms of both efficiency and accuracy.

Towards Online Real-Time Memory-based Video Inpainting Transformers

Guillaume Thiry,Hao Tang,Radu Timofte,Luc Van Gool

Video inpainting tasks have seen significant improvements in the past years with the rise of deep neural networks and, in particular, vision transformers. Although these models show promising reconstruction quality and temporal consistency, they are still unsuitable for live videos, one of the last steps to make them completely convincing and usable. The main limitations are that these state-of-the-art models inpaint using the whole video (offline processing) and show an insufficient frame rate. In our approach, we propose a framework to adapt existing inpainting transformers to these constraints by memorizing and refining redundant computations while maintaining a decent inpainting quality. Using this framework with some of the most recent inpainting models, we show great online results with a consistent throughput above 20 frames per second. Code and pretrained models will be made available upon acceptance.

Edge-Varying Fourier Graph Network for Multivariate Time Series Forecasting

Kun Yi,Qi Zhang

The key problem in multivariate time series (MTS) analysis and forecasting aims to disclose the underlying couplings between variables that drive the co-movements. Considerable recent successful MTS methods are built with graph neural networks (GNNs) due to their essential capacity for relational modeling. However, previous work often used a static graph structure of time-series variables for modeling MTS failing to capture their ever-changing correlations over time. To this end, a fully-connected supra-graph connecting any two variables at any two timestamps is adaptively learned to capture the high-resolution variable dependencies via an efficient graph convolutional network. Specifically, we construct the Edge-Varying Fourier Graph Networks (EV-FGN) equipped with Fourier Graph Shift Operator (FGSO) which efficiently performs graph convolution in the frequency domain. As a result, a high-efficiency scale-free parameter learning scheme is derive d for MTS analysis and forecasting according to the convolution theorem. Extensive experiments show that EV-FGN outperforms state-of-the-art methods on seven real-world MTS datasets.

Learning Symbolic Models for Graph-structured Physical Mechanism
Hongzhi Shi,Jingtao Ding,Yufan Cao,quanming yao,Li Liu,Yong Li

Graph-structured physical mechanisms are ubiquitous in real-world scenarios, thus revealing underneath formulas is of great importance for scientific discovery. However, classical symbolic regression methods fail on this task since they can only handle input-output pairs that are not graph-structured. In this paper, we propose a new approach that generalizes symbolic regression to graph-structured physical mechanisms. The essence of our method is to model the formula skeleton with a message-passing flow, which helps transform the discovery of the skeleton into the search for the message-passing flow. Such a transformation guarantees that we are able to search a message-passing flow, which is efficient and Pareto-optimal in terms of both accuracy and simplicity. Subsequently, the underneath formulas can be identified by interpreting component functions of the searched message-passing flow, reusing classical symbolic regression methods. We conduct extensive experiments on datasets from different physical domains, including mechanics, electricity, and thermology, and on real-world datasets of pedestrian dynamics without ground-truth formulas. The experimental results not only verify the rationale of our design but also demonstrate that the proposed method can automatically learn precise and interpretable formulas for graph-structured physical mechanisms.

Unleashing Mask: Explore the Intrinsic Out-of-distribution Detection Capability
Jianing Zhu,Hengzhuang Li,Jiangchao Yao,Tongliang Liu,Jianliang Xu,Bo Han

Out-of-distribution (OOD) detection is an important aspect for safely deploying machine learning models in real-world applications. Previous approaches either design better scoring functions or utilize the knowledge from unknown outliers to equip the well-trained models with the ability of OOD detection. However, few of them explore to excavate the intrinsic OOD detection capability of a given model. In this work, we discover the existence of an intermediate stage of a model trained on in-distribution data having higher OOD detection performance than that of its final stage across different settings, and further identify the critical attribution to be learning with atypical samples. Based on such empirical insights, we propose a new method, Unleashing Mask (UM), to reveal the once-covered detection capability of a given model. To be specific, we utilize the mask to figure out the memorized atypical samples and fine-tune the model to forget them. Extensive experiments have been conducted to characterize and verify the effectiveness of our method.

****

Dirichlet-based Uncertainty Calibration for Active Domain Adaptation
Mixue Xie,Shuang Li,Rui Zhang,Chi Harold Liu

Active domain adaptation (DA) aims to maximally boost the model adaptation on a new target domain by actively selecting limited target data to annotate, whereas traditional active learning methods may be less effective since they do not consider the domain shift issue. Despite active DA methods address this by further proposing targetness to measure the representativeness of target domain characteristics, their predictive uncertainty is usually based on the prediction of deterministic models, which can easily be miscalibrated on data with distribution shift. Considering this, we propose a Dirichlet-based Uncertainty Calibration (DUC) approach for active DA, which simultaneously achieves the mitigation of miscalibration and the selection of informative target samples. Specifically, we place a Dirichlet prior on the prediction and interpret the prediction as a distribution on the probability simplex, rather than a point estimate like deterministic models. This manner enables us to consider all possible predictions, mitigating the miscalibration of unilateral prediction. Then a two-round selection strategy based on different uncertainty origins is designed to select target samples that are both representative of target domain and conducive to discriminability. Ex tensive experiments on cross-domain image classification and semantic segmentation validate the superiority of DUC.

****

Accurate Image Restoration with Attention Retractable Transformer

Jiale Zhang,Yulun Zhang,Jinjin Gu,Yongbing Zhang,Linghe Kong,Xin Yuan

Recently, Transformer-based image restoration networks have achieved promising improvements over convolutional neural networks due to parameter-independent global interactions. To lower computational cost, existing works generally limit self-attention computation within non-overlapping windows. However, each group of tokens are always from a dense area of the image. This is considered as a dense attention strategy since the interactions of tokens are restrained in dense regions. Obviously, this strategy could result in restricted receptive fields. To address this issue, we propose \textbf{A}ttention \textbf{R}etractable \textbf{T}ransformer (ART) for image restoration, which presents both dense and sparse attention modules in the network. The sparse attention module allows tokens from sparse areas to interact and thus provides a wider receptive field. Furthermore, the alternating application of dense and sparse attention modules greatly enhances representation ability of Transformer while providing retractable attention on the input image.We conduct extensive experiments on image super-resolution, denoising, and JPEG compression artifact reduction tasks. Experimental results validate that our proposed ART outperforms state-of-the-art methods on various benchmark datasets both quantitatively and visually. We also provide code and models at~\url{https://github.com/gladzhang/ART}.

****

Adan: Adaptive Nesterov Momentum Algorithm for Faster Optimizing Deep Models

Xingyu Xie,Pan Zhou,Huan Li,Zhouchen Lin,Shuicheng YAN

Adaptive gradient algorithms combine the moving average idea with heavy ball acceleration to estimate accurate first- and second-order moments of the gradient for accelerating convergence. However, Nesterov acceleration which converges faster than heavy ball acceleration in theory and also in many empirical cases, is much less investigated under the adaptive gradient setting. In this work, we propose the ADAptive Nesterov momentum algorithm, Adan for short, to speed up the training of deep neural networks effectively. Adan first reformulates the vanilla Nesterov acceleration to develop a new Nesterov momentum estimation (NME) method, which avoids the extra computation and memory overhead of computing gradient at the extrapolation point. Then Adan adopts NME to estimate the first- and second-order moments of the gradient in adaptive gradient algorithms for convergence acceleration. Besides, we prove that Adan finds an ϵ-approximate first-order stationary point within $O(\epsilon^{-3.5})$ stochastic gradient complexity on the non-convex stochastic problems (e.g., deep learning problems), matching the best-known lower bound. Extensive experimental results show that Adan surpasses the corresponding SoTA optimizers on vision, language, and RL tasks and sets new SoTAs for many popular networks and frameworks, e.g., ResNet, ConvNext, ViT, Swin, MAE, LSTM, Transformer-XL, and BERT. More surprisingly, Adan can use half of the training cost (epochs) of SoTA optimizers to achieve higher or comparable performance on ViT, ResNet, MAE, etc., and also shows great tolerance to a large range of minibatch size, e.g., from 1k to 32k. We hope Adan can contribute to developing deep learning by reducing training costs and relieving the engineering burden of trying different optimizers on various architectures.

Efficient Trojan Injection: 90% Attack Success Rate Using 0.04% Poisoned Samples

Pengfei Xia,Yueqi Zeng,Ziqiang Li,Wei Zhang,Bin Li

This study focuses on reducing the number of poisoned samples needed when backdooring an image classifier. We present Efficient Trojan Injection (ETI), a pipeline that significantly improves the poisoning efficiency through trigger design, sample selection, and the exploitation of individual consistency. Using ETI, two backdoored datasets, CIFAR-10-B0-20 and CIFAR-100-B0-30, are constructed and released, in which 0.04% (20/50,000) and 0.06% (30/50,000) of the train images are poisoned. Across 240 models with different network architectures and training hyperparameters, the average attack success rates on these two sets are 92.1% and

90.4%, respectively. These results indicate that it is feasible to inject a Trojan into an image classifier with only a few tens of poisoned samples, which is about an order of magnitude less than before.

Priors, Hierarchy, and Information Asymmetry for Skill Transfer in Reinforcement Learning

Sasha Salter,Kristian Hartikainen,Walter Goodwin,Ingmar Posner

The ability to discover behaviours from past experience and transfer them to new tasks is a hallmark of intelligent agents acting sample-efficiently in the real world. Equipping embodied reinforcement learners with the same ability may be crucial for their successful deployment in robotics. While hierarchical and KL-regularized reinforcement learning individually hold promise here, arguably a hybrid approach could combine their respective benefits. Key to these fields is the use of information asymmetry across architectural modules to bias which skills are learnt. While asymmetry choice has a large influence on transferability, existing methods base their choice primarily on intuition in a domain-independent, potentially sub-optimal, manner. In this paper, we theoretically and empirically show the crucial expressivity-transferability trade-off of skills across sequential tasks, controlled by information asymmetry. Given this insight, we introduce Attentive Priors for Expressive and Transferable Skills (APES), a hierarchical KL-regularized method, heavily benefiting from both priors and hierarchy. Unlike existing approaches, APES automates the choice of asymmetry by learning it in a data-driven, domain-dependent, way based on our expressivity-transferability theorems. Experiments over complex transfer domains of varying levels of extrapolation and sparsity, such as robot block stacking, demonstrate the criticality of the correct asymmetric choice, with APES drastically outperforming previous methods.

Self-Supervised Set Representation Learning for Unsupervised Meta-Learning

Dong Bok Lee,Seanie Lee,Kenji Kawaguchi,Yunji Kim,Jihwan Bang,Jung-Woo Ha,Sung Ju Hwang

Unsupervised meta-learning (UML) essentially shares the spirit of self-supervised learning (SSL) in that their goal aims at learning models without any human supervision so that the models can be adapted to downstream tasks. Further, the learning objective of self-supervised learning, which pulls positive pairs closer and repels negative pairs, also resembles metric-based meta-learning. Metric-based meta-learning is one of the most successful meta-learning methods, which learns to minimize the distance between representations from the same class.

One notable aspect of metric-based meta-learning, however, is that it is widely interpreted as a set-level problem since the inference of discriminative class prototypes (or set representations) from few examples is crucial for the performance of downstream tasks. Motivated by this, we propose Set-SimCLR, a novel self-supervised set representation learning framework for targeting UML problem. Specifically, our Set-SimCLR learns a set encoder on top of instance representations to maximize the agreement between two sets of augmented samples, which are generated by applying stochastic augmentations to a given image. We theoretically analyze how our proposed set representation learning can potentially improve the generalization performance at the meta-test. We also empirically validate its effectiveness on various benchmark datasets, showing that Set-SimCLR largely outperforms both UML and instance-level self-supervised learning baselines.

Neural Episodic Control with State Abstraction

Zhuo Li,Derui Zhu,Yujing Hu,Xiaofei Xie,Lei Ma,YAN ZHENG,Yan Song,Yingfeng Chen,Jianjun Zhao

Existing Deep Reinforcement Learning (DRL) algorithms suffer from sample inefficiency. Generally, episodic control-based approaches are solutions that leverage highly rewarded past experiences to improve sample efficiency of DRL algorithms. However, previous episodic control-based approaches fail to utilize the latent information from the historical behaviors (\eg, state transitions, topological similarities, \etc) and lack scalability during DRL training. This work introduce s Neural Episodic Control with State Abstraction (NECSA), a simple but effective state abstraction-based episodic control containing a more comprehensive episodic memory, a novel state evaluation, and a multi-step state analysis. We evaluate our approach to the MuJoCo and Atari tasks in OpenAI gym domains. The experimental results indicate that NECSA achieves higher sample efficiency than the state-of-the-art episodic control-based approaches. Our data and code are available at the project website\footnote{\url{https://sites.google.com/view/drl-necsa}}.

Minibatch Stochastic Three Points Method for Unconstrained Smooth Minimization
Soumia Boucherouite,Grigory Malinovsky,Peter Richtárik,El houcine Bergou
In this paper, we propose a new zero order optimization method called minibatch stochastic three points (MiSTP) method to solve an unconstrained minimization problem in a setting where only an approximation of the objective function evaluation is possible. It is based on the recently proposed stochastic three points (STP) method (Bergou et al., 2020). At each iteration, MiSTP generates a random search direction in a similar manner to STP, but chooses the next iterate based solely on the approximation of the objective function rather than its exact evaluations. We also analyze our method’s complexity in the nonconvex and convex cases and evaluate its performance on multiple machine learning tasks.

Multigraph Topology Design for Cross-Silo Federated Learning
Tuong Khanh Long Do,Binh Xuan Nguyen,Toan Tran,Erman Tjiputra,Quang D. Tran,Hien Nguyen,Vuong Pham,Anh Nguyen
Cross-silo federated learning utilizes a few hundred reliable data silos with high-speed access links to jointly train a model. While this approach becomes a popular setting in federated learning, designing a robust topology to reduce the training time is still an open problem.

In this paper, we present a new multigraph topology for cross-silo federated learning. We first construct the multigraph using the overlay graph. We then parse this multigraph into different simple graphs with isolated nodes. The existence of isolated nodes allows us to perform model aggregation without waiting for other nodes, hence reducing the training time. We further propose a new distributed learning algorithm to use with our multigraph topology. The intensive experiments on public datasets show that our proposed method significantly reduces the training time compared with recent state-of-the-art topologies while ensuring convergence and maintaining the accuracy.

Universal Speech Enhancement with Score-based Diffusion
Joan Serrà,Santiago Pascual,Jordi Pons,Recep Oguz Araz,Davide Scaini
Removing background noise from speech audio has been the subject of considerable effort, especially in recent years due to the rise of virtual communication and amateur recordings. Yet background noise is not the only unpleasant disturbance that can prevent intelligibility: reverb, clipping, codec artifacts, problematic equalization, limited bandwidth, or inconsistent loudness are equally disturbing and ubiquitous. In this work, we propose to consider the task of speech enhancement as a holistic endeavor, and present a universal speech enhancement system that tackles 55 different distortions at the same time. Our approach consists of a generative model that employs score-based diffusion, together with a multi-resolution conditioning network that performs enhancement with mixture density networks. We show that this approach significantly outperforms the state of the art in a subjective test performed by expert listeners. We also show that it achieves competitive objective scores with just 4-8 diffusion steps, despite not considering any particular strategy for fast sampling. We hope that both our methodology and technical contributions encourage researchers and practitioners to adopt a universal approach to speech enhancement, possibly framing it as a generative task.

Partial Advantage Estimator for Proximal Policy Optimization
Xiulei Song,Yizhao Jin,Gregory Slabaugh,Simon Lucas
Estimation of value in policy gradient methods is a fundamental problem. General

ized Advantage Estimation (GAE) is an exponentially-weighted estimator of an advantage function similar to TD(λ). It substantially reduces the variance of policy gradient estimates at the expense of bias. In practical applications, a truncated GAE is used due to the incompleteness of the trajectory, which results in a large bias during estimation. To address this challenge, instead of using the all truncated GAE, we propose to take a part of the calculated GAE for updates, which significantly reduces the bias due to the incomplete trajectory. We perform experiments in MuJoCo and μRTS to investigate the effect of different partial coefficient and sampling lengths. We show that our partial GAE approach yields better empirical results in both environments.

Critical Sampling for Robust Evolution Behavior Learning of Unknown Dynamical Systems

Ce Zhang,Siqi Wu,Kailiang Wu,Zhihai He

We study the following new and important problem: given an unknown dynamical system, what is the minimum number of samples needed for effective learning of its governing laws and accurate prediction of its future evolution behavior, and how to select these critical samples? In this work, we propose to explore this problem based on a design approach. Specifically, starting from a small initial set of samples, we adaptively discover and collect critical samples to achieve increasingly accurate learning of the system evolution. One central challenge here is that we do not know the network modeling error of the ground-truth system state, which is however needed for critical sampling. To address this challenge, we introduce a multi-step reciprocal prediction network where a forward evolution network and a backward evolution network are designed to learn and predict the temporal evolution behavior in the forward and backward time directions, respectively. Very interestingly, we find that the desired network modeling error is highly correlated with the multi-step reciprocal prediction error. More importantly, this multi-step reciprocal prediction error can be directly computed from the current system state without knowing the ground-truth or data statistics. This allows us to perform dynamic selection of critical samples from regions with high network modeling errors and develop an adaptive sampling-learning method for dynamical systems. To achieve accurate and robust learning from this small set of critical samples, we introduce a joint spatial-temporal evolution network which incorporates spatial dynamics modeling into the temporal evolution prediction for robust learning of the system evolution operator with few samples. Our extensive experimental results demonstrate that our proposed method is able to dramatically reduce the numbers of samples needed for effective learning and accurate prediction of evolution behaviors of unknown dynamical systems by up to hundreds of times, especially for high-dimensional dynamical systems.

Causal Representation Learning for Instantaneous and Temporal Effects in Interactive Systems

Phillip Lippe,Sara Magliacane,Sindy Löwe,Yuki M Asano,Taco Cohen,Efstratios Gavves

Causal representation learning is the task of identifying the underlying causal variables and their relations from high-dimensional observations, such as images. Recent work has shown that one can reconstruct the causal variables from temporal sequences of observations under the assumption that there are no instantaneous causal relations between them. In practical applications, however, our measurement or frame rate might be slower than many of the causal effects. This effectively creates ``instantaneous'' effects and invalidates previous identifiability results. To address this issue, we propose iCITRIS, a causal representation learning method that allows for instantaneous effects in intervened temporal sequences when intervention targets can be observed, e.g., as actions of an agent. iCITRIS identifies the potentially multidimensional causal variables from temporal observations, while simultaneously using a differentiable causal discovery method to learn their causal graph. In experiments on three datasets of interactive systems, iCITRIS accurately identifies the causal variables and their causal graph.

Visual Imitation Learning with Patch Rewards

Minghuan Liu,Tairan He,Weinan Zhang,Shuicheng YAN,Zhongwen Xu

Visual imitation learning enables reinforcement learning agents to learn to behave from expert visual demonstrations such as videos or image sequences, without explicit, well-defined rewards.

Previous reseaches either adopt supervised learning techniques or induce simple and coarse scalar rewards from pixels, neglecting the dense information contained in the image demonstrations.

In this work, we propose to measure the expertise of various local regions of image samples, or called patches, and recover multi-dimensional patch rewards accordingly.

Patch reward is a more precise rewarding characterization that serves as fine-grained expertise measurement and visual explainability tool.

Specifically, we present Adversarial Imitation Learning with Patch Rewards (PatchAIL), which employs a patch-based discriminator to measure the expertise of different local parts from given images and provide patch rewards.

The patch-based knowledge is also used to regularize the aggregated reward and stabilize the training.

We evaluate our method on the standard pixel-based benchmark DeepMind Control Suite.

The experiment results have demonstrated that PatchAIL outperforms baseline methods and provides valuable interpretations for visual demonstrations.

Planning Immediate Landmarks of Targets for Model-Free Skill Transfer across Agents

Minghuan Liu,Zhengbang Zhu,Menghui Zhu,Yuzheng Zhuang,Weinan Zhang,Jianye HAO

In reinforcement learning applications, agents usually need to deal with various input/output features when specified with different state and action spaces by their developers or physical restrictions, indicating re-training from scratch and considerable sample inefficiency, especially when agents follow similar solution steps to achieve tasks.

In this paper, we aim to transfer pre-trained skills to alleviate the above challenge. Specifically, we propose PILoT, i.e., Planning Immediate Landmarks of Targets. PILoT utilizes the universal decoupled policy optimization to learn a goal-conditioned state planner; then, we distill a goal-planner to plan immediate landmarks in a model-free style that can be shared among different agents. In our experiments, we show the power of PILoT on various transferring challenges, including few-shot transferring across action spaces and dynamics, from low-dimensional vector states to image inputs, from simple robot to complicated morphology; and we also illustrate PILoT provides a zero-shot transfer solution from a simple 2D navigation task to the harder Ant-Maze task.

AdaDQH Optimizer: Evolving from Stochastic to Adaptive by Auto Switch of Precondition Matrix

Yun Yue,Zhiling Ye,Jiadi Jiang,Yongchao Liu,Ke Zhang

Adaptive optimizers (e.g., Adam) have achieved tremendous success in deep learning. The key component of the optimizer is the precondition matrix, which provides more gradient information and adjusts the step size of each gradient direction. Intuitively, the closer the precondition matrix approximates the Hessian, the faster convergence and better generalization the optimizer can achieve in terms of iterations. However, this performance improvement is usually accompanied by a huge increase in the amount of computation. In this paper, we propose a new optimizer called AdaDQH to achieve better generalization with acceptable computational overhead. The intuitions are the trade-off of the precondition matrix between computation time and approximation of Hessian, and the auto switch of the precondition matrix from Stochastic Gradient Descent (SGD) to the adaptive optimizer. We evaluate AdaDQH on public datasets of Computer Vision (CV), Natural Language Processing (NLP) and Recommendation Systems (RecSys). The experimental results reveal that, compared to the State-Of-The-Art (SOTA) optimizers, AdaDQH can ach ieve significantly better or highly competitive performance. Furthermore, we analyze how AdaDQH is able to auto switch from stochastic to adaptive and the actual effects in different scenes. The code is available in the supplemental material.

CodeT: Code Generation with Generated Tests

Bei Chen,Fengji Zhang,Anh Nguyen,Daoguang Zan,Zeqi Lin,Jian-Guang Lou,Weizhu Chen

The task of generating code solutions for a given programming problem can benefit from the use of pre-trained language models such as Codex, which can produce multiple diverse samples. However, a major challenge for this task is to select the most appropriate solution from the multiple samples generated by the pre-trained language models. A natural way to evaluate the quality and correctness of a code solution is to run it against a set of test cases, but the manual creation of such test cases is often costly and time-consuming. In this paper, we propose a novel method, CodeT, that leverages the same pre-trained language models to automatically generate test cases for the code samples, thus reducing the human effort and increasing the coverage of the test scenarios. CodeT then executes the code samples using the generated test cases, and performs a dual execution agreement, which considers both the consistency of the outputs against the generated test cases and the agreement of the outputs with other code samples. We conduct comprehensive experiments on four benchmarks, HumanEval, MBPP, APPS and CodeContests, using five different pre-trained language models with varying sizes and capabilities. Our results show that CodeT can significantly improve the performance of code solution selection over previous methods, achieving remarkable and consistent gains across different models and benchmarks. For instance, CodeT improves the pass@1 metric on HumanEval to 65.8%, which represents an absolute improvement of 18.8% over the code-davinci-002 model, and an absolute improvement of more than 20% over the previous state-of-the-art results.

Learning Specialized Activation Functions for Physics-informed Neural Networks

Honghui Wang,Lu Lu,Shiji Song,Gao Huang

At the heart of network architectures lie the non-linear activation functions, the choice of which affects the model optimization and task performance. In computer vision and natural language processing, the Rectified Linear Unit is widely adopted across different tasks. However, there is no such default choice of activation functions in the context of physics-informed neural networks (PINNs). It is observed that PINNs exhibit high sensitivity to activation functions due to the various characteristics of each physics system, which makes the choice of the suitable activation function for PINNs a critical issue. Existing works usually choose activation functions in an inefficient trial-and-error manner. To address this problem, we propose to search automatically for the optimal activation function when solving different PDEs. This is achieved by learning an adaptive activation function as linear combinations of a set of candidate functions, whose coefficients can be directly optimized by gradient descent. In addition to its efficient optimization, the proposed method enables the discovery of novel activation function and the incorporation with prior knowledge about the PDE system. We can further enhance its search space with adaptive slope. The effectiveness of the proposed adaptive activation function is demonstrated on a series of benchmarks, including the Poisson's equation, Burgers' equation, Allen-Cahn equation, convection equation, Korteweg–de Vries equation and Cahn-Hilliard equation. The performance gain of the proposed method is further interpreted from the neural tangent kernel perspective. Code will be released.

Dateformer: Transformer Extends Look-back Horizon to Predict Longer-term Time Series

Julong Young,Junhui Chen,Feihu Huang,Jian Peng

Transformers have demonstrated impressive strength in long-term series forecasting. Existing prediction research mostly focused on mapping past short sub-series (lookback window) to future series (forecast window). The longer training datas et time series will be discarded, once training is completed. Models can merely rely on lookback window information for inference, which impedes models from analyzing time series from a global perspective. And these windows used by Transformers are quite narrow because they must model each time-step therein. Under this point-wise processing style, broadening windows will rapidly exhaust their model capacity. This, for fine-grained time series, leads to a bottleneck in information input and prediction output, which is mortal to long-term series forecasting. To overcome the barrier, we propose a brand-new methodology to use Transformer for time series prediction. Specifically, we split time series into patches by day and reform point-wise to patch-wise processing, which considerably enhances the information input and output of Transformers. To further help models leverage the whole training set's global information during inference, we distill the information, store it in time representations, and replace series with time representations as the main modeling entities. Our designed time-modeling Transformer---Dateformer yields state-of-the-art accuracy on 7 real-world datasets with a 33.6% relative improvement and extends the maximum forecast range to half-year.

****

CAMVR: Context-Adaptive Multi-View Representation Learning for Dense Retrieval

zhilin liao,XIANGTING HOU,Dongfang Lou,Ningyu Zhang,Huajun Chen

The recently proposed MVR (Multi-View Representation) model achieves remarkable performance in open-domain dense retrieval. In MVR, the document can match with multi-view queries by encoding the document into multiple representations. However, these representations tend to collapse into the same one when the percentage of documents answering multiple queries in training data is low. In this paper, we propose a CAMVR (Context-Adaptive Multi-View Representation) learning framework, which explicitly avoids the collapse problem by aligning each viewer token with different document snippets. In CAMVR, each viewer token is placed before each snippet to capture the local and global information with the consideration that answers of different view queries may scatter in one document. In addition, the view of the snippet containing the answer is used to explicitly supervise the learning process, from which the interpretability of view representation is provided. The extensive experiments show that CAMVR outperforms the existing models and achieves state-of-the-art results.

****

BIL: Bandit Inference Learning for Online Representational Similarity Test

Xiaoting Ji,Shuoxun Xu,Wenhai Cui,Linglong Kong,Xiaodong Yan

Similarity analysis is commonly used to determine the size of the discrepancy between two representations of a distribution pattern. In contrast to classical representational similarity analysis, which identifies disparate types of representations based on their shared similarity structures in distance matrices, this article proposes an online hypothesis testing procedure that will be able to determine whether a representation's difference from a constant is more significant than a predefined margin for streaming data. As a basic reinforcement learning model, two-armed bandits (TAB) are used to construct test statistics that update online. To achieve the most efficient testing results, an optimal strategy is developed for the TAB process. Asymptotic test statistics are discussed in theory, as are its corresponding explicit density functions, which are more accumulated than the normal distribution commonly applied in classical statistical analysis. Since the power of the proposed representative similarity test (RST) method is higher than that of the classical test, simulation studies support the validity of the proposed method.

Adam Accumulation to Reduce Memory Footprints of both Activations and Gradients for Large-scale DNN Training

Yijia Zhang,Yibo Han,Shijie Cao,Guohao Dai,Youshan Miao,Ting Cao,Fan Yang,Ningyi Xu

Running out of GPU memory has become a main bottleneck for large-scale DNN training. How to reduce the memory footprint during training has received intensive research attention. We find that previous gradient accumulation reduces activation memory but fails to be compatible with gradient memory reduction due to a cont radiction between preserving gradients and releasing gradients. To address this issue, we propose a novel optimizer accumulation method for Adam, named Adam Accumulation (AdamA), which enables reducing both activation and gradient memory. Specifically, AdamA directly integrates gradients into optimizer states and accumulates optimizer states over micro-batches, so that gradients can be released immediately after use. We mathematically and experimentally demonstrate AdamA yields the same convergence properties as Adam. Evaluated on transformer-based models, AdamA achieves up to 23% memory reduction compared to gradient accumulation with less than 2% degradation in training throughput. Notably, AdamA can work together with memory reduction methods for optimizer states to fit 1.26x~3.14x larger models over PyTorch and DeepSpeed baseline on GPUs with different memory capacities.

Learning to Generate Columns with Application to Vertex Coloring

Yuan Sun,Andreas T Ernst,Xiaodong Li,Jake Weiner

We present a new column generation approach based on Machine Learning (ML) for solving combinatorial optimization problems. The aim of our method is to generate high-quality columns that belong to an optimal integer solution, in contrast to the traditional approach that aims at solving linear programming relaxations. To achieve this aim, we design novel features to characterize a column, and develop an effective ML model to predict whether a column belongs to an optimal integer solution. We then use the ML model as a filter to select high-quality columns generated from a sampling method and use the selected columns to construct an integer solution. Our method is computationally fast compared to the traditional methods that generate columns by repeatedly solving a pricing problem. We demonstrate the efficacy of our method on the vertex coloring problem, by empirically showing that the columns selected by our ML model are significantly better, in terms of the integer solution that can be constructed from them, than those selected randomly or based only on their reduced cost. Further, we show that the columns generated by our method can be used as a warm start to boost the performance of a column generation-based heuristic.

TPC-NAS: Sub-Five-Minute Neural Architecture Search for Image Classification, Object-Detection, and Super-Resolution

Ming-shan Huang,Tzi-Dar Chiueh

Neural network models have become more sophisticated with the explosive development of AI and its applications. Automating the model search process is essential to explore a full range of neural architectures for satisfactory performance. However, most current NAS algorithms consume significant time and computing resources, and many cater only to image classification applications. This paper proposes the total path count (TPC) score, which requires only simple calculation based on the architecture information, as an efficient accuracy predictor. TPC score is not only simple to come by but also very effective. The Kendall rank correlation coefficient of the TPC scores and the accuracies of 20 architectures for the CIFAR100 problem is as high as 0.87. This paper also proposes TPC-NAS, a zero-shot NAS method leveraging the novel TPC score. TPC-NAS requires no training and inference, and can complete a NAS task for Imagenet and other vision applications in less than five CPU minutes. Then, we apply TPC-NAS to image classification, object detection, and super-resolution applications for further validation. In image classification, TPC-NAS finds an architecture that achieves 76.4% top-1 accuracy in ImageNet with 355M FLOPs, outperforming other NAS solutions. Starting with yolov4-p5, TPC-NAS comes up with a high-performance model with at least 2% mAP improvement over other NAS algorithms’ results in object detection. Finally, in the super-resolution application, TPC-NAS discovers a model with fewer than 300K parameters and generates images with 32.09dB PSNR in the Urban100 dataset. These three experiments convince us that the TPC-NAS method can swiftly deliver high-quality CNN architectures in diverse applications. The related source code is available at https://github.com/TPC-NAS/TPC.

The Role of ImageNet Classes in Fréchet Inception Distance

Tuomas Kynkäänniemi,Tero Karras,Miika Aittala,Timo Aila,Jaakko Lehtinen

Fréchet Inception Distance (FID) is the primary metric for ranking models in data-driven generative modeling. While remarkably successful, the metric is known to sometimes disagree with human judgement. We investigate a root cause of these discrepancies, and visualize what FID "looks at" in generated images. We show that the feature space that FID is (typically) computed in is so close to the ImageNet classifications that aligning the histograms of Top-N classifications between sets of generated and real images can reduce FID substantially — without actually improving the quality of results. Thus, we conclude that FID is prone to intentional or accidental distortions. As a practical example of an accidental distortion, we discuss a case where an ImageNet pre-trained FastGAN achieves a FID comparable to StyleGAN2, while being worse in terms of human evaluation.

****

Diffusion Models Already Have A Semantic Latent Space

Mingi Kwon,Jaeseok Jeong,Youngjung Uh

Diffusion models achieve outstanding generative performance in various domains. Despite their great success, they lack semantic latent space which is essential for controlling the generative process. To address the problem, we propose asymmetric reverse process (Asyrp) which discovers the semantic latent space in frozen pretrained diffusion models. Our semantic latent space, named h-space, has nice properties for accommodating semantic image manipulation: homogeneity, linearity, robustness, and consistency across timesteps. In addition, we measure editing strength and quality deficiency of a generative process at timesteps to provide a principled design of the process for versatility and quality improvements. Our method is applicable to various architectures (DDPM++, iDDPM, and ADM) and datasets (CelebA-HQ, AFHQ-dog, LSUN-church, LSUN-bedroom, and METFACES).

****

Improving group robustness under noisy labels using predictive uncertainty

Dongpin Oh,Dae Lee,Jeunghyun Byun,Bonggun Shin

The standard empirical risk minimization (ERM) can underperform on certain minority groups (i.e., waterbirds in lands or landbirds in water) due to the spurious correlation between the input and its label. Several studies have improved the worst-group accuracy by focusing on the high-loss samples. The hypothesis behind this is that such high-loss samples are spurious-cue-free (SCF) samples. However, these approaches can be problematic since the high-loss samples may also be samples with noisy labels in the real-world scenarios. To resolve this issue, we utilize the predictive uncertainty of a model to improve the worst-group accuracy under noisy labels. To motivate this, we theoretically show that the high-uncertainty samples are the SCF samples in the binary classification problem. This theoretical result implies that the predictive uncertainty is an adequate indicator to identify SCF samples in a noisy label setting. Motivated from this, we propose a novel Entropy based Debiasing (END) framework that prevents models from learning the spurious cues while being robust to the noisy labels. In the END framework, we first train the \textit{identification model} to obtain the SCF samples from a training set using its predictive uncertainty. Then, another model is trained on the dataset augmented with an oversampled SCF set. The experimental results show that our END framework outperforms other strong baselines on several real-world benchmarks that consider both the noisy labels and the spurious-cues.

Mutual Information Regularized Offline Reinforcement Learning

Xiao Ma,Bingyi Kang,Zhongwen Xu,Min Lin,Shuicheng YAN

Offline reinforcement learning (RL) aims at learning an effective policy from offline datasets without active interactions with the environment. The major challenge of offline RL is the distribution shift that appears when out-of-distribution actions are queried, which makes the policy improvement direction biased by extrapolation errors. Most existing methods address this problem by penalizing the policy for deviating from the behavior policy during policy improvement or making conservative updates for value functions during policy evaluation. In this work, we propose a novel MISA framework to approach offline RL from the perspecti

ve of Mutual Information between States and Actions in the dataset by directly constraining the policy improvement direction. Intuitively, mutual information measures the mutual dependence of actions and states, which reflects how a behavior agent reacts to certain environment states during data collection. To effectively utilize this information to facilitate policy learning, MISA constructs lower bounds of mutual information parameterized by the policy and Q-values. We show that optimizing this lower bound is equivalent to maximizing the likelihood of a one-step improved policy on the offline dataset. In this way, we constrain the policy improvement direction to lie in the data manifold. The resulting algorithm simultaneously augments the policy evaluation and improvement by adding a mutual information regularization. MISA is a general offline RL framework that unifies conservative Q-learning (CQL) and behavior regularization methods (e.g., TD3+BC) as special cases. Our experiments show that MISA performs significantly better than existing methods and achieves new state-of-the-art on various tasks of the D4RL benchmark.
****
EVC: Towards Real-Time Neural Image Compression with Mask Decay
Wang Guo-Hua,Jiahao Li,Bin Li,Yan Lu
Neural image compression has surpassed state-of-the-art traditional codecs (H.266/VVC) for rate-distortion (RD) performance, but suffers from large complexity and separate models for different rate-distortion trade-offs. In this paper, we propose an Efficient single-model Variable-bit-rate Codec (EVC), which is able to run at 30 FPS with 768x512 input images and still outperforms VVC for the RD performance. By further reducing both encoder and decoder complexities, our small model even achieves 30 FPS with 1920x1080 input images. To bridge the performance gap between our different capacities models, we meticulously design the mask decay, which transforms the large model's parameters into the small model automatically. And a novel sparsity regularization loss is proposed to mitigate shortcomings of L_p regularization. Our algorithm significantly narrows the performance gap by 50% and 30% for our medium and small models, respectively. At last, we advocate the scalable encoder for neural image compression. The encoding complexity is dynamic to meet different latency requirements. We propose decaying the large encoder multiple times to reduce the residual representation progressively. Both mask decay and residual representation learning greatly improve the RD performance of our scalable encoder. Our code is at https://github.com/microsoft/DCVC.
****
Zero-Shot Image Restoration Using Denoising Diffusion Null-Space Model
Yinhuai Wang,Jiwen Yu,Jian Zhang
Most existing Image Restoration (IR) models are task-specific, which can not be generalized to different degradation operators. In this work, we propose the Denoising Diffusion Null-Space Model (DDNM), a novel zero-shot framework for arbitrary linear IR problems, including but not limited to image super-resolution, colorization, inpainting, compressed sensing, and deblurring. DDNM only needs a pre-trained off-the-shelf diffusion model as the generative prior, without any extra training or network modifications. By refining only the null-space contents during the reverse diffusion process, we can yield diverse results satisfying both data consistency and realness. We further propose an enhanced and robust version, dubbed DDNM+, to support noisy restoration and improve restoration quality for hard tasks. Our experiments on several IR tasks reveal that DDNM outperforms other state-of-the-art zero-shot IR methods. We also demonstrate that DDNM+ can solve complex real-world applications, e.g., old photo restoration.
****
Predicting Cellular Responses with Variational Causal Inference and Refined Relational Information
Yulun Wu,Rob Barton,Zichen Wang,Vassilis N. Ioannidis,Carlo De Donno,Layne C Price,Luis F. Voloch,George Karypis
Predicting the responses of a cell under perturbations may bring important benefits to drug discovery and personalized therapeutics. In this work, we propose a novel graph variational Bayesian causal inference framework to predict a cell's

gene expressions under counterfactual perturbations (perturbations that this cell did not factually receive), leveraging information representing biological knowledge in the form of gene regulatory networks (GRNs) to aid individualized cellular response predictions. Aiming at a data-adaptive GRN, we also developed an adjacency matrix updating technique for graph convolutional networks and used it to refine GRNs during pre-training, which generated more insights on gene relations and enhanced model performance. Additionally, we propose a robust estimator within our framework for the asymptotically efficient estimation of marginal perturbation effect, which is yet to be carried out in previous works. With extensive experiments, we exhibited the advantage of our approach over state-of-the-art deep learning models for individual response prediction.

Exploit Unlabeled Data on the Server! Federated Learning via Uncertainty-aware Ensemble Distillation and Self-Supervision

Jae-Min Park,Won-jun Jang,Tae-Hyun Oh,Si-Hyeon Lee

Federated Learning (FL) is a distributed machine learning paradigm that involves the cooperation of multiple clients to train a server model. In practice, it is hard to assume that each client possesses large-scale data or many clients are always available to participate in FL for the same round, which may lead to data deficiency. This deficiency degrades the entire learning process. To resolve this challenge, we propose a Federated learning with entropy-weighted ensemble Distillation and Self-supervised learning (FedDS). FedDS reliably deals with situations where not only the amount of data per client but also the number of clients is scarce. This advantage is achieved by leveraging the prevalent unlabeled data in the server. We demonstrate the effectiveness of FedDS on classification tasks for CIFAR-10/100 and PathMNIST. In CIFAR-10, our method shows the improvement over FedAVG by 12.54% in data deficient regime, and by 17.16% and 23.56% in more challenging scenarios of noisy label or Byzantine client cases, respectively.

Sample Importance in SGD Training

Alessio Quercia,Hanno Scharr,Ira Assent

Deep learning requires increasingly bigger models and datasets to improve generalization on unseen data, where some training data samples may be more informative than others. We investigate this assumption in supervised image classification by biasing SGD (Stochastic Gradient Descent) to sample important samples more often during training of a classifier. In contrast to state-of-the-art, our approach does not require additional training iterations to estimate the sample importance, because it computes estimates once during training using the training prediction probabilities. In experiments, we see that our learning technique converges on par or faster in terms of training iterations and can achieve higher test accuracy compared to state-of-the-art, especially when datasets are not suitably balanced. Results suggest that sample importance has intrinsic balancing properties and that an importance weighted class distribution can converge faster than the usual balanced class distribution. Finally, in contrast to recent work, we find that sample importance is model dependent. Therefore, calculating sample importance during training, rather than in a pre-processing step, may be the only viable way to go.

ResAct: Reinforcing Long-term Engagement in Sequential Recommendation with Residual Actor

Wanqi Xue,Qingpeng Cai,Ruohan Zhan,Dong Zheng,Peng Jiang,Kun Gai,Bo An

Long-term engagement is preferred over immediate engagement in sequential recommendation as it directly affects product operational metrics such as daily active users (DAUs) and dwell time. Meanwhile, reinforcement learning (RL) is widely regarded as a promising framework for optimizing long-term engagement in sequential recommendation. However, due to expensive online interactions, it is very difficult for RL algorithms to perform state-action value estimation, exploration and feature extraction when optimizing long-term engagement. In this paper, we propose ResAct which seeks a policy that is close to, but better than, the online-serving policy. In this way, we can collect sufficient data near the learned pol icy so that state-action values can be properly estimated, and there is no need to perform online exploration. ResAct optimizes the policy by first reconstructing the online behaviors and then improving it via a Residual Actor. To extract long-term information, ResAct utilizes two information-theoretical regularizers to confirm the expressiveness and conciseness of features. We conduct experiments on a benchmark dataset and a large-scale industrial dataset which consists of tens of millions of recommendation requests. Experimental results show that our method significantly outperforms the state-of-the-art baselines in various long-term engagement optimization tasks.

****

Dataset Pruning: Reducing Training Data by Examining Generalization Influence

Shuo Yang,Zeke Xie,Hanyu Peng,Min Xu,Mingming Sun,Ping Li

The great success of deep learning heavily relies on increasingly larger training data, which comes at a price of huge computational and infrastructural costs. This poses crucial questions that, do all training data contribute to model's performance? How much does each individual training sample or a sub-training-set affect the model's generalization, and how to construct the smallest subset from the entire training data as a proxy training set without significantly sacrificing the model's performance? To answer these, we propose dataset pruning, an optimization-based sample selection method that can (1) examine the influence of removing a particular set of training samples on model's generalization ability with theoretical guarantee, and (2) construct the smallest subset of training data that yields strictly constrained generalization gap. The empirically observed generalization gap of dataset pruning is substantially consistent with our theoretical expectations. Furthermore, the proposed method prunes 40% training examples on the CIFAR-10 dataset, halves the convergence time with only 1.3% test accuracy decrease, which is superior to previous score-based sample selection methods.

Visual Timing For Sound Source Depth Estimation in the Wild

Wei Sun,Lili Qiu

Depth estimation enables a wide variety of 3D applications, such as robotics and autonomous driving. Despite significant work on various depth sensors, it is challenging to develop an all-in-one method to meet multiple basic criteria. In this paper, we propose a novel audio-visual learning scheme by integrating semantic features with physical spatial cues to boost monocular depth with only one microphone. Inspired by the flash-to-bang theory, we develop FBDepth, the first passive audio-visual depth estimation framework. It is based on the difference between the time-of-flight (ToF) of the light and the sound. We formulate sound source depth estimation as an audio-visual event localization task for collision events. To approach decimeter-level depth accuracy, we design a coarse-to-fine pipeline to push the temporary localization accuracy from event-level to millisecond-level by aligning audio-visual correspondence and manipulating optical flow. FBDepth feeds the estimated visual timestamp together with the audio clip and object visual features to regress the source depth. We use a mobile phone to collect 3.6K+ video clips with 24 different objects at up to 60m. FBDepth shows superior performance especially at a long range compared to monocular and stereo methods.

StrucTexTv2: Masked Visual-Textual Prediction for Document Image Pre-training

Yuechen Yu,Yulin Li,Chengquan Zhang,Xiaoqiang Zhang,Zengyuan Guo,Xiameng Qin,Kun Yao,Junyu Han,Errui Ding,Jingdong Wang

In this paper, we present StrucTexTv2, an effective document image pre-training framework, by performing masked visual-textual prediction. It consists of two self-supervised pre-training tasks: masked image modeling and masked language modeling, based on text region-level image masking. The proposed method randomly masks some image regions according to the bounding box coordinates of text words. The objectives of our pre-training tasks are reconstructing the pixels of masked image regions and the corresponding masked tokens simultaneously. Hence the pre-trained encoder can capture more textual semantics in comparison to the masked image modeling that usually predicts the masked image patches. Compared to the ma sked multi-modal modeling methods for document image understanding that rely on both the image and text modalities, StrucTexTv2 models image-only input and potentially deals with more application scenarios free from OCR pre-processing. Extensive experiments on mainstream benchmarks of document image understanding demonstrate the effectiveness of StrucTexTv2. It achieves competitive or even new state-of-the-art performance in various downstream tasks such as image classification, layout analysis, table structure recognition, document OCR, and information extraction under the end-to-end scenario.

Link Prediction without Graph Neural Networks

Zexi Huang,Mert Kosan,Arlei Lopes da Silva,Ambuj Singh

Link prediction, which consists of predicting edges based on graph features, is a fundamental task in many graph applications. As for several related problems, Graph Neural Networks (GNNs), which are based on an attribute-centric message-passing paradigm, have become the predominant framework for link prediction. GNNs have consistently outperformed traditional topology-based heuristics, but what contributes to their performance? Are there simpler approaches that achieve comparable or better results? To answer these questions, we first identify important limitations in how GNN-based link prediction methods handle the intrinsic class imbalance of the problem---due to the graph sparsity---in their training and evaluation. Moreover, we propose Gelato, a novel topology-centric framework that applies a topological heuristic to a graph enhanced by attribute information via graph learning. Our model is trained end-to-end with an N-pair loss on an unbiased training set to address class imbalance. Experiments show that Gelato is 145% more accurate, trains 11 times faster, infers 6,000 times faster, and has less than half of the trainable parameters compared to state-of-the-art GNNs for link prediction.

****

AdaStride: Using Adaptive Strides in Sequential Data for Effective Downsampling

Yoonhyung Lee,Kyomin Jung

The downsampling layer has been one of the most commonly used deep learning (DL) components in sequential data processing due to its several advantages. First, it improves the generalization performance of networks by acting as an information bottleneck, where it extracts task-relevant features and discards others. Second, it reduces data resolution allowing CNN layers to have larger receptive fields with smaller kernel sizes. Third, the reduced data resolution facilitates the use of Transformer networks in case of high-resolution data. Accordingly, there have been many studies on downsampling methods, but they have a limitation in that they apply the same downsampling ratio across a data instance. Using the same downsampling ratio uniformly for an entire data instance does not reflect the fact that the task-relevant information is not uniformly distributed in real data. In this paper, we introduce AdaStride, a downsampling method that can apply adaptively varying downsampling ratios across a sequential data instance given an overall downsampling ratio. Specifically, AdaStride learns to deploy adaptive strides in a sequential data instance. Therefore, it can preserve more information from task-relevant parts of a data instance by using smaller strides for those parts and larger strides for less relevant parts. To achieve this, we propose a novel training method called vector positioning that rearranges each time step of an input on a one-dimensional line segment without reordering, which is used to build an alignment matrix for the downsampling. In experiments conducted on three different tasks of audio classification, automatic speech recognition, and discrete representation learning, AdaStride outperforms other widely used standard downsampling methods showing its generality and effectiveness. In addition, we analyze how our AdaStride learns the effective adaptive strides to improve its performance in the tasks.

****

Subclass-balancing Contrastive Learning for Long-tailed Recognition

Chengkai Hou,Jieyu Zhang,Haonan Wang,Tianyi Zhou

Long-tailed recognition with imbalanced classes naturally emerges in practical machine learning applications. Existing methods such as data reweighing, resampli ng, and supervised contrastive learning enforce the class balance with a price of introducing imbalance between instances of head class and tail class, which may ignore the underlying rich semantic substructures of the former and exaggerate the biases in the latter. We overcome these drawbacks by a novel "subclass-balancing contrastive learning (SBCL)'' approach that clusters each head class into multiple subclasses of similar sizes as the tail classes and enforce representations to capture the two-layer class hierarchy between the original classes and their subclasses. Since the clustering is conducted in the representation space and updated during the course of training, the subclass labels preserve the semantic substructures of head classes. Meanwhile, it does not overemphasize tail class samples so each individual instance contribute to the representation learning equally. Hence, our method achieves both the instance- and subclass-balance, while the original class labels are also learned through contrastive learning among subclasses from different classes. We evaluate SBCL over a list of long-tailed benchmark datasets and it achieves the state-of-the-art performance. In addition, we present extensive analyses and ablation studies of SBCL to verify its advantages.

Effective Cross-instance Positive Relations for Generalized Category Discovery

Shaozhe Hao,Kai Han,Kwan-Yee K. Wong

We tackle the issue of generalized category discovery (GCD). GCD considers the open-world problem of automatically clustering a partially labelled dataset, in which the unlabelled data contain instances from novel categories and also the labelled classes. In this paper, we address the GCD problem without a known category number in the unlabelled data. We propose a framework, named CiP, to bootstrap the representation by exploiting Cross-instance Positive relations for contrastive learning in the partially labelled data which are neglected in existing methods. First, to obtain reliable cross-instance relations to facilitate the representation learning, we introduce a semi-supervised hierarchical clustering algorithm, named selective neighbor clustering (SNC), which can produce a clustering hierarchy directly from the connected components in the graph constructed by selective neighbors. We also extend SNC to be capable of label assignment for the unlabelled instances with the given class number. Moreover, we present a method to estimate the unknown class number using SNC with a joint reference score considering clustering indexes of both labelled and unlabelled data. Finally, we thoroughly evaluate our CiP framework on public generic image recognition datasets (CIFAR-10, CIFAR-100, and ImageNet-100) and challenging fine-grained datasets (CUB, Stanford Cars, and Herbarium19), all establishing the new state-of-the-art.

Plateau in Monotonic Linear Interpolation --- A "Biased" View of Loss Landscape for Deep Networks

Xiang Wang,Annie N. Wang,Mo Zhou,Rong Ge

Monotonic linear interpolation (MLI) --- on the line connecting a random initialization with the minimizer it converges to, the loss and accuracy are monotonic --- is a phenomenon that is commonly observed in the training of neural networks. Such a phenomenon may seem to suggest that optimization of neural networks is easy. In this paper, we show that the MLI property is not necessarily related to the hardness of optimization problems, and empirical observations on MLI for deep neural networks depend heavily on the biases. In particular, we show that interpolating both weights and biases linearly leads to very different influences on the final output, and when different classes have different last-layer biases on a deep network, there will be a long plateau in both the loss and accuracy interpolation (which existing theory of MLI cannot explain). We also show how the last-layer biases for different classes can be different even on a perfectly balanced dataset using a simple model. Empirically we demonstrate that similar intuitions hold on practical networks and realistic datasets.

Expected Gradients of Maxout Networks and Consequences to Parameter Initialization

Hanna Tseran,Guido Montufar

We study the gradients of a maxout network with respect to inputs and parameters and obtain bounds for the moments depending on the architecture and the parameter distribution. We observe that the distribution of the input-output Jacobian depends on the input, which complicates a stable parameter initialization. Based on the moments of the gradients, we formulate parameter initialization strategies that avoid vanishing and exploding gradients in wide networks. Experiments with deep fully-connected and convolutional networks show that this strategy improves SGD and Adam training of deep maxout networks. In addition, we obtain refined bounds on the expected number of linear regions, results on the expected curve length distortion, and results on the NTK.

The KFIoU Loss for Rotated Object Detection

Xue Yang,Yue Zhou,Gefan Zhang,Jirui Yang,Wentao Wang,Junchi Yan,XIAOPENG ZHANG,Qi Tian

Differing from the well-developed horizontal object detection area whereby the computing-friendly IoU based loss is readily adopted and well fits with the detection metrics, rotation detectors often involve a more complicated loss based on SkewIoU which is unfriendly to gradient-based training. In this paper, we propose an effective approximate SkewIoU loss based on Gaussian modeling and Gaussian product, which mainly consists of two items. The first term is a scale-insensitive center point loss, which is used to quickly narrow the distance between the center points of the two bounding boxes. In the distance-independent second term, the product of the Gaussian distributions is adopted to inherently mimic the mechanism of SkewIoU by its definition, and show its alignment with the SkewIoU loss at trend-level within a certain distance (i.e. within 9 pixels). This is in contrast to recent Gaussian modeling based rotation detectors e.g. GWD loss and KLD loss that involve a human-specified distribution distance metric which require additional hyperparameter tuning that vary across datasets and detectors. The resulting new loss called KFIoU loss is easier to implement and works better compared with exact SkewIoU loss, thanks to its full differentiability and ability to handle the non-overlapping cases. We further extend our technique to the 3-D case which also suffers from the same issues as 2-D. Extensive results on various datasets with different base detectors show the effectiveness of our approach.

****

Crossformer: Transformer Utilizing Cross-Dimension Dependency for Multivariate Time Series Forecasting

Yunhao Zhang,Junchi Yan

Recently many deep models have been proposed for multivariate time series (MTS) forecasting. In particular, Transformer-based models have shown great potential because they can capture long-term dependency. However, existing Transformer-based models mainly focus on modeling the temporal dependency (cross-time dependency) yet often omit the dependency among different variables (cross-dimension dependency), which is critical for MTS forecasting. To fill the gap, we propose Crossformer, a Transformer-based model utilizing cross-dimension dependency for MTS forecasting. In Crossformer, the input MTS is embedded into a 2D vector array through the Dimension-Segment-Wise (DSW) embedding to preserve time and dimension information. Then the Two-Stage Attention (TSA) layer is proposed to efficiently capture the cross-time and cross-dimension dependency. Utilizing DSW embedding and TSA layer, Crossformer establishes a Hierarchical Encoder-Decoder (HED) to use the information at different scales for the final forecasting. Extensive experimental results on six real-world datasets show the effectiveness of Crossformer against previous state-of-the-arts.

Go-Explore with a guide: Speeding up search in sparse reward settings with goal-directed intrinsic rewards

Chong Min John Tan,Mehul Motani

Reinforcement Learning (RL) agents have traditionally been very sample-intensive to train, especially in environments with sparse rewards. Seeking inspiration from neuroscience experiments of rats learning the structure of a maze without ne eding extrinsic rewards, we seek to incorporate additional intrinsic rewards to guide behavior. We propose a potential-based goal-directed intrinsic reward (GDIR), which provides a reward signal regardless of whether the task is achieved, and ensures that learning can always take place. While GDIR may be similar to approaches such as reward shaping in incorporating goal-based rewards, we highlight that GDIR is innate to the agent and hence applicable across a wide range of environments without needing to rely on a properly shaped environment reward. We also note that GDIR is different from curiosity-based intrinsic motivation, which can diminish over time and lead to inefficient exploration. Go-Explore is a well-known state-of-the-art algorithm for sparse reward domains, and we demonstrate that by incorporating GDIR in the ``Go" and ``Explore" phases, we can improve Go-Explore's performance and enable it to learn faster across multiple environments, for both discrete (2D grid maze environments, Towers of Hanoi, Game of Nim) and continuous (Cart Pole and Mountain Car) state spaces. Furthermore, to consolidate learnt trajectories better, our method also incorporates a novel approach of hippocampal replay to update the values of GDIR and reset state visit and selection counts of states along the successful trajectory. As a benchmark, we also show that our proposed approaches learn significantly faster than traditional extrinsic-reward-based RL algorithms such as Proximal Policy Optimization, TD-learning, and Q-learning.

****

Is Stochastic Gradient Descent Near Optimal?

Yifan Zhu,Hong Jun Jeon,Benjamin Van Roy

The success of neural networks over the past decade has established them as effective models for many relevant data generating processes. Statistical theory on neural networks indicates graceful scaling of sample complexity. For example, Joen & Van Roy (An information-theoretic framework for supervised learning, 2022) demonstrate that, when data is generated by a ReLU teacher network with W parameters, an optimal learner needs only $\tilde{O}(W/\epsilon)$ samples to attain expected error ϵ. However, existing computational theory suggests that, even for single-hidden-layer teacher networks, to attain small error for all such teacher networks, the computation required to achieve this sample complexity is intractable. In this work, we fit single-hidden-layer neural networks to data generated by single-hidden-layer ReLU teacher networks with parameters drawn from a natural distribution. We demonstrate that stochastic gradient descent (SGD) with automated width selection attains small expected error with a number of samples and total number of queries both nearly linear in the input dimension and width. This suggests that SGD nearly achieves the information-theoretic sample complexity bounds of Joen & Van Roy (2022) in a computationally efficient manner. An important difference between our positive empirical results and the negative theoretical results is that the latter address worst-case error of deterministic algorithms, while our analysis centers on expected error of a stochastic algorithm.

****

BrainBERT: Self-supervised representation learning for intracranial recordings

Christopher Wang,Vighnesh Subramaniam,Adam Uri Yaari,Gabriel Kreiman,Boris Katz,Ignacio Cases,Andrei Barbu

We create a reusable Transformer, BrainBERT, for intracranial recordings bringing modern representation learning approaches to neuroscience. Much like in NLP and speech recognition, this Transformer enables classifying complex concepts, i.e., decoding neural data, with higher accuracy and with much less data by being pretrained in an unsupervised manner on a large corpus of unannotated neural recordings. Our approach generalizes to new subjects with electrodes in new positions and to unrelated tasks showing that the representations robustly disentangle the neural signal. Just like in NLP where one can study language by investigating what a language model learns, this approach opens the door to investigating the brain by what a model of the brain learns. As a first step along this path, we demonstrate a new analysis of the intrinsic dimensionality of the computations in different areas of the brain. To construct these representations, we combine a technique for producing super-resolution spectrograms of neural data with an ap proach designed for generating contextual representations of audio by masking. In the future, far more concepts will be decodable from neural recordings by using representation learning, potentially unlocking the brain like language models unlocked language.

Logic-aware Pre-training of Language Models

Siru Ouyang,Zhuosheng Zhang,hai zhao

Pre-trained language models (PrLMs) have been shown useful for enhancing a broad range of natural language understanding (NLU) tasks. However, the capacity for capturing logic relations in challenging NLU still remains a bottleneck even for state-of-the-art PrLM enhancement, which greatly stalls their reasoning abilities. To bridge the gap, we propose logic pre-training of language models to equip PrLMs with logical reasoning ability. To let logic pre-training perform on a clear, accurate, and generalized knowledge basis, we introduce \textit{fact} instead of the plain language unit in previous PrLMs. The \textit{fact} is extracted through syntactic parsing in avoidance of unnecessary complex knowledge injection. Meanwhile, it enables training logic-aware models to be conducted on a more general language text. To explicitly guide the PrLM to capture logic relations, three complementary self-supervised pre-training objectives are introduced: 1) logical structure completion to accurately capture fact-level logic from the original context, 2) logical path prediction on a logical graph to uncover global logic relationships among facts, 3) logical connectives masking to capture discourse-level for fact groups. We evaluate our model on a broad range of NLP tasks, including natural language inference, relation extraction, and machine reading comprehension with logical reasoning. Experimental results show that our model achieves significant performance in all the downstream tasks, especially in logical reasoning-related tasks.

Individual Fairness of Data Provider Regarding Privacy Risk and Gain

Toshiki Shibahara,Takayuki Miura,Masanobu Kii,Atsunori Ichikawa

Fairness and privacy risks are important concerns of machine learning (ML) when deploying ML to the real world. Recent studies have focused on group fairness and privacy protection, but no study focuses on individual fairness (IF) and privacy protection. In this paper, we propose a new definition of IF from the perspective of privacy protection and experimentally evaluate privacy-preserving ML based on the proposed IF. For the proposed definition, we assume that users provide their data to an ML service and consider the principle that all users should obtain gains corresponding to their privacy risks. As a user's gain, we calculate the accuracy improvement on the user's data when providing the data to the ML service. We conducted experiments on the image and tabular datasets using three neural networks (NNs) and two tree-based algorithms with differential privacy guarantee. The experimental results of NNs show that we cannot stably improve the proposed IF by changing the strength of privacy protection and applying defenses against membership inference attacks. The results of tree-based algorithms show that privacy risks were extremely small without depending on the strength of privacy protection but raise a new question about the motivation of users for providing their data.

Semi-connected Joint Entity Recognition and Relation Extraction of Contextual Entities in Family History Records

Daniel Segrera

Entity extraction is an important step in document understanding. Higher accuracy entity extraction on fine-grained entities can be achieved by combining the utility of Named Entity Recognition (NER) and Relation Extraction (RE) models. In this paper, a semi-connected joint model is proposed that implements NER and Relation extraction. This joint model utilizes relations between entities to infer context-dependent fine-grain named entities in text corpora. The RE module is prevented from conveying information to the NER module which reduces the error accumulation during training. That improves on the fine-grained NER F1-score of existing state-of-the-art from .4753 to .8563 on our data. This provides the potent ial for further applications in historical document processing. These applications will enable automated searching of historical documents, such as those used in economics research and family history.

****

On the Universality of Langevin Diffusion for Private Euclidean (Convex) Optimization

Arun Ganesh,Abhradeep Guha Thakurta,Jalaj Kumar Upadhyay

In this paper, we revisit the problem of differentially private empirical risk minimization (DP-ERM) and differentially private stochastic convex optimization (DP-SCO). We show that a well-studied continuous time algorithm from statistical physics, called Langevin diffusion (LD), simultaneously provides optimal privacy/utility trade-offs for both DP-ERM and DP-SCO, under ϵ-DP, and (ϵ,δ)-DP both for convex and strongly convex loss functions. We provide new time and dimension independent uniform stability properties of LD, with which we provide the corresponding optimal excess population risk guarantees for ϵ-DP. An important attribute of our DP-SCO guarantees for ϵ-DP is that they match the non-private optimal bounds as $\epsilon\to\infty$.

****

General Neural Gauge Fields

Fangneng Zhan,Lingjie Liu,Adam Kortylewski,Christian Theobalt

The recent advance of neural fields, such as neural radiance fields, has significantly pushed the boundary of scene representation learning. Aiming to boost the computation efficiency and rendering quality of 3D scenes, a popular line of research maps the 3D coordinate system to another measuring system, e.g., 2D manifolds and hash tables, for modeling neural fields. The conversion of coordinate systems can be typically dubbed as \emph{gauge transformation}, which is usually a pre-defined mapping function, e.g., orthogonal projection or spatial hash function. This begs a question: can we directly learn a desired gauge transformation along with the neural field in an end-to-end manner? In this work, we extend this problem to a general paradigm with a taxonomy of discrete and continuous cases, and develop an end-to-end learning framework to jointly optimize the gauge transformation and neural fields. To counter the problem that the learning of gauge transformations can collapse easily, we derive a general regularization mechanism from the principle of information conservation during the gauge transformation. To circumvent the high computation cost in gauge learning with regularization, we directly derive an information-invariant gauge transformation which allows to preserve scene information inherently and yield superior performance.

****

Learning Disentanglement in Autoencoders through Euler Encoding

Jaehoon Cha,Jeyan Thiyagalingam

Noting the importance of factorizing (or disentangling) the latent space, we propose a novel, non-probabilistic disentangling framework for autoencoders, based on the principles of symmetry transformations that are independent of one another. To the best of our knowledge, this is the first deterministic model that is aiming to achieve disentanglement based on autoencoders without pairs of images or labels, by explicitly introducing inductive biases into a model architecture through Euler encoding. The proposed model is then compared with a number of state-of-the-art models, relevant to disentanglement, including symmetry-based and generative models based on autoencoders. Our evaluation using six different disentanglement metrics, including the unsupervised disentanglement metric we propose here in this paper, shows that the proposed model can offer better disentanglement, especially when variances of the features are different, where other methods may struggle. We believe that this model opens several opportunities for linear disentangled representation learning based on deterministic autoencoders.

Nonlinear Reconstruction for Operator Learning of PDEs with Discontinuities

Samuel Lanthaler,Roberto Molinaro,Patrik Hadorn,Siddhartha Mishra

Discontinuous solutions arise in a large class of hyperbolic and advection-dominated PDEs. This paper investigates, both theoretically and empirically, the operator learning of PDEs with discontinuous solutions. We rigorously prove, in term s of lower approximation bounds, that methods which entail a linear reconstruction step (e.g. DeepONets or PCA-Nets) fail to efficiently approximate the solution operator of such PDEs. In contrast, we show that certain methods employing a non-linear reconstruction mechanism can overcome these fundamental lower bounds and approximate the underlying operator efficiently. The latter class includes Fourier Neural Operators and a novel extension of DeepONets termed shift-DeepONets. Our theoretical findings are confirmed by empirical results for advection equations, inviscid Burgers’ equation and the compressible Euler equations of gas dynamics.

****

Grafting Vision Transformers

Jongwoo Park,Kumara Kahatapitiya,Donghyun Kim,Shivchander Sudalairaj,Quanfu Fan,Michael S Ryoo

Vision Transformers (ViTs) have recently become the state-of-the-art across many computer vision tasks. In contrast to convolutional networks (CNNs), ViTs enable global information sharing even within shallow layers of a network, i.e., among high-resolution features. However, this perk was later overlooked with the success of pyramid architectures such as Swin Transformer, which show better performance-complexity trade-offs. In this paper, we present a simple and efficient add-on component (termed GrafT) that considers global dependencies and multi-scale information throughout the network, in both high- and low-resolution features alike. GrafT can be easily adopted in both homogeneous and pyramid Transformers while showing consistent gains. It has the flexibility of branching- out at arbitrary depths, widening a network with multiple scales. This grafting operation enables us to share most of the parameters and computations of the backbone, adding only minimal complexity, but with a higher yield. In fact, the process of progressively compounding multi-scale receptive fields in GrafT enables communications between local regions. We show the benefits of the proposed method on multiple benchmarks, including image classification (ImageNet-1K), semantic segmentation (ADE20K), object detection and instance segmentation (COCO2017). Our code and models will be made available.

Generate rather than Retrieve: Large Language Models are Strong Context Generators

Wenhao Yu,Dan Iter,Shuohang Wang,Yichong Xu,Mingxuan Ju,Soumya Sanyal,Chenguang Zhu,Michael Zeng,Meng Jiang

Knowledge-intensive tasks, such as open-domain question answering (QA), require access to a large amount of world or domain knowledge. A common approach for knowledge-intensive tasks is to employ a retrieve-then-read pipeline that first retrieves a handful of relevant contextual documents from an external corpus such as Wikipedia and then predicts an answer conditioned on the retrieved documents. In this paper, we present a novel perspective for solving knowledge-intensive tasks by replacing document retrievers with large language model generators. We call our method generate-then-read (GenRead), which first prompts a large language model to generate contextual documents based on a given question, and then reads the generated documents to produce the final answer. Furthermore, we propose a novel clustering-based prompting method that selects distinct prompts, in order to generate diverse documents that cover different perspectives, leading to better recall over acceptable answers. We conduct extensive experiments on three different knowledge-intensive tasks, including open-domain QA, fact checking, and dialogue system. Notably, GenRead achieves 71.6 and 54.4 exact match scores on TriviaQA and WebQ, significantly outperforming the state-of-the-art retrieve-then-read pipeline DPR-FiD by +4.0 and +3.9, without retrieving any documents from any external knowledge source. Lastly, we demonstrate the model performance can be further improved by combining retrieval and generation. Our code and generated documents can be found at https://github.com/wyu97/GenRead.

Online Continual Learning for Progressive Distribution Shift (OCL-PDS): A Practitioner's Perspective

Runtian Zhai,Stefan Schroedl,Aram Galstyan,Anoop Kumar,Greg Ver Steeg,Pradeep Na

tarajan
We introduce the novel OCL-PDS problem - Online Continual Learning for Progressive Distribution Shift. PDS refers to the subtle, gradual, and continuous distribution shift that widely exists in modern deep learning applications. It is widely observed in industry that PDS can cause significant performance drop. While previous work in continual learning and domain adaptation addresses this problem to some extent, our investigations from the practitioner's perspective reveal flawed assumptions that limit their applicability on daily challenges faced in real-world scenarios, and this work aims to close the gap between academic research and industry. For this new problem, we build 4 new benchmarks from the Wilds dataset, and implement 12 algorithms and baselines including both supervised and semi-supervised methods, which we test extensively on the new benchmarks. We hope that this work can provide practitioners with tools to better handle realistic PDS, and help scientists design better OCL algorithms.
****
Discovering Informative and Robust Positives for Video Domain Adaptation
Chang Liu,Kunpeng Li,Michael Stopa,Jun Amano,Yun Fu
Unsupervised domain adaptation for video recognition is challenging where the domain shift includes both spatial variations and temporal dynamics. Previous works have focused on exploring contrastive learning for cross-domain alignment. However, limited variations in intra-domain positives, false cross-domain positives, and false negatives hinder contrastive learning from fulfilling intra-domain discrimination and cross-domain closeness. This paper presents a non-contrastive learning framework without relying on negative samples for unsupervised video domain adaptation. To address the limited variations in intra-domain positives, we set unlabeled target videos as anchors and explored to mine "informative intra-domain positives" in the form of spatial/temporal augmentations and target nearest neighbors (NNs).

To tackle the false cross-domain positives led by noisy pseudo-labels, we reversely set source videos as anchors and sample the synthesized target videos as "robust cross-domain positives" from an estimated target distribution, which are naturally more robust to the pseudo-label noise. Our approach is demonstrated to be superior to state-of-the-art methods through extensive experiments on several cross-domain action recognition benchmarks.

Understanding Why Generalized Reweighting Does Not Improve Over ERM
Runtian Zhai,Chen Dan,J Zico Kolter,Pradeep Kumar Ravikumar
Empirical risk minimization (ERM) is known to be non-robust in practice to distributional shift where the training and the test distributions are different. A suite of approaches, such as importance weighting, and variants of distributionally robust optimization (DRO), have been proposed to solve this problem. But a line of recent work has empirically shown that these approaches do not significantly improve over ERM in real applications with distribution shift. The goal of this work is to obtain a comprehensive theoretical understanding of this intriguing phenomenon. We first posit the class of Generalized Reweighting (GRW) algorithms, as a broad category of approaches that iteratively update model parameters based on iterative reweighting of the training samples. We show that when overparameterized models are trained under GRW, the resulting models are close to that obtained by ERM. We also show that adding small regularization which does not greatly affect the empirical training accuracy does not help. Together, our results show that a broad category of what we term GRW approaches are not able to achieve distributionally robust generalization. Our work thus has the following sobering takeaway: to make progress towards distributionally robust generalization, we either have to develop non-GRW approaches, or perhaps devise novel classification/regression loss functions that are adapted to GRW approaches.

Betty: An Automatic Differentiation Library for Multilevel Optimization
Sang Keun Choe,Willie Neiswanger,Pengtao Xie,Eric Xing
Gradient-based multilevel optimization (MLO) has gained attention as a framework

for studying numerous problems, ranging from hyperparameter optimization and meta-learning to neural architecture search and reinforcement learning. However, gradients in MLO, which are obtained by composing best-response Jacobians via the chain rule, are notoriously difficult to implement and memory/compute intensive. We take an initial step towards closing this gap by introducing Betty, a software library for large-scale MLO. At its core, we devise a novel dataflow graph for MLO, which allows us to (1) develop efficient automatic differentiation for MLO that reduces the computational complexity from $\mathcal{O}(d^3)$ to $\mathcal{O}(d^2)$, (2) incorporate systems support such as mixed-precision and data-parallel training for scalability, and (3) facilitate implementation of MLO programs of arbitrary complexity while allowing a modular interface for diverse algorithmic and systems design choices. We empirically demonstrate that Betty can be used to implement an array of MLO programs, while also observing up to 11% increase in test accuracy, 14% decrease in GPU memory usage, and 20% decrease in training wall time over existing implementations on multiple benchmarks. We also showcase that Betty enables scaling MLO to models with hundreds of millions of parameters. We open-source the code at https://github.com/leopard-ai/betty.

PatchBlender: A Motion Prior for Video Transformers

Gabriele Prato,Yale Song,Janarthanan Rajendran,R Devon Hjelm,Neel Joshi,Sarath Chandar

Transformers have become one of the dominant architectures in the field of computer vision. However, there are yet several challenges when applying such architectures to video data. Most notably, these models struggle to model the temporal patterns of video data effectively. Directly targeting this issue, we introduce PatchBlender, a learnable blending function that operates over patch embeddings across the temporal dimension of the latent space. We show that our method is successful at enabling vision transformers to encode the temporal component of video data. On Something-Something v2 and MOVi-A, we show that our method improves the performance of a ViT-B. PatchBlender has the advantage of being compatible with almost any Transformer architecture and since it is learnable, the model can adaptively turn on or off the prior. It is also extremely lightweight compute-wise, 0.005% the GFLOPs of a ViT-B.

Linear Connectivity Reveals Generalization Strategies

Jeevesh Juneja,Rachit Bansal,Kyunghyun Cho,João Sedoc,Naomi Saphra

In the mode connectivity literature, it is widely accepted that there are common circumstances in which two neural networks, trained similarly on the same data, will maintain loss when interpolated in the weight space. In particular, transfer learning is presumed to ensure the necessary conditions for linear mode connectivity across training runs. In contrast to existing results from image classification, we find that among text classifiers (trained on MNLI, QQP, and CoLA), some pairs of finetuned models have large barriers of increasing loss on the linear paths between them. On each task, we find distinct clusters of models which are linearly connected on the test loss surface, but are disconnected from models outside the cluster---models that occupy separate basins on the surface. By measuring performance on specially-crafted diagnostic datasets, we find that these clusters correspond to different generalization strategies. For example, on MNLI, one cluster behaves like a bag of words model under domain shift, while another cluster uses syntactic heuristics. Our work demonstrates how the geometry of the loss surface can guide models towards different heuristic functions in standard finetuning settings.

CEREAL: Few-Sample Clustering Evaluation

Nihal V. Nayak,Ethan R. Elenberg,Clemens Rosenbaum

Evaluating clustering quality with reliable evaluation metrics like normalized mutual information (NMI) requires labeled data that can be expensive to annotate. We focus on the underexplored problem of estimating clustering quality with limited labels. We adapt existing approaches from the few-sample model evaluation literature to actively sub-sample, with a learned surrogate model, the most infor mative data points for annotation to estimate the evaluation metric. However, we find that their estimation can be biased and only relies on the labeled data. To that end, we introduce CEREAL, a comprehensive framework for few-sample clustering evaluation that extends active sampling approaches in three key ways. First, we propose novel NMI-based acquisition functions that account for the distinctive properties of clustering and uncertainties from a learned surrogate model. Next, we use ideas from semi-supervised learning and train the surrogate model with both the labeled and unlabeled data. Finally, we pseudo-label the unlabeled data with the surrogate model. We run experiments to estimate NMI in an active sampling pipeline on three datasets across vision and language. Our results show that CEREAL reduces the area under the absolute error curve by up to 57% compared to the best sampling baseline. We perform an extensive ablation study to show that our framework is agnostic to the choice of clustering algorithm and evaluation metric. We also extend CEREAL from clusterwise annotations to pairwise annotations. Overall, CEREAL can efficiently evaluate clustering with limited human annotations.

Gradient-Guided Importance Sampling for Learning Binary Energy-Based Models

Meng Liu,Haoran Liu,Shuiwang Ji

Learning energy-based models (EBMs) is known to be difficult especially on discrete data where gradient-based learning strategies cannot be applied directly. Although ratio matching is a sound method to learn discrete EBMs, it suffers from expensive computation and excessive memory requirements, thereby resulting in difficulties in learning EBMs on high-dimensional data. Motivated by these limitations, in this study, we propose ratio matching with gradient-guided importance sampling (RMwGGIS). Particularly, we use the gradient of the energy function w.r.t. the discrete data space to approximately construct the provably optimal proposal distribution, which is subsequently used by importance sampling to efficiently estimate the original ratio matching objective. We perform experiments on density modeling over synthetic discrete data, graph generation, and training Ising models to evaluate our proposed method. The experimental results demonstrate that our method can significantly alleviate the limitations of ratio matching, perform more effectively in practice, and scale to high-dimensional problems. Our implementation is available at https://github.com/divelab/RMwGGIS.

Your Neighbors Are Communicating: Towards Powerful and Scalable Graph Neural Networks

Meng Liu,Haiyang Yu,Shuiwang Ji

Message passing graph neural networks (GNNs) are known to have their expressiveness upper-bounded by 1-dimensional Weisfeiler-Lehman (1-WL) algorithm. To achieve more powerful GNNs, existing attempts either require ad hoc features, or involve operations that incur high time and space complexities. In this work, we propose a general and provably powerful GNN framework that preserves the scalability of message passing scheme. In particular, we first propose to empower 1-WL for graph isomorphism test by considering edges among neighbors, giving rise to NC-1-WL. The expressiveness of NC-1-WL is shown to be strictly above 1-WL and below 3-WL theoretically. Further, we propose the NC-GNN framework as a differentiable neural version of NC-1-WL. Our simple implementation of NC-GNN is provably as powerful as NC-1-WL. Experiments demonstrate that our NC-GNN achieves remarkable performance on various benchmarks.

PATCorrect: Non-autoregressive Phoneme-augmented Transformer for ASR Error Correction

Ziji Zhang,Zhehui Wang,Rajesh Kamma,Sharanya Eswaran,Narayanan Sadagopan

Speech-to-text errors made by automatic speech recognition (ASR) system negatively impact downstream models relying on ASR transcriptions. Language error correction models as a post-processing text editing approach have been recently developed for refining the source sentences. However, efficient models for correcting errors in ASR transcriptions that meet the low latency requirements of industrial grade production systems have not been well studied. In this work, we propose a novel non-autoregressive (NAR) error correction approach to improve the transcription quality by reducing word error rate (WER) and achieve robust performance across different upstream ASR systems. Our approach augments the text encoding of the Transformer model with a phoneme encoder that embeds pronunciation information. The representations from phoneme encoder and text encoder are combined via a multi-modal fusion before feeding into the length tagging predictor for predicting target sequence lengths. The joint encoders also provide inputs to the attention mechanism in the NAR decoder. We experiment on 3 open-source ASR systems with varying speech-to-text transcription quality and their erroneous transcriptions on 2 public English corpus datasets. Results show that our PATCorrect (Phoneme Augmented Transformer for ASR error Correction) consistently outperforms state-of-the-art NAR error correction method on English corpus across different upstream ASR systems. For example, PATCorrect improves WER reduction by 20% compared to methods using text only modality and also achieves an inference latency comparable to other NAR models at tens of millisecond scale, especially on GPU hardware, while still being 4.2 - 6.7x times faster than autoregressive models on Common Voice and LibriSpeech datasets.

Composing Ensembles of Pre-trained Models via Iterative Consensus

Shuang Li,Yilun Du,Joshua B. Tenenbaum,Antonio Torralba,Igor Mordatch

Large pre-trained models exhibit distinct and complementary capabilities dependent on the data they are trained on. Language models such as GPT-3 are capable of textual reasoning but cannot understand visual information, while vision models such as DALL-E can generate photorealistic photos but fail to understand complex language descriptions. In this work, we propose a unified framework for composing ensembles of different pre-trained models -- combining the strengths of each individual model to solve various multimodal problems in a zero-shot manner. We use pre-trained models as "generators" or "scorers" and compose them via closed-loop iterative consensus optimization. The generator constructs proposals and the scorers iteratively provide feedback to refine the generated result. Such closed-loop communication enables models to correct errors caused by other models, significantly boosting performance on downstream tasks, e.g. improving accuracy on grade school math problems by 7.5%, without requiring any model finetuning. We demonstrate that consensus achieved by an ensemble of scorers outperforms the feedback of a single scorer, by leveraging the strengths of each expert model. Results show that the proposed method can be used as a general purpose framework for a wide range of zero-shot multimodal tasks, such as image generation, video question answering, mathematical reasoning, and robotic manipulation.

Automated Data Augmentations for Graph Classification

Youzhi Luo,Michael Curtis McThrow,Wing Yee Au,Tao Komikado,Kanji Uchino,Koji Maruhashi,Shuiwang Ji

Data augmentations are effective in improving the invariance of learning machines. We argue that the core challenge of data augmentations lies in designing data transformations that preserve labels. This is relatively straightforward for images, but much more challenging for graphs. In this work, we propose GraphAug, a novel automated data augmentation method aiming at computing label-invariant augmentations for graph classification. Instead of using uniform transformations as in existing studies, GraphAug uses an automated augmentation model to avoid compromising critical label-related information of the graph, thereby producing label-invariant augmentations at most times. To ensure label-invariance, we develop a training method based on reinforcement learning to maximize an estimated label-invariance probability. Experiments show that GraphAug outperforms previous graph augmentation methods on various graph classification tasks.

Learning Label Encodings for Deep Regression

Deval Shah,Tor M. Aamodt

Deep regression networks are widely used to tackle the problem of predicting a continuous value for a given input. Task-specialized approaches for training regr ession networks have shown significant improvement over generic approaches, such as direct regression. More recently, a generic approach based on regression by binary classification using binary-encoded labels has shown significant improvement over direct regression. The space of label encodings for regression is large. Lacking heretofore have been automated approaches to find a good label encoding for a given application. This paper introduces Regularized Label Encoding Learning (RLEL) for end-to-end training of an entire network and its label encoding. RLEL provides a generic approach for tackling regression. Underlying RLEL is our observation that the search space of label encodings can be constrained and efficiently explored by using a continuous search space of real-valued label encodings combined with a regularization function designed to encourage encodings with certain properties. These properties balance the probability of classification error in individual bits against error correction capability. Label encodings found by RLEL result in lower or comparable errors to manually designed label encodings. Applying RLEL results in 10.9% and 12.4% improvement in Mean Absolute Error (MAE) over direct regression and multiclass classification, respectively. Our evaluation demonstrates that RLEL can be combined with off-the-shelf feature extractors and is suitable across different architectures, datasets, and tasks. Code is available at https://github.com/ubc-aamodt-group/RLEL_regression.

Riemannian Metric Learning via Optimal Transport
Christopher Scarvelis,Justin Solomon

We introduce an optimal transport-based model for learning a metric tensor from cross-sectional samples of evolving probability measures on a common Riemannian manifold. We neurally parametrize the metric as a spatially-varying matrix field and efficiently optimize our model's objective using a simple alternating scheme. Using this learned metric, we can non-linearly interpolate between probability measures and compute geodesics on the manifold. We show that metrics learned using our method improve the quality of trajectory inference on scRNA and bird migration data at the cost of little additional cross-sectional data.

Computational-Unidentifiability in Representation for Fair Downstream Tasks
Taeuk Jang,Xiaoqian Wang

Deep representation learning methods are highlighted as they outperform classical algorithms in various downstream tasks, such as classification, clustering, generative models, etc. Due to their success and impact on the real world, fairness concern is rising with noticeable attention. However, the focus of the fairness problem was limited to a certain downstream task, mostly classification, and few were studied from the perspective of representation itself. We claim that the fairness problems to various downstream tasks originated from the input feature space, i.e., the learned representation space. While several studies explored fair representation for the classification task, the fair representation learning method for unsupervised learning is not actively discussed. To fill this gap, we define a new notion of fairness, computational-unidentifiability, which suggests the fairness of the representation as the distributional independence of the sensitive groups. We demonstrate motivating problems that achieving computationally-unidentifiable representation is critical for fair downstream tasks. Moreover, we propose a novel fairness metric, Fair Fréchet distance (FFD), to quantify the computational-unidentifiability and address the limitation of a well-known fairness metric for unsupervised learning, i.e., balance. The proposed metric is efficient in computation and preserves theoretical properties. We empirically validate the effectiveness of the computationally-unidentifiable representations in various downstream tasks.

****

Reliability of CKA as a Similarity Measure in Deep Learning
MohammadReza Davari,Stefan Horoi,Amine Natik,Guillaume Lajoie,Guy Wolf,Eugene Belilovsky

Comparing learned neural representations in neural networks is a challenging but important problem, which has been approached in different ways. The Centered Kernel Alignment (CKA) similarity metric, particularly its linear variant, has rec ently become a popular approach and has been widely used to compare representations of a network's different layers, of architecturally similar networks trained differently, or of models with different architectures trained on the same data. A wide variety of claims about similarity and dissimilarity of these various representations have been made using CKA results. In this work we present analysis that formally characterizes CKA sensitivity to a large class of simple transformations, which can naturally occur in the context of modern machine learning. This provides a concrete explanation to CKA sensitivity to outliers, which has been observed in past works, and to transformations that preserve the linear separability of the data, an important generalization attribute. We empirically investigate several weaknesses of the CKA similarity metric, demonstrating situations in which it gives unexpected or counterintuitive results. Finally we study approaches for modifying representations to maintain functional behaviour while changing the CKA value. Our results illustrate that, in many cases, the CKA value can be easily manipulated without substantial changes to the functional behaviour of the models, and call for caution when leveraging activation alignment metrics.

Gradient Properties of Hard Thresholding Operator
Saeed Damadi,Jinglai Shen

Sparse optimization receives increasing attention in many applications such as compressed sensing, variable selection in regression problems, and recently neural network compression in machine learning. For example, the problem of compressing a neural network is a bi-level, stochastic, and nonconvex problem that can be cast into a sparse optimization problem. Hence, developing efficient methods for sparse optimization plays a critical role in applications. The goal of this paper is to develop analytical techniques for general, large size sparse optimization problems using the hard thresholding operator. To this end, we study the iterative hard thresholding (IHT) algorithm, which has been extensively studied in the literature because it is scalable, fast, and easily implementable. In spite of extensive research on the IHT scheme, we develop several new techniques that not only recover many known results but also lead to new results. Specifically, we first establish a new and critical gradient descent property of the hard thresholding (HT) operator. Our gradient descent result can be related to the distance between points that are sparse. However, the distance between sparse points cannot provide any information about the gradient in the sparse setting. To the best of our knowledge, the other way around (the gradient to the distance) has not been shown so far in the literature. Also, our gradient descent property allows one to study the IHT when the stepsize is less than or equal to 1/L, where L>0 is the Lipschitz constant of the gradient of an objective function. Note that the existing techniques in the literature can only handle the case when the stepsize is strictly less than 1/L. By exploiting this we introduce and study HT-stable and HT-unstable stationary points and show no matter how close an initialization is to a HT-unstable stationary point (saddle point in sparse sense), the IHT sequence leaves it. Finally, we show that no matter what sparse initial point is selected, the IHT sequence converges if the function values at HT-stable stationary points are distinct, where the last condition is a new assumption that has not been found in the literature. We provide a video of 4000 independent runs where the IHT algorithm is initialized very close to a HT-unstable stationary point and show the sequences escape them.

****

Fair Attribute Completion on Graph with Missing Attributes
Dongliang Guo,Zhixuan Chu,Sheng Li

Tackling unfairness in graph learning models is a challenging task, as the unfairness issues on graphs involve both attributes and topological structures. Existing work on fair graph learning simply assumes that attributes of all nodes are available for model training and then makes fair predictions. In practice, however, the attributes of some nodes might not be accessible due to missing data or privacy concerns, which makes fair graph learning even more challenging. In this paper, we propose FairAC, a fair attribute completion method, to complement mis sing information and learn fair node embeddings for graphs with missing attributes. FairAC adopts an attention mechanism to deal with the attribute missing problem and meanwhile, it mitigates two types of unfairness, i.e., feature unfairness from attributes and topological unfairness due to attribute completion. FairAC can work on various types of homogeneous graphs and generate fair embeddings for them and thus can be applied to most downstream tasks to improve their fairness performance. To our best knowledge, FairAC is the first method that jointly addresses the graph attribution completion and graph unfairness problems. Experimental results on benchmark datasets show that our method achieves better fairness performance with less sacrifice in accuracy, compared with the state-of-the-art methods of fair graph learning. Code is available at: https://github.com/donglgcn/FairAC.

Comfort Zone: A Vicinal Distribution for Regression Problems

Roee Weiss Lifshitz,Omri Azencot

Domain-dependent data augmentation methods generate artificial samples using transformations suited for the underlying data domain, for example rotations on images and time warping on time series data. However, domain-independent approaches, e.g. mixup, are applicable to various data modalities, and as such they are general and versatile. While mixup-based techniques are used extensively in classification problems, their effect on regression tasks is somewhat less explored. To bridge this gap, we study the problem of domain-independent augmentation for regression, and we introduce comfort-zone: a new data-driven, domain-independent data augmentation method. Essentially, our approach samples new examples from the tangent planes of the train distribution. Augmenting data in this way aligns with the network tendency towards capturing the dominant features of its input signals. Evaluating comfort-zone on regression and time series forecasting benchmarks, we show that it improves the generalization of several neural architectures. We also find that mixup and noise injection are less effective in comparison to comfort-zone.

****

Implicit Neural Spatial Representations for Time-dependent PDEs

Honglin Chen,Rundi Wu,Eitan Grinspun,Changxi Zheng,Peter Yichen Chen

Numerically solving partial differential equations (PDEs) often entails spatial and temporal discretizations. Traditional methods (e.g., finite
difference, finite element, smoothed-particle hydrodynamics) frequently adopt explicit spatial discretizations, such as grids, meshes, and point clouds, where each degree-of-freedom corresponds to a location in space. While these explicit spatial correspondences are intuitive to model and understand, these representations are not necessarily optimal for accuracy, memory-usage, or adaptivity. In this work, we explore implicit neural representation as an alternative spatial discretization, where spatial information is implicitly stored in the neural network weights. With implicit neural spatial representation, PDE-constrained time-stepping translates into updating neural network weights, which naturally integrates with commonly adopted optimization time integrators. We validate our approach on a variety of classic PDEs with examples involving large elastic deformations, turbulent fluids, and multiscale phenomena. While slower to compute than traditional representations, our approach exhibits higher accuracy, lower memory consumption, and dynamically adaptive allocation of degrees of freedom without complex remeshing.

****

Deep Ranking Ensembles for Hyperparameter Optimization

Abdus Salam Khazi,Sebastian Pineda Arango,Josif Grabocka

Automatically optimizing the hyperparameters of Machine Learning algorithms is one of the primary open questions in AI. Existing work in Hyperparameter Optimization (HPO) trains surrogate models for approximating the response surface of hyperparameters as a regression task. In contrast, we hypothesize that the optimal strategy for training surrogates is to preserve the ranks of the performances of hyperparameter configurations as a Learning to Rank problem. As a result, we present a novel method that meta-learns neural network surrogates optimized for ra nking the configurations' performances while modeling their uncertainty via ensembling. In a large-scale experimental protocol comprising 12 baselines, 16 HPO search spaces and 86 datasets/tasks, we demonstrate that our method achieves new state-of-the-art results in HPO.

****

Multi-skill Mobile Manipulation for Object Rearrangement

Jiayuan Gu,Devendra Singh Chaplot,Hao Su,Jitendra Malik

We study a modular approach to tackle long-horizon mobile manipulation tasks for object rearrangement, which decomposes a full task into a sequence of subtasks. To tackle the entire task, prior work chains multiple stationary manipulation skills with a point-goal navigation skill, which are learned individually on subtasks. Although more effective than monolithic end-to-end RL policies, this framework suffers from compounding errors in skill chaining, e.g., navigating to a bad location where a stationary manipulation skill can not reach its target to manipulate. To this end, we propose that the manipulation skills should include mobility to have flexibility in interacting with the target object from multiple locations and at the same time the navigation skill could have multiple end points which lead to successful manipulation. We operationalize these ideas by implementing mobile manipulation skills rather than stationary ones and training a navigation skill trained with region goal instead of point goal. We evaluate our multi-skill mobile manipulation method M3 on 3 challenging long-horizon mobile manipulation tasks in the Home Assistant Benchmark (HAB), and show superior performance as compared to the baselines.

Robustness to corruption in pre-trained Bayesian neural networks

Xi Wang,Laurence Aitchison

We develop ShiftMatch, a new training-data-dependent likelihood for robustness to corruption in Bayesian neural networks (BNNs). ShiftMatch is inspired by the training-data-dependent “EmpCov” priors from Izmailov et al. (2021a), and efficiently matches test-time spatial correlations to those at training time. Critically, ShiftMatch is designed to leave the neural network’s training time likelihood unchanged, allowing it to use publicly available samples from pre-trained BNNs. Using pre-trained HMC samples, ShiftMatch gives strong performance improvements on CIFAR-10-C, outperforms EmpCov priors (though ShiftMatch uses extra information from a minibatch of corrupted test points), and is perhaps the first Bayesian method capable of convincingly outperforming plain deep ensembles.

****

Single-shot General Hyper-parameter Optimization for Federated Learning

Yi Zhou,Parikshit Ram,Theodoros Salonidis,Nathalie Baracaldo,Horst Samulowitz,Heiko Ludwig

We address the problem of hyper-parameter optimization (HPO) for federated learning (FL-HPO). We introduce Federated Loss SuRface Aggregation (FLoRA), a general FL-HPO solution framework that can address use cases of tabular data and any Machine Learning (ML) model including gradient boosting training algorithms, SVMs, neural networks, among others and thereby further expands the scope of FL-HPO. FLoRA enables single-shot FL-HPO: identifying a single set of good hyper-parameters that are subsequently used in a single FL training. Thus, it enables FL-HPO solutions with minimal additional communication overhead compared to FL training without HPO. Utilizing standard smoothness assumptions, we theoretically characterize the optimality gap of FLoRA for any convex and non-convex loss functions, which explicitly accounts for the heterogeneous nature of the parties' local data distributions, a dominant characteristic of FL systems. Our empirical evaluation of FLoRA for multiple FL algorithms on seven OpenML datasets demonstrates significant model accuracy improvements over the baselines, and robustness to increasing number of parties involved in FL-HPO training.

Weakly-supervised HOI Detection via Prior-guided Bi-level Representation Learning

Bo Wan,Yongfei Liu,Desen Zhou,Tinne Tuytelaars,Xuming He

Human object interaction (HOI) detection plays a crucial role in human-centric s

cene understanding and serves as a fundamental building block for many vision tasks. One generalizable and scalable strategy for HOI detection is to use weak supervision, learning from image-level annotations only. This is inherently challenging due to ambiguous human-object associations, large search space of detecting HOIs and highly noisy training signal. A promising strategy to address those challenges is to exploit knowledge from large-scale pretrained models (e.g., CLIP), but a direct knowledge distillation strategy does not perform well on the weakly-supervised setting. In contrast, we develop a CLIP-guided HOI representation capable of incorporating the prior knowledge at both image level and HOI instance level, and adopt a self-taught mechanism to prune incorrect human-object associations. Experimental results on HICO-DET and V-COCO
show that our method outperforms the previous works by a sizable margin, showing the efficacy of our HOI representation.
****

Meta-learning Adaptive Deep Kernel Gaussian Processes for Molecular Property Prediction

Wenlin Chen,Austin Tripp,José Miguel Hernández-Lobato

We propose Adaptive Deep Kernel Fitting with Implicit Function Theorem (ADKF-IFT), a novel framework for learning deep kernel Gaussian processes (GPs) by interpolating between meta-learning and conventional deep kernel learning. Our approach employs a bilevel optimization objective where we meta-learn generally useful feature representations across tasks, in the sense that task-specific GP models estimated on top of such features achieve the lowest possible predictive loss on average. We solve the resulting nested optimization problem using the implicit function theorem (IFT). We show that our ADKF-IFT framework contains previously proposed Deep Kernel Learning (DKL) and Deep Kernel Transfer (DKT) as special cases. Although ADKF-IFT is a completely general method, we argue that it is especially well-suited for drug discovery problems and demonstrate that it significantly outperforms previous state-of-the-art methods on a variety of real-world few-shot molecular property prediction tasks and out-of-domain molecular property prediction and optimization tasks.
****

ERL-Re^2: Efficient Evolutionary Reinforcement Learning with Shared State Representation and Individual Policy Representation

Jianye HAO,Pengyi Li,Hongyao Tang,YAN ZHENG,Xian Fu,Zhaopeng Meng

Deep Reinforcement Learning (Deep RL) and Evolutionary Algorithm (EA) are two major paradigms of policy optimization with distinct learning principles, i.e., gradient-based v.s. gradient-free. An appealing research direction is integrating Deep RL and EA to devise new methods by fusing their complementary advantages. However, existing works on combining Deep RL and EA have two common drawbacks:1) the RL agent and EA agents learn their policies individually, neglecting efficient sharing of useful common knowledge; 2) parameter-level policy optimization guarantees no semantic level of behavior evolution for the EA side. In this paper, we propose Evolutionary Reinforcement Learning with Two-scale State Representation and Policy Representation (ERL-Re^2), a novel solution to the aforementioned two drawbacks. The key idea of ERL-Re^2 is two-scale representation: all EA and RL policies share the same nonlinear state representation while maintaining individual linear policy representations. The state representation conveys expressive common features of the environment learned by all the agents collectively; the linear policy representation provides a favorable space for efficient policy optimization, where novel behavior-level crossover and mutation operations can be performed. Moreover, the linear policy representation allows convenient generalization of policy fitness with the help of Policy-extended Value Function Approximator (PeVFA), further improving the sample efficiency of fitness estimation. The experiments on a range of continuous control tasks show that ERL-Re^2 consistently outperforms advanced baselines and achieves the State Of The Art (SOTA). Our code is available on https://github.com/yeshenpy/ERL-Re2.

Least-to-Most Prompting Enables Complex Reasoning in Large Language Models

Denny Zhou,Nathanael Schärli,Le Hou,Jason Wei,Nathan Scales,Xuezhi Wang,Dale Sch

uurmans,Claire Cui,Olivier Bousquet,Quoc V Le,Ed H. Chi
Although chain-of-thought prompting has shown impressive results on many natural language reasoning tasks, it often performs poorly on tasks which need to solve problems harder than the demonstration examples. To tackle such easy-to-hard generalization issues, we propose a novel prompting strategy, least-to-most prompting. It is implemented through two stage prompting: reducing a complex problem into a list of subproblems, and then sequentially solving these subproblems, whereby solving a given subproblem is facilitated by the answers to previously solved subproblems. Experiments on symbolic manipulation, compositional generalization and math reasoning show that least-to-most prompting can generalize to the examples that are harder than those seen in the prompt, and outperform chain-of-thought prompting by a large margin. A notable result is that the GPT-3 code-davinci-002 model with least-to-most-prompting solves the SCAN benchmark regardless of splits (such as length split) with an accuracy of 99.7% using 14 examples versus an accuracy of 16.2% by chain-of-thought prompting, and neural-symbolic models in the literature specialized for solving SCAN are trained with the full training set of more than 15,000 examples.
****
Deep Ensembles for Graphs with Higher-order Dependencies
Steven Krieg,William Burgis,Patrick Soga,Nitesh Chawla
Graph neural networks (GNNs) continue to achieve state-of-the-art performance on many graph learning tasks, but rely on the assumption that a given graph is a sufficient approximation of the true neighborhood structure. In the presence of higher-order sequential dependencies, we show that the tendency of traditional graph representations to underfit each node's neighborhood causes existing GNNs to generalize poorly. To address this, we propose a novel Deep Graph Ensemble (DGE), which captures neighborhood variance by training an ensemble of GNNs on different neighborhood subspaces of the same node within a higher-order network structure. We show that DGE consistently outperforms existing GNNs on semisupervised and supervised tasks on six real-world data sets with known higher-order dependencies, even under a similar parameter budget. We demonstrate that learning diverse and accurate base classifiers is central to DGE's success, and discuss the implications of these findings for future work on GNNs.
****
Simplicial Embeddings in Self-Supervised Learning and Downstream Classification
Samuel Lavoie,Christos Tsirigotis,Max Schwarzer,Ankit Vani,Michael Noukhovitch,Kenji Kawaguchi,Aaron Courville
Simplicial Embeddings (SEM) are representations learned through self-supervised learning (SSL), wherein a representation is projected into L simplices of V dimensions each using a \texttt{softmax} operation. This procedure conditions the representation onto a constrained space during pretraining and imparts an inductive bias for group sparsity. For downstream classification, we formally prove that the SEM representation leads to better generalization than an unnormalized representation.
Furthermore, we empirically demonstrate that SSL methods trained with SEMs have improved generalization on natural image datasets such as CIFAR-100 and ImageNet. Finally, when used in a downstream classification task, we show that SEM features exhibit emergent semantic coherence where small groups of learned features are distinctly predictive of semantically-relevant classes.

Lossless Filter Pruning via Adaptive Clustering for Convolutional Neural Networks
Tao Niu,Yinglei Teng,Panpan Zou,Yiding Liu
The filter pruning method introduces structural sparsity by removing selected filters and is thus particularly effective for reducing complexity. However, previous works face two common limitations. 1) The pruned filters are prevented from contributing to the final outputs, resulting in performance degradation, especially when it comes to a large pruning rate. 2) To recover accuracy, the time-consuming fine-tuning step is required. The cost in time and the need for training data make it difficult to deploy in real-world scenarios. To address the aforemen

tioned limitations, we propose a novel filter pruning method called Cluster Pruning (CP). Our CP reconstructs the redundant filters from the perspective of similarity and removes them equivalently using the proposed channel addition operation in a lossless manner. Pruning in such a way allows CP to preserve as many learned features as possible while getting rid of the need for fine-tuning. Specifically, each filter is first distinguished by clustering and then reconstructed as the centroid to which it belongs. Filters are then updated to eliminate the effect caused by mistakenly selected. After convergence, CP can equivalently remove identical filters through the proposed channel addition operation. The strategies for adjusting the pruning rate and the adaptive coefficient for clustering make our CP even smoother and more efficient. Extensive experiments on CIFAR-10 and ImageNet datasets show that our method achieves the best trade-off between performance and complexity compared with other state-of-the-art algorithms.

Vision Transformer Adapter for Dense Predictions

Zhe Chen,Yuchen Duan,Wenhai Wang,Junjun He,Tong Lu,Jifeng Dai,Yu Qiao

This work investigates a simple yet powerful dense prediction task adapter for Vision Transformer (ViT). Unlike recently advanced variants that incorporate vision-specific inductive biases into their architectures, the plain ViT suffers inferior performance on dense predictions due to weak prior assumptions. To address this issue, we propose the ViT-Adapter, which allows plain ViT to achieve comparable performance to vision-specific transformers. Specifically, the backbone in our framework is a plain ViT that can learn powerful representations from large-scale multi-modal data. When transferring to downstream tasks, a pre-training-free adapter is used to introduce the image-related inductive biases into the model, making it suitable for these tasks. We verify ViT-Adapter on multiple dense prediction tasks, including object detection, instance segmentation, and semantic segmentation. Notably, without using extra detection data, our ViT-Adapter-L yields state-of-the-art 60.9 box AP and 53.0 mask AP on COCO test-dev. We hope that the ViT-Adapter could serve as an alternative for vision-specific transformers and facilitate future research. Code and models will be released at https://github.com/czczup/ViT-Adapter.

Towards Understanding Why Mask Reconstruction Pretraining Helps in Downstream Tasks

Jiachun Pan,Pan Zhou,Shuicheng YAN

For unsupervised pretraining, mask-reconstruction pretraining (MRP) approaches, e.g. MAE and data2vec, randomly mask input patches and then reconstruct the pixels or semantic features of these masked patches via an auto-encoder. Then for a downstream task, supervised fine-tuning the pretrained encoder remarkably surpasses the conventional "supervised learning" (SL) trained from scratch. However, it is still unclear 1) how MRP performs semantic (feature) learning in the pretraining phase and 2) why it helps in downstream tasks. To solve these problems, we first theoretically show that on an auto-encoder of a two/one-layered convolution encoder/decoder, MRP can capture all discriminative semantics of each potential semantic class in the pretraining dataset. Then considering the fact that the pretraining dataset is of huge size and high diversity and thus covers most semantics in downstream dataset, in fine-tuning phase, the pretrained encoder can capture as much semantics as it can in downstream datasets, and would not lost these semantics with theoretical guarantees. In contrast, SL only randomly captures some semantics due to lottery ticket hypothesis. So MRP provably achieves better performance than SL on the classification tasks.   Experimental results testify to our data assumptions and also our theoretical implications.

Similarity and Generalization: from Noise to Corruption

Veronica Guidetti,Nayara Fonseca

Contrastive learning aims to extract distinctive features from data by finding an embedding representation where similar samples are close to each other, and different ones are far apart. We study how NNs generalize the concept of similarity in the presence of noise, investigating two phenomena: Double Descent (DD) beh avior and online/offline correspondence. While DD examines how the network adjusts to the dataset during a long training time or by increasing the number of parameters, online/offline correspondence compares the network performances varying the quality (diversity) of the dataset. We focus on the simplest contrastive learning representative: Siamese Neural Networks (SNNs). We point out that SNNs can be affected by two distinct sources of noise: Pair Label Noise (PLN) and Single Label Noise (SLN). The effect of SLN is asymmetric, but it preserves similarity relations, while PLN is symmetric but breaks transitivity. We find that DD also appears in SNNs and is exacerbated by noise. We show that the dataset topology crucially affects generalization. While sparse datasets show the same performances under SLN and PLN for an equal amount of noise, SLN outperforms PLN in the overparametrized region in dense datasets. Indeed, in this regime, PLN similarity violation becomes macroscopical, corrupting the dataset to the point where complete overfitting cannot be achieved. We call this phenomenon Density-Induced Break of Similarity (DIBS). Probing the equivalence between online optimization and offline generalization in SNNs, we find that their correspondence breaks down in the presence of label noise for all the scenarios considered.

MEGAN: Multi Explanation Graph Attention Network

Jonas Teufel,Luca Torresi,Patrick Nicholas Reiser,Pascal Friederich

Explainable artificial intelligence (XAI) methods are expected to improve trust during human-AI interactions, provide tools for model analysis and extend human understanding of complex problems. Attention-based models are an important subclass of XAI methods, partly due to their full differentiability and the potential to improve explanations by means of explanation-supervised training. We propose the novel multi-explanation graph attention network (MEGAN). Our graph regression and classification model features multiple explanation channels, which can be chosen independently of the task specifications. We first validate our model on a synthetic graph regression dataset, where our model produces single-channel explanations with quality similar to GNNExplainer. Furthermore, we demonstrate the advantages of multi-channel explanations on one synthetic and two real-world datasets: The prediction of water solubility of molecular graphs and sentiment classification of movie reviews. We find that our model produces explanations consistent with human intuition, opening the way to learning from our model in less well-understood tasks.

Practical Approaches for Fair Learning with Multitype and Multivariate Sensitive Attributes

Tennison Liu,Alex Chan,Boris van Breugel,Mihaela van der Schaar

It is important to guarantee that machine learning algorithms deployed in the real world do not result in unfairness or unintended social consequences. Fair ML has largely focused on the protection of single attributes in the simpler setting where both attributes and target outcomes are binary. However, the practical application in many a real-world problem entails the simultaneous protection of multiple sensitive attributes, which are often not simply binary, but continuous or categorical. To address this more challenging task, we introduce FairCOCCO, a fairness measure built on cross-covariance operators on reproducing kernel Hilbert Spaces. This leads to two practical tools: first, the FairCOCCO Score, a normalized metric that can quantify fairness in settings with single or multiple sensitive attributes of arbitrary type; and second, a subsequent regularization term that can be incorporated into arbitrary learning objectives to obtain fair predictors. These contributions address crucial gaps in the algorithmic fairness literature, and we empirically demonstrate consistent improvements against state-of-the-art techniques in balancing predictive power and fairness on real-world datasets.

Self-Supervised Category-Level Articulated Object Pose Estimation with Part-Level SE(3) Equivariance

Xueyi Liu,Ji Zhang,Ruizhen Hu,Haibin Huang,He Wang,Li Yi

Category-level articulated object pose estimation aims to estimate a hierarchy o f articulation-aware object poses of an unseen articulated object from a known category. To reduce the heavy annotations needed for supervised learning methods, we present a novel self-supervised strategy that solves this problem without any human labels. Our key idea is to factorize canonical shapes and articulated object poses from input articulated shapes through part-level equivariant shape analysis. Specifically, we first introduce the concept of part-level SE(3) equivariance and devise a network to learn features of such property. Then, through a carefully designed fine-grained pose-shape disentanglement strategy, we expect that canonical spaces to support pose estimation could be induced automatically. Thus, we could further predict articulated object poses as per-part rigid transformations describing how parts transform from their canonical part spaces to the camera space. Extensive experiments demonstrate the effectiveness of our method on both complete and partial point clouds from synthetic and real articulated object datasets.

Universal Mini-Batch Consistency for Set Encoding Functions

Jeffrey Ryan Willette,Bruno Andreis,Juho Lee,Sung Ju Hwang

Previous works have established solid foundations for neural set functions, complete with architectures which preserve the necessary properties for operating on sets, such as invariance to permutations of the set elements. Subsequent work has highlighted the utility of Mini-Batch Consistency (MBC), the ability to sequentially process any permutation of a set partition scheme (e.g. streaming chunks of data) while maintaining consistency guarantees on the output, although there are limited options for MBC architectures. We propose a framework which can convert an arbitrary non-MBC model to one which satisfies MBC. In doing so, we allow all set functions to universally be considered in an MBC setting (UMBC). Additionally, we explore a Monte Carlo dropout strategy made possible by our framework which allows performing Monte Carlo dropout on streaming sets while never seeing the entire set at once. We validate UMBC with theoretical proofs, unit tests, and also provide qualitative/quantitative experiments on Gaussian data, clean and corrupted point cloud classification, and amortized clustering on ImageNet. Additionally, we investigate the probabilistic calibration of set-functions under test-time distributional shifts. Our results demonstrate the utility of universal mini-batch consistency, and we further discover that our dropout strategy improves uncertainty calibration.

Divide to Adapt: Mitigating Confirmation Bias for Domain Adaptation of Black-Box Predictors

Jianfei Yang,Xiangyu Peng,Kai Wang,Zheng Zhu,Jiashi Feng,Lihua Xie,Yang You

Domain Adaptation of Black-box Predictors (DABP) aims to learn a model on an unlabeled target domain supervised by a black-box predictor trained on a source domain. It does not require access to both the source-domain data and the predictor parameters, thus addressing the data privacy and portability issues of standard domain adaptation methods. Existing DABP approaches mostly rely on knowledge distillation (KD) from the black-box predictor, i.e., training the model with its noisy target-domain predictions, which however inevitably introduces the confirmation bias accumulated from the prediction noises and leads to degrading performance. To mitigate such bias, we propose a new strategy, \textit{divide-to-adapt}, that purifies cross-domain knowledge distillation by proper domain division. This is inspired by an observation we make for the first time in domain adaptation: the target domain usually contains easy-to-adapt and hard-to-adapt samples that have different levels of domain discrepancy w.r.t. the source domain, and deep models tend to fit easy-to-adapt samples first. Leveraging easy-to-adapt samples with less noise can help KD alleviate the negative effect of prediction noises from black-box predictors. In this sense, the target domain can be divided into an easy-to-adapt subdomain with less noise and a hard-to-adapt subdomain at the early stage of training. Then the adaptation is achieved by semi-supervised learning. We further reduce distribution discrepancy between subdomains and develop weak-strong augmentation strategy to filter the predictor errors progressively. As such, our method is a simple yet effective solution to reduce error accumul ation in cross-domain knowledge distillation for DABP. Moreover, we prove that the target error of DABP is bounded by the noise ratio of two subdomains, i.e., the confirmation bias, which provides the theoretical justifications for our method. Extensive experiments demonstrate our method achieves state of the art on all DABP benchmarks, outperforming the existing best approach by 7.0\% on VisDA-17, and is even comparable with the standard domain adaptation methods that use the source-domain data.

Thalamus: a brain-inspired algorithm for biologically-plausible continual learning and disentangled representations

Ali Hummos

Animals thrive in a constantly changing environment and leverage the temporal structure to learn well-factorized causal representations. In contrast, traditional neural networks suffer from forgetting in changing environments and many methods have been proposed to limit forgetting with different trade-offs. Inspired by the brain thalamocortical circuit, we introduce a simple algorithm that uses optimization at inference time to generate internal representations of the current task dynamically. The algorithm alternates between updating the model weights and a latent task embedding, allowing the agent to parse the stream of temporal experience into discrete events and organize learning about them. On a continual learning benchmark, it achieves competitive end average accuracy by mitigating forgetting, but importantly, the interaction between the weights dynamics and the latent dynamics organizes knowledge into flexible structures with a cognitive interface to control them. Tasks later in the sequence can be solved through knowledge transfer as they become reachable within the well-factorized latent space. The algorithm meets many of the desiderata of an ideal continually learning agent in open-ended environments, and its simplicity suggests fundamental computations in circuits with abundant feedback control loops such as the thalamocortical circuits in the brain

A Generalized EigenGame With Extensions to Deep Multiview Representation Learning

James William Harvey Chapman,Ana Lawry Aguila,Lennie Wells

Generalized Eigenvalue Problems (GEPs) encompass a range of interesting scientific computing problems. Canonical Correlation Analysis (CCA) and Partial Least Squares (PLS) are two such examples of GEPs which are often used to learn representations of multiview data. Development of efficient stochastic approaches to these problems would allow them to scale to large datasets. Furthermore, existing deep learning based extensions of CCA require large minibatch sizes in the stochastic setting to achieve good performance. Inspired by recent formulations of Principal Components Analysis and GEPs as games with differentiable utilities, we develop an alternative game theoretic approach to solving GEPs in which all constraints are softly enforced by Lagrange multipliers. We show that our approach shares much of the theoretical grounding of the previous game theoretic approaches but has fewer hyperparameters, is faster to converge, and permits extension to general function approximators like neural networks for certain GEPs including CCA. We demonstrate the effectiveness of our method for solving GEPs using canonical multiview datasets and demonstrate state-of-the-art performance for the Deep CCA problem for multiview representation learning.

****

Deep Variational Implicit Processes

Luis A. Ortega,Simon Rodriguez Santana,Daniel Hernández-Lobato

Implicit processes (IPs) are a generalization of Gaussian processes (GPs). IPs may lack a closed-form expression but are easy to sample from. Examples include, among others, Bayesian neural networks or neural samplers. IPs can be used as priors over functions, resulting in flexible models with well-calibrated prediction uncertainty estimates. Methods based on IPs usually carry out function-space approximate inference, which overcomes some of the difficulties of parameter-space approximate inference. Nevertheless, the approximations employed often limit the expressiveness of the final model, resulting, e.g., in a Gaussian predictive distribution, which can be restrictive. We propose here a multi-layer generalization of IPs called the Deep Variational Implicit process (DVIP). This generalization is similar to that of deep GPs over GPs, but it is more flexible due to the use of IPs as the prior distribution over the latent functions. We describe a scalable variational inference algorithm for training DVIP and show that it outperforms previous IP-based methods and also deep GPs. We support these claims via extensive regression and classification experiments. We also evaluate DVIP on large datasets with up to several million data instances to illustrate its good scalability and performance.

Denoising Masked Autoencoders Help Robust Classification

QuanLin Wu,Hang Ye,Yuntian Gu,Huishuai Zhang,Liwei Wang,Di He

In this paper, we propose a new self-supervised method, which is called denoising masked autoencoders (DMAE), for learning certified robust classifiers of images. In DMAE, we corrupt each image by adding Gaussian noises to each pixel value and randomly masking several patches. A Transformer-based encoder-decoder model is then trained to reconstruct the original image from the corrupted one. In this learning paradigm, the encoder will learn to capture relevant semantics for the downstream tasks, which is also robust to Gaussian additive noises. We show that the pre-trained encoder can naturally be used as the base classifier in Gaussian smoothed models, where we can analytically compute the certified radius for any data point. Although the proposed method is simple, it yields significant performance improvement in downstream classification tasks. We show that the DMAE ViT-Base model, which just uses 1/10 parameters of the model developed in recent work (Carlini et al., 2022), achieves competitive or better certified accuracy in various settings. The DMAE ViT-Large model significantly surpasses all previous results, establishing a new state-of-the-art on ImageNet dataset. We further demonstrate that the pre-trained model has good transferability to the CIFAR-10 dataset, suggesting its wide adaptability. Models and code are available at https://github.com/quanlin-wu/dmae.

Estimating individual treatment effects under unobserved confounding using binary instruments

Dennis Frauen,Stefan Feuerriegel

Estimating conditional average treatment effects (CATEs) from observational data is relevant in many fields such as personalized medicine. However, in practice, the treatment assignment is usually confounded by unobserved variables and thus introduces bias. A remedy to remove the bias is the use of instrumental variables (IVs). Such settings are widespread in medicine (e.g., trials where the treatment assignment is used as binary IV). In this paper, we propose a novel, multiply robust machine learning framework, called MRIV, for estimating CATEs using binary IVs and thus yield an unbiased CATE estimator. Different from previous work for binary IVs, our framework estimates the CATE directly via a pseudo-outcome regression. (1)~We provide a theoretical analysis where we show that our framework yields multiple robust convergence rates: our CATE estimator achieves fast convergence even if several nuisance estimators converge slowly. (2)~We further show that our framework asymptotically outperforms state-of-the-art plug-in IV methods for CATE estimation, in the sense that it achieves a faster rate of convergence if the CATE is smoother than the individual outcome surfaces. (3)~We build upon our theoretical results and propose a tailored deep neural network architecture called MRIV-Net for CATE estimation using binary IVs. Across various computational experiments, we demonstrate empirically that our MRIV-Net achieves state-of-the-art performance. To the best of our knowledge, our MRIV is the first multiply robust machine learning framework tailored to estimating CATEs in the binary IV setting.

Approximate Bayesian Inference with Stein Functional Variational Gradient Descent

Tobias Pielok,Bernd Bischl,David Rügamer

We propose a general-purpose variational algorithm that forms a natural analogue of Stein variational gradient descent (SVGD) in function space. While SVGD successively updates a set of particles to match a target density, the method introduced here of Stein functional variational gradient descent (SFVGD) updates a set of particle functions to match a target stochastic process (SP). The update step is found by minimizing the functional derivative of the Kullback-Leibler divergence between SPs. SFVGD can either be used to train Bayesian neural networks (BNNs) or for ensemble gradient boosting. We show the efficacy of training BNNs with SFVGD on various real-world datasets.

Soundness and Completeness: An Algorithmic Perspective on Evaluation of Feature Attribution

Yawei Li,Yang Zhang,Bernd Bischl,Mina Rezaei

Feature attribution is a fundamental approach to explaining neural networks by quantifying the importance of input features for a model's prediction. Although a variety of feature attribution methods have been proposed, there is little consensus on the assessment of attribution methods. In this study, we empirically show the limitations of \emph{order-based} and \emph{model-retraining} metrics. To overcome the limitations and enable evaluation with higher granularity, we propose a novel method to evaluate the \emph{completeness} and \emph{soundness} of feature attribution methods. Our proposed evaluation metrics are mathematically grounded on algorithm theory and require no knowledge of "ground truth" informative features. We validate our proposed metrics by conducting experiments on synthetic and real-world datasets. Lastly, we use the proposed metrics to benchmark a wide range of feature attribution methods. Our evaluation results provide an innovative perspective on comparing feature attribution methods. Code is in the supplementary material.

SCoMoE: Efficient Mixtures of Experts with Structured Communication

zhiyuan zeng,Deyi Xiong

Mixture-of-Experts (MoE) models are promising architectures for massively multilingual neural machine translation and large language models due to the advantage of sublinear scaling. However, the training of large MoE models is usually bottlenecked by the all-to-all communication (Lepikhin et al., 2020). To reduce the communication cost, we propose SCoMoE, an MoE architecture with structured all-to-all communication, inspired by the hierarchical architecture of the communication topology. SCoMoE encourages data to be communicated across devices through fast intra-accelerator/node communication channels, reducing communication throughput in the slow inter-node communication channel. We slice the data on the sequence dimension (SCoMoE-Seq) into three communication groups and project the data on the feature dimension (SCoMoE-Feat) into low-dimensional representations. To compensate the potential performance drop caused by the routing locality in SCoMoE, we further propose a token clustering approach to aggregating related tokens from different devices before the MoE layers. The sigmoid gating in the balanced router used in the token clustering is substituted with the softmax gating with differential sorting. Experiments on bilingual and massively multilingual machine translation demonstrate that SCoMoE achieves a speedup of 1.44x over GShard with comparable performance, and substantially outperforms Gshard (2.8 BLEU) on OPUS-100 with a speedup of 1.25x.

****

Locally Invariant Explanations: Towards Stable and Unidirectional Explanations through Local Invariant Learning

Amit Dhurandhar,Karthikeyan Natesan Ramamurthy,Kartik Ahuja,Vijay Arya

Locally interpretable model agnostic explanations (LIME) method is one of the most popular methods used to explain black-box models at a per example level. Although many variants have been proposed, few provide a simple way to produce high fidelity explanations that are also stable and intuitive. In this work, we provide a novel perspective by proposing a model agnostic local explanation method inspired by the invariant risk minimization (IRM) principle -- originally proposed for (global) out-of-distribution generalization -- to provide such high fidelity explanations that are also stable and unidirectional across nearby examples. O

ur method is based on a game theoretic formulation where we theoretically show that our approach has a strong tendency to eliminate features where the gradient of the black-box function abruptly changes sign in the locality of the example we want to explain, while in other cases it is more careful and will choose a more conservative (feature) attribution, a behavior which can be highly desirable for recourse. Empirically, we show on tabular, image and text data that the quality of our explanations with neighborhoods formed using random perturbations are much better than LIME and in some cases even comparable to other methods that use realistic neighbors sampled from the data manifold. This is desirable given that learning a manifold to either create realistic neighbors or to project explanations is typically expensive or may even be impossible. Moreover, our algorithm is simple and efficient to train, and can ascertain stable input features for local decisions of a black-box without access to side information such as a (partial) causal graph as has been seen in some recent works.
****

PLOT: Prompt Learning with Optimal Transport for Vision-Language Models
Guangyi Chen,Weiran Yao,Xiangchen Song,Xinyue Li,Yongming Rao,Kun Zhang
With the increasing attention to large vision-language models such as CLIP, there has been a significant amount of effort dedicated to building efficient prompts. Unlike conventional methods of only learning one single prompt, we propose to learn multiple comprehensive prompts to describe diverse characteristics of categories such as intrinsic attributes or extrinsic contexts. However, directly matching each prompt to the same visual feature is problematic, as it pushes the prompts to converge to one point. To solve this problem, we propose to apply optimal transport to match the vision and text modalities. Specifically, we first model images and the categories with visual and textual feature sets. Then, we apply a two-stage optimization strategy to learn the prompts. In the inner loop, we optimize the optimal transport distance to align visual features and prompts by the Sinkhorn algorithm, while in the outer loop, we learn the prompts by this distance from the supervised data. Extensive experiments are conducted on the few-shot recognition task and the improvement demonstrates the superiority of our method. The code is available at https://github.com/CHENGY12/PLOT.

An Additive Instance-Wise Approach to Multi-class Model Interpretation
Vy Vo,Van Nguyen,Trung Le,Quan Hung Tran,Reza Haf,Seyit Camtepe,Dinh Phung
Interpretable machine learning offers insights into what factors drive a certain prediction of a black-box system. A large number of interpreting methods focus on identifying explanatory input features, which generally fall into two main categories: attribution and selection. A popular attribution-based approach is to exploit local neighborhoods for learning instance-specific explainers in an additive manner. The process is thus inefficient and susceptible to poorly-conditioned samples. Meanwhile, many selection-based methods directly optimize local feature distributions in an instance-wise training framework, thereby being capable of leveraging global information from other inputs. However, they can only interpret single-class predictions and many suffer from inconsistency across different settings, due to a strict reliance on a pre-defined number of features selected. This work exploits the strengths of both methods and proposes a framework for learning local explanations simultaneously for multiple target classes. Our model explainer significantly outperforms additive and instance-wise counterparts on faithfulness with more compact and comprehensible explanations. We also demonstrate the capacity to select stable and important features through extensive experiments on various data sets and black-box model architectures.

Knowledge-Consistent Dialogue Generation with Language Models and Knowledge Graphs
Minki Kang,Jin Myung Kwak,Jinheon Baek,Sung Ju Hwang
Pre-trained language models have achieved impressive performances on dialogue generation tasks. However, when generating responses for a conversation that requires factual knowledge, they are far from perfect, due to the absence of mechanisms to retrieve, encode, and reflect the knowledge in the generated responses. So

me knowledge-grounded dialogue generation methods tackle this problem by leveraging the structured knowledge from Knowledge Graphs (KGs). However, existing methods do not guarantee that the model utilizes a relevant piece of knowledge from the KG before generating knowledge-consistent dialogues. To overcome this limitation, we propose SUbgraph Retrieval-augmented GEneration (SURGE), a framework for generating context-relevant and knowledge-consistent dialogues with a KG. Specifically, our method first retrieves the relevant subgraph from the KG, and then enforces consistency across facts by perturbing their word embeddings conditioned on the retrieved subgraph. Then, it learns a latent representation space using contrastive learning which ensures that the generated texts have high similarity to the retrieved subgraphs. We validate the performance of our SURGE framework on the OpendialKG and KOMODIS datasets and show that our method generates high-quality dialogues that faithfully reflect the knowledge from the KG.

Towards Semi-Supervised Learning with Non-Random Missing Labels

Yue Duan,Zhen Zhao,Lei Qi,Luping Zhou,Lei Wang,Yinghuan Shi

Semi-supervised learning (SSL) tackles the label missing problem by enabling the effective usage of unlabeled data. While existing SSL methods focus on the traditional setting, a practical and challenging scenario called label Missing Not At Random (MNAR) is usually ignored. In MNAR, the labeled and unlabeled data fall into different class distributions resulting in biased label imputation, which deteriorates the performance of SSL models. In this work, class transition tracking based Pseudo-Rectifying Guidance (PRG) is devised for MNAR. We explore the class-level guidance information obtained by the Markov random walk, which is modeled on a dynamically created graph built over the class tracking matrix. PRG unifies the history information of each class transition caused by the pseudo-rectifying procedure to activate the model's enthusiasm for neglected classes, so as the quality of pseudo-labels on both popular classes and rare classes in MNAR could be improved. We show the superior performance of PRG across a variety of the MNAR scenarios and the conventional SSL setting, outperforming the latest SSL solutions by a large margin. Checkpoints and evaluation code are available at the anonymous link https://anonymous.4open.science/r/PRG4SSL-MNAR-8DE2 while the source code will be available upon paper acceptance.

DASHA: Distributed Nonconvex Optimization with Communication Compression and Optimal Oracle Complexity

Alexander Tyurin,Peter Richtárik

We develop and analyze DASHA: a new family of methods for nonconvex distributed optimization problems. When the local functions at the nodes have a finite-sum or an expectation form, our new methods, DASHA-PAGE, DASHA-MVR and DASHA-SYNC-MVR, improve the theoretical oracle and communication complexity of the previous state-of-the-art method MARINA by Gorbunov et al. (2020). In particular, to achieve an $\varepsilon$-stationary point, and considering the random sparsifier Rand$K$ as an example, our methods compute the optimal number of gradients $\mathcal{O}\left(\frac{\sqrt{m}}{\varepsilon\sqrt{n}}\right)$ and $\mathcal{O}\left(\frac{\sigma}{\varepsilon^{3/2}n}\right)$ in finite-sum and expectation form cases, respectively, while maintaining the SOTA communication complexity $\mathcal{O}\left(\frac{d}{\varepsilon \sqrt{n}}\right)$. Furthermore, unlike MARINA, the new methods DASHA, DASHA-PAGE and DASHA-MVR send compressed vectors only, which makes them more practical for federated learning. We extend our results to the case when the functions satisfy the Polyak-Lojasiewicz condition. Finally, our theory is corroborated in practice: we see a significant improvement in experiments with nonconvex classification and training of deep learning models.

****

LDMIC: Learning-based Distributed Multi-view Image Coding

Xinjie Zhang,Jiawei Shao,Jun Zhang

Multi-view image compression plays a critical role in 3D-related applications. Existing methods adopt a predictive coding architecture, which requires joint encoding to compress the corresponding disparity as well as residual information. This demands collaboration among cameras and enforces the epipolar geometric cons traint between different views, which makes it challenging to deploy these methods in distributed camera systems with randomly overlapping fields of view. Meanwhile, distributed source coding theory indicates that efficient data compression of correlated sources can be achieved by independent encoding and joint decoding, which motivates us to design a learning-based distributed multi-view image coding (LDMIC) framework. With independent encoders, LDMIC introduces a simple yet effective joint context transfer module based on the cross-attention mechanism at the decoder to effectively capture the global inter-view correlations, which is insensitive to the geometric relationships between images. Experimental results show that LDMIC significantly outperforms both traditional and learning-based MIC methods while enjoying fast encoding speed. Code is released at https://github.com/Xinjie-Q/LDMIC.

Additive Poisson Process: Learning Intensity of Higher-Order Interaction in Poisson Processes

Simon Luo,Feng Zhou,lamiae azizi,Mahito Sugiyama

We present the Additive Poisson Process (APP), a novel framework that can model the higher-order interaction effects of the intensity functions in Poisson processes using projections into lower-dimensional space. Our model combines the techniques in information geometry to model higher-order interactions on a statistical manifold and in generalized additive models to use lower-dimensional projections to overcome the effects from the curse of dimensionality. Our approach solves a convex optimization problem by minimizing the KL divergence from a sample distribution in lower-dimensional projections to the distribution modeled by an intensity function in the Poisson process. Our empirical results show that our model is able to use samples observed in the lower dimensional space to estimate the higher-order intensity function with extremely sparse observations.

Sound Randomized Smoothing in Floating-Point Arithmetic

Vaclav Voracek,Matthias Hein

Randomized smoothing is sound when using infinite precision. However, we show that randomized smoothing is no longer sound for limited floating-point precision. We present a simple example where randomized smoothing certifies a radius of 1.26 around a point, even though there is an adversarial example in the distance 0.8 and show how this can be abused to give false certificates for CIFAR10. We discuss the implicit assumptions of randomized smoothing and show that they do not apply to generic image classification models whose smoothed versions are commonly certified. In order to overcome this problem, we propose a sound approach to randomized smoothing when using floating-point precision with essentially equal speed for quantized input. It yields sound certificates or image classifiers which for the ones tested so far are very similar to the unsound practice of randomized smoothing. Our only assumption is that we have access to a fair coin.

Assessing Model Out-of-distribution Generalization with Softmax Prediction Probability Baselines and A Correlation Method

Weijie Tu,Weijian Deng,Tom Gedeon,Liang Zheng

This paper studies the use of Softmax prediction to assess model generalization under distribution shift. Specifically, given an out-of distribution (OOD) test set and a pool of classifiers, we aim to develop a Softmax prediction-based measure which has a monotonic relationship with OOD generalization performance. We first show existing uncertainty measures (e.g., entropy and maximum Softmax prediction) are fairly useful of predicting generalization in some OOD scenarios. We then move ahead with proposing a new measure, Softmax Correlation (SoftmaxCorr). To obtain the SoftmaxCorr score for a classifier, we compute the class-class correlation matrix from all the Softmax vectors in a test set, and then its cosine similarity with an identity matrix. We show that the class-class correlation matrix reveals significant knowledge about the confusion matrix: its high similarity with the identity matrix means predictions have low confusion (uncertainty) and evenly cover all classes, and vice versa. Across three setups including Image

Net, CIFAR-10, and WILDS, we show that SoftmaxCorr is well predictive of model accuracy on both in-distribution and OOD datasets.

Collaborative Pure Exploration in Kernel Bandit

Yihan Du,Wei Chen,Yuko Kuroki,Longbo Huang

In this paper, we propose a novel Collaborative Pure Exploration in Kernel Bandit model (CoPE-KB), where multiple agents collaborate to complete different but related tasks with limited communication. Our model generalizes prior CoPE formulation with the single-task and classic MAB setting to allow multiple tasks and general reward structures. We propose a novel communication scheme with an efficient kernelized estimator, and design optimal algorithms CoKernelFC and CoKernelFB for CoPE-KB with fixed-confidence and fixed-budget objectives, respectively. Nearly matching upper and lower bounds in both sampling and communication complexity are established to demonstrate the optimality of our algorithms. Our theoretical results explicitly quantify how task similarities influence learning speedup, and only depend on the effective dimension of feature space. Our novel techniques including an efficient kernelized estimator and linear structured instance transformation, which overcome the communication difficulty in high-dimensional feature space and derive communication round lower bounds, can be of independent interests.

Provably Efficient Risk-Sensitive Reinforcement Learning: Iterated CVaR and Worst Path

Yihan Du,Siwei Wang,Longbo Huang

In this paper, we study a novel episodic risk-sensitive Reinforcement Learning (RL) problem, named Iterated CVaR RL, which aims to maximize the tail of the reward-to-go at each step, and focuses on tightly controlling the risk of getting into catastrophic situations at each stage. This formulation is applicable to real-world tasks that demand strong risk avoidance throughout the decision process, such as autonomous driving, clinical treatment planning and robotics. We investigate two performance metrics under Iterated CVaR RL, i.e., Regret Minimization and Best Policy Identification. For both metrics, we design efficient algorithms ICVaR-RM and ICVaR-BPI, respectively, and provide nearly matching upper and lower bounds with respect to the number of episodes K. We also investigate an interesting limiting case of Iterated CVaR RL, called Worst Path RL, where the objective becomes to maximize the minimum possible cumulative reward. For Worst Path RL, we propose an efficient algorithm with constant upper and lower bounds. Finally, the techniques we develop for bounding the change of CVaR due to the value function shift and decomposing the regret via a distorted visitation distribution are novel, and can find applications in other risk-sensitive online learning problems.

FedREP: A Byzantine-Robust, Communication-Efficient and Privacy-Preserving Framework for Federated Learning

Yi-Rui Yang,Kun Wang,Wu-Jun Li

Federated learning (FL) has recently become a hot research topic, in which Byzantine robustness, communication efficiency and privacy preservation are three important aspects. However, the tension among these three aspects makes it hard to simultaneously take all of them into account. In view of this challenge, we theoretically analyze the conditions that a communication compression method should satisfy to be compatible with existing Byzantine-robust methods and privacy-preserving methods. Motivated by the analysis results, we propose a novel communication compression method called consensus sparsification (ConSpar). To the best of our knowledge, ConSpar is the first communication compression method that is designed to be compatible with both Byzantine-robust methods and privacy-preserving methods. Based on ConSpar, we further propose a novel FL framework called FedREP, which is Byzantine-robust, communication-efficient and privacy-preserving. We theoretically prove the Byzantine robustness and the convergence of FedREP. Empirical results show that FedREP can significantly outperform communication-efficient privacy-preserving baselines. Furthermore, compared with Byzantine-robust communication-efficient baselines, FedREP can achieve comparable accuracy with an extra advantage of privacy preservation.

Few-Shot Transferable Robust Representation Learning via Bilevel Attacks

Hyeonjeong Ha,Minseon Kim,Sung Ju Hwang

Existing adversarial learning methods for enhancing the robustness of deep neural networks assume the availability of a large amount of data from which we can generate adversarial examples. However, in an adversarial meta-learning setting, the model needs to train with only a few adversarial examples to learn a robust model for unseen tasks, which is a very difficult goal to achieve. Further, learning transferable robust representations for unseen domains is a difficult problem even with a large amount of data. To tackle such a challenge, we propose a novel adversarial self-supervised meta-learning framework with bilevel attacks which aims to learn robust representations that can generalize across tasks and domains. Specifically, in the inner loop, we update the parameters of the given encoder by taking inner gradient steps using two different sets of augmented samples, and generate adversarial examples for each view by maximizing the instance classification loss. Then, in the outer loop, we meta-learn the encoder parameter to maximize the agreement between the two adversarial examples, which enables it to learn robust representations. We experimentally validate the effectiveness of our approach on unseen domain adaptation tasks, on which it achieves impressive performance. Specifically, our method significantly outperforms the state-of-the-art meta-adversarial learning methods on few-shot learning tasks, as well as self-supervised learning baselines in standard learning settings with large-scale datasets.

****

Targeted Adversarial Self-Supervised Learning

Minseon Kim,Hyeonjeong Ha,Sooel Son,Sung Ju Hwang

Recently, unsupervised adversarial training (AT) has been extensively studied to attain robustness with the models trained upon unlabeled data. To this end, previous studies have applied existing supervised adversarial training techniques to self-supervised learning (SSL) frameworks. However, all have resorted to untargeted adversarial learning as obtaining targeted adversarial examples is unclear in the SSL setting lacking of label information. In this paper, we propose a novel targeted adversarial training method for the SSL frameworks. Specifically, we propose a target selection algorithm for the adversarial SSL frameworks; it is designed to select the most confusing sample for each given instance based on similarity and entropy, and perturb the given instance toward the selected target sample. Our method significantly enhances the robustness of an SSL model without requiring large batches of images or additional models, unlike existing works aimed at achieving the same goal. Moreover, our method is readily applicable to general SSL frameworks that only uses positive pairs. We validate our method on benchmark datasets, on which it obtains superior robust accuracies, outperforming existing unsupervised adversarial training methods.

NIERT: Accurate Numerical Interpolation through Unifying Scattered Data Representations using Transformer Encoder

Shizhe Ding,Dongbo Bu

Numerical interpolation for scattered data, i.e., estimating values for target points based on those of some observed points, is widely used in computational science and engineering. The existing approaches either require explicitly pre-defined basis functions, which makes them inflexible and limits their performance in practical scenarios, or train neural networks as interpolators, which still have limited interpolation accuracy as they treat observed and target points separately and cannot effectively exploit the correlations among data points. Here, we present a learning-based approach to numerical interpolation for scattered data using encoder representation of Transformers (called NIERT). Unlike the recent learning-based approaches, NIERT treats observed and target points in a unified fashion through embedding them into the same representation space, thus gaining the advantage of effectively exploiting the correlations among them. The spec ially-designed partial self-attention mechanism used by NIERT makes it escape from the unexpected interference of target points on observed points. We further show that the partial self-attention is essentially a learnable interpolation module combining multiple neural basis functions, which provides interpretability of NIERT. Through pre-training on large-scale synthetic datasets, NIERT achieves considerable improvement in interpolation accuracy for practical tasks. On both synthetic and real-world datasets, NIERT outperforms the existing approaches, e.g., on the TFRD-ADlet dataset for temperature field reconstruction, NIERT achieves an MAE of 1.897×10^{-3}, substantially better than the state-of-the-art approach (MAE: 27.074×10^{-3}). The source code of NIERT is available at https://anonymous.4open.science/r/NIERT-2BCF.

Triplet Similarity Learning on Concordance Constraint

Jiansheng Fang,Jiajian Li,Jiang Liu

Triplet-based loss functions have been the paradigm of choice for robust deep metric learning (DML). However, conventional triplet-based losses require carefully tuning a decision boundary, i.e., violation margin. When performing online triplet mining on each mini-batch, choosing a good global and constant prior value for violation margin is challenging and irrational. To circumvent this issue, we propose a novel yet efficient concordance-induced triplet (CIT) loss as an objective function to train DML models. We formulate the similarity of triplet samples as a concordance constraint problem, then directly optimize concordance during DML model learning. Triplet concordance refers to the predicted ordering of intra-class and inter-class similarities being correct, which is invariant to any monotone transformation of the decision boundary of triplet samples. Hence, our CIT loss is free from the plague of adopting the violation margin as a prior constraint. In addition, due to the high training complexity of triplet-based losses, we introduce a partial likelihood term for CIT loss to impose additional penalties on hard triplet samples, thus enforcing fast convergence. We extensively experiment on a variety of DML tasks to demonstrate the elegance and simplicity of our CIT loss against its counterparts. In particular, on face recognition, person re-identification, as well as image retrieval datasets, our method can achieve comparable performances with state-of-the-arts without tuning any hyper-parameters laboriously.

Temporal Label Smoothing for Early Prediction of Adverse Events

Hugo Yèche,Alizée Pace,Gunnar Ratsch,Rita Kuznetsova

Models that can predict adverse events ahead of time with low false-alarm rates are critical to the acceptance of decision support systems in the medical community. This challenging machine learning task remains typically treated as a simple binary classification, with few bespoke methods proposed to leverage temporal dependency across samples. We propose Temporal Label Smoothing (TLS), a novel learning strategy that modulates smoothing strength as a function of proximity to the event of interest. This regularization technique reduces model confidence at the class boundary, where the signal is often noisy or uninformative, thus allowing training to focus on clinically informative data points away from this boundary region. From a theoretical perspective, we also show that our method can be framed as an extension of multi-horizon prediction, a learning heuristic proposed in other early prediction work. TLS empirically matches or outperforms all competitor methods across all evaluation measures on various early prediction benchmark tasks. In particular, our approach significantly improves performance on clinically-relevant metrics such as event recall under low false-alarm rates.

Test-Time Robust Personalization for Federated Learning

Liangze Jiang,Tao Lin

Federated Learning (FL) is a machine learning paradigm where many clients collaboratively learn a shared global model with decentralized training data. Personalization on FL models additionally adapts the global model to different clients, achieving promising results on consistent local training & test distributions. However, for real-world personalized FL applications, it is crucial to go one ste p further: robustifying FL models under the evolving local test set during deployment, where various types of distribution shifts can arise. In this work, we identify the pitfalls of existing works under test-time distribution shifts and propose Federated Test-time Head Ensemble plus tuning (FedTHE+), which personalizes FL models with robustness to various test-time distribution shifts. We illustrate the advancement of FedTHE+ (and its degraded computationally efficient variant FedTHE) over strong competitors, for training various neural architectures (CNN, ResNet, and Transformer) on CIFAR10 and ImageNet and evaluating on diverse test distributions. Along with this, we build a benchmark for assessing the performance and robustness of personalized FL methods during deployment. Code: \url{https://github.com/LINs-lab/FedTHE}.

What's Wrong with the Robustness of Object Detectors?

ZiYi Dong,Pengxu Wei,Liang Lin

Despite tremendous successes achieved, object detection models confront the vulnerability to adversarial attacks. Even with imperceptible adversarial perturbations in images, they probably yield erroneous detection predictions, posing a threat to various realistic applications, e.g., medical diagnosis and automatic driving. Although some existing methods can improve the adversarial robustness of detectors, they still suffer from the detection robustness bottleneck: the significant performance degradation on clean images and the limited robustness on adversarial images. In this paper, we conduct empirically a comprehensive investigation on what's wrong with the robustness of object detectors in four different seminal architectures, i.e., two-stage, one-stage, anchor-free, and Transformer-based detectors, inspiring more research interest on this task. We also devise a Detection Confusion Matrix (DCM) and Classification-Ablative Validation (ClsAVal) for further detection robustness analyses. We explore underlying factors that account for robustness bottleneck. It is empirically demonstrated that robust detectors have reliable localization robustness and poor classification robustness. The classification module easily mis-classifies the foreground objects into the background. Furthermore, Robust Derformable-DETR suffers from a poor classification and localization robustness. Our source codes, trained models, and detailed experiment results will be publicly available.

LAVA: Data Valuation without Pre-Specified Learning Algorithms

Hoang Anh Just,Feiyang Kang,Tianhao Wang,Yi Zeng,Myeongseob Ko,Ming Jin,Ruoxi Jia

Traditionally, data valuation is posed as a problem of equitably splitting the validation performance of a learning algorithm among the training data. As a result, the calculated data values depend on many design choices of the underlying learning algorithm. However, this dependence is undesirable for many use cases of data valuation, such as setting priorities over different data sources in a data acquisition process and informing pricing mechanisms in a data marketplace. In these scenarios, data needs to be valued before the actual analysis and the choice of the learning algorithm is still undetermined then. Another side-effect of the dependence is that to assess the value of individual points, one needs to re-run the learning algorithm with and without a point, which incurs a large computation burden.

This work leapfrogs over the current limits of data valuation methods by introducing a new framework that can value training data in a way that is oblivious to the downstream learning algorithm. Our main results are as follows. $\textbf{(1)}$ We develop a proxy for the validation performance associated with a training set based on a non-conventional $\textit{class-wise}$ $\textit{Wasserstein distance}$ between the training and the validation set. We show that the distance characterizes the upper bound of the validation performance for any given model under certain Lipschitz conditions. $\textbf{(2)}$ We develop a novel method to value individual data based on the sensitivity analysis of the $\textit{class-wise}$ Wasserstein distance. Importantly, these values can be directly obtained $\tex

tit{for free}$ from the output of off-the-shelf optimization solvers once the Wasserstein distance is computed. $\textbf{(3) }$We evaluate our new data valuation framework over various use cases related to detecting low-quality data
and show that, surprisingly, the learning-agnostic feature of our framework enables a $\textit{significant improvement}$ over the state-of-the-art performance while being $\textit{orders of magnitude faster.}$
****
FONDUE: an Algorithm to Find the Optimal Dimensionality of the Latent Representations of Variational Autoencoders
Lisa Bonheme,Marek Grzes
When training a variational autoencoder (VAE) on a given dataset, determining the optimal number of latent variables is mostly done by grid search: a costly process in terms of computational time and carbon footprint.
In this paper, we explore the intrinsic dimension estimation (IDE) of the data and latent representations learned by VAEs.
We show that the discrepancies between the IDE of the mean and sampled representations of a VAE after only a few steps of training reveal the presence of passive variables in the latent space, which, in well-behaved VAEs, indicates a superfluous number of dimensions.
Using this property, we propose FONDUE: an algorithm which quickly finds the number of latent dimensions after which the mean and sampled representations start to diverge (i.e., when passive variables are introduced), providing a principled method for selecting the number of latent dimensions for VAEs and autoencoders.
****
How do Variational Autoencoders Learn? Insights from Representational Similarity
Lisa Bonheme,Marek Grzes
The ability of Variational Autoencoders (VAEs) to learn disentangled representations has made them popular for practical applications. However, their behaviour is not yet fully understood. For example, the questions of when they can provide disentangled representations, or suffer from posterior collapse are still areas of active research. Despite this, there are no layerwise comparisons of the representations learned by VAEs, which would further our understanding of these models. In this paper, we thus look into the internal behaviour of VAEs using representational similarity techniques. Specifically, using the CKA and Procrustes similarities, we found that the encoders' representations are learned long before the decoders', and this behaviour is independent of hyperparameters, learning objectives, and datasets. Moreover, the encoders' representations in all but the mean and variance layers are similar across hyperparameters and learning objectives.

Meta-prediction Model for Distillation-Aware NAS on Unseen Datasets
Hayeon Lee,Sohyun An,Minseon Kim,Sung Ju Hwang
Distillation-aware Network Architecture Search (DaNAS) aims to search for an optimal student architecture that obtains the best performance and/or efficiency when distilling the knowledge from a given teacher model. Previous DaNAS methods have mostly tackled the search for the network architecture for fixed source/target tasks and the teacher, which are not generalized well on a new task, thus need to perform a costly search for any new combination of the domains and the teachers. For standard NAS tasks without KD, meta-learning-based computationally efficient NAS methods have been proposed, which learn the generalized search process over multiple tasks and transfer the knowledge obtained over those tasks to a new task. However, since they assume learning from scratch without KD from a teacher, they might not be ideal for DaNAS scenarios, which could significantly affect the final performances of the architectures obtained from the search. To eliminate the excessive computational cost of DaNAS methods and the sub-optimality of rapid NAS
methods, we propose a distillation-aware meta accuracy prediction model, DaSS (Distillation-aware Student Search), which can predict a given architecture’s final performances on a dataset when performing KD with a given teacher, without having actually to train it on the target task. The experimental results demonstrat

e that our proposed meta-prediction model successfully generalizes to multiple unseen datasets for DaNAS tasks, largely outperforming existing meta-NAS methods and rapid NAS baselines. Code is available at https://github.com/CownowAn/DaSS.

Manifold Characteristics That Predict Downstream Task Performance

Ruan Henry Van der Merwe,Gregory Newman,Etienne Barnard

Pretraining methods are typically compared by evaluating the accuracy of linear classifiers, transfer learning performance, or visually inspecting the representation manifold's (RM) lower-dimensional projections. We show that the differences between methods can be understood more clearly by investigating the RM directly, which allows for a more detailed comparison. To this end, we propose a framework and new metric to measure and compare different RMs. We also investigate and report on the RM characteristics for various pretraining methods. These characteristics are measured by applying sequentially larger local alterations to the input data, using white noise injections and Projected Gradient Descent (PGD) adversarial attacks, and then tracking each datapoint. We calculate the total distance moved for each datapoint and the relative change in distance between successive alterations. We show that self-supervised methods learn an RM where alterations lead to large but constant size changes, indicating a smoother RM than fully supervised methods. We then combine these measurements into one metric, the Representation Manifold Quality Metric (RMQM), where larger values indicate larger and less variable step sizes, and show that RMQM correlates positively with performance on downstream tasks.

Context Autoencoder for Self-Supervised Representation Learning

Xiaokang Chen,Mingyu Ding,Xiaodi Wang,Ying Xin,Shentong Mo,Yunhao Wang,Shumin Han,Ping Luo,Gang Zeng,Jingdong Wang

We present a novel masked image modeling (MIM) approach, context autoencoder (CAE), for self-supervised representation pretraining. The goal is to pretrain an encoder by solving the pretext task: estimate the masked patches from the visible patches in an image. Our approach first feeds the visible patches into the encoder, extracting the representations. Then, we make predictions from visible patches to masked patches in the encoded representation space. We introduce an alignment constraint, encouraging that the representations for masked patches, predicted from the encoded representations of visible patches, are aligned with the masked patch presentations computed from the encoder. In other words, the predicted representations are expected to lie in the encoded representation space, which empirically shows the benefit to representation learning. Last, the predicted masked patch representations are mapped to the targets of the pretext task through a decoder.

One additional characteristic is that our approach encourages the separation of the representation learning part (encoder), and the pretext task completion part that will be replaced by the downstream task part. In contrast, previous MIM methods (e.g., BEiT and MAE) couple the two parts, potentially limiting the representation learning quality. We demonstrate the effectiveness of our CAE through superior transfer performance in downstream tasks: semantic segmentation, and object detection and instance segmentation.

Learning to Linearize Deep Neural Networks for Secure and Efficient Private Inference

Souvik Kundu,Shunlin Lu,Yuke Zhang,Jacqueline Tiffany Liu,Peter Anthony Beerel

The large number of ReLU non-linearity operations in existing deep neural networks makes them ill-suited for latency-efficient private inference (PI). Existing techniques to reduce ReLU operations often involve manual effort and sacrifice significant accuracy. In this paper, we first present a novel measure of non-linearity layers’ ReLU sensitivity, enabling mitigation of the time-consuming manual efforts in identifying the same. Based on this sensitivity, we then present SENet, a three-stage training method that for a given ReLU budget, automatically assigns per-layer ReLU counts, decides the ReLU locations for each layer’s activation map, and trains a model with significantly fewer ReLUs to potentially yield latency and communication efficient PI. Experimental evaluations with multiple models on various datasets show SENet’s superior performance both in terms of reduced ReLUs and improved classification accuracy compared to existing alternatives. In particular, SENet can yield models that require up to ~2× fewer ReLUs while yielding similar accuracy. For a similar ReLU budget SENet can yield models with ~2.32% improved classification accuracy, evaluated on CIFAR-100.

****

Wasserstein Fair Autoencoders

Sungdong Lee,Hyunjong Lee,Joong-Ho Won

Autoencoders, or nonlinear factor models parameterized by neural networks, have become an indispensable tool for generative modeling and representation learning in high dimensions. Imposing structural constraints such as conditional independence on the latent variables (representation, or factors) in order to capture invariance or fairness with autoencoders has been attempted through adding ad hoc penalties to the loss function mostly in the variational autoencoder (VAE) context, often based on heuristic arguments. In this paper, we demonstrate that Wasserstein autoencoders (WAEs) are highly flexible in embracing structural constraints. Well-known extensions of VAEs for this purpose are gracefully handled within the framework of the seminal result by Tolstikhin et al. (2018). In particular, given a conditional independence structure of the generative model (decoder), corresponding encoder structure and penalties are induced from the functional constraints that define the WAE. This property of WAEs opens up a principled way of penalizing autoencoders to impose structural constraints. Utilizing this generative model structure, we present results on fair representation and conditional generation tasks, and compare them with other preceding methods.

Denoising Diffusion Error Correction Codes

Yoni Choukroun,Lior Wolf

Error correction code (ECC) is an integral part of the physical communication layer, ensuring reliable data transfer over noisy channels.

Recently, neural decoders have demonstrated their advantage over classical decoding techniques.

However, recent state-of-the-art neural decoders suffer from high complexity and lack the important iterative scheme characteristic of many legacy decoders.

In this work, we propose to employ denoising diffusion models for the soft decoding of linear codes at arbitrary block lengths.

Our framework models the forward channel corruption as a series of diffusion steps that can be reversed iteratively.

Three contributions are made: (i) a diffusion process suitable for the decoding setting is introduced, (ii) the neural diffusion decoder is conditioned on the number of parity errors, which indicates the level of corruption at a given step, (iii) a line search procedure based on the code's syndrome obtains the optimal reverse diffusion step size.

The proposed approach demonstrates the power of diffusion models for ECC and is able to achieve state-of-the-art accuracy, outperforming the other neural decoders by sizable margins, even for a single reverse diffusion step.

****

Progressive Purification for Instance-Dependent Partial Label Learning

Ning Xu,Biao Liu,Jiaqi Lv,Congyu Qiao,Xin Geng

Partial-label learning (PLL) aims to train multi-class classifiers from instances with partial labels (PLs)---a PL for an instance is a set of candidate labels where a fixed but unknown candidate is the true label. In the last few years, the instance-independent generation process of PLs has been extensively studied, on the basis of which many practical and theoretical advances have been made in PLL, while relatively less attention has been paid to the practical setting of instance-dependent PLs, namely, the PL depends not only on the true label but the instance itself. In this paper, we propose a theoretically grounded and practically effective approach called progressive purification (POP) for instance-dependent PLL: in each epoch, POP updates the learning model while purifies each PL by progressively moving out false candidate labels for the next epoch of the model training. Theoretically, we prove that POP enlarges the region where the model is reliable by a promising rate, and eventually approximates the Bayes optimal classifier with mild assumptions; technically, POP is flexible with arbitrary losses and compatible with deep networks, so the previous advanced PLL losses can be embedded in it and the performance is often significantly improved.

****

Meta Knowledge Condensation for Federated Learning

Ping Liu,Xin Yu,Joey Tianyi Zhou

Existing federated learning paradigms usually extensively exchange distributed models, rather than original data, at a central solver to achieve a more powerful model. However, this would incur severe communication burden between a server and multiple clients especially when data distributions are heterogeneous. As a result, current federated learning methods often require plenty of communication rounds in training. Unlike existing paradigms, we introduce an alternative perspective to significantly decrease the federate learning communication cost without leaking original data. In this work, we first present a meta knowledge representation method that extracts meta knowledge from distributed clients. The extracted meta knowledge encodes essential information that can be used to improve the current model. As the training progresses, the contributions of the same training samples to a federated model should also vary. Thus, we introduce a dynamic weight assignment mechanism that enables informative samples to contribute adaptively to the current model update. Then, informative meta knowledge from all active clients is sent to the server for model update. Training model on the combined meta knowledge that is regarded as a condense form of original data can significantly mitigate the heterogeneity issues. Moreover, to further ameliorate data heterogeneity, we also exchange meta knowledge among clients as conditional initialisation for meta knowledge extraction. Extensive experiments demonstrate the effectiveness and efficiency of our proposed method. Remarkably, our method outperforms the state-of-the-art by a large margin (from 74.07% to 92.95%) on MNIST with a restricted communication budget (\textit{i.e.}, 10 rounds).

****

Improved Fully Quantized Training via Rectifying Batch Normalization

Kaixin Xu,Jie Lin,Zhe Wang,Peng Hu,Ziyuan Zhao

Quantization-aware Training (QAT) is able to reduce the training cost by quantizing neural network weights and activations in the forward pass and improve the speed at the inference stage. QAT can be extended to Fully-Quantized Training (FQT), which further accelerates the training by quantizing gradients in the backward pass as back-propagation typically occupies half of the training time. Unfortunately, gradient quantization is challenging as Stochastic Gradient Descent (SGD) based training is sensitive to the precision of the gradient signal. Particularly, the noise introduced by gradient quantization accumulates during backward pass, which causes the exploding gradient problem and results in unstable training and significant accuracy drop. Though Batch Normalization (BatchNorm) is a de-facto resort to stabilize training in regular full-precision scenario, we observe that it fails to prevent the gradient explosion when gradient quantizers are injected in the backward pass. Surprisingly, our theory shows that BatchNorm could amplify the noise accumulation, which in turn hastens the explosion of gradients. A BatchNorm rectification method is derived from our theory to suppress the amplification effect and bridge the performance gap between full-precision training and FQT. Adding this simple rectification loss to baselines generates better results than most prior FQT algorithms on various neural network architectures and datasets, regardless of the gradient bit-widths used (8,4, and 2 bits).

Exploring Active 3D Object Detection from a Generalization Perspective

Yadan Luo,Zhuoxiao Chen,Zijian Wang,Xin Yu,Zi Huang,Mahsa Baktashmotlagh

To alleviate the high annotation cost in LiDAR-based 3D object detection, active learning is a promising solution that learns to select only a small portion of unlabeled data to annotate, without compromising model performance. Our empirical study, however, suggests that mainstream uncertainty-based and diversity-based active learning policies are not effective when applied in the 3D detection tas

k, as they fail to balance the trade-off between point cloud informativeness and box-level annotation costs. To overcome this limitation, we jointly investigate three novel criteria in our framework CRB for point cloud acquisition - label conciseness, feature representativeness and
geometric balance, which hierarchically filters out the point clouds of redundant 3D bounding box labels, latent features and geometric characteristics (e.g., point cloud density) from the unlabeled sample pool and greedily selects informative ones with fewer objects to annotate. Our theoretical analysis demonstrates that the proposed criteria aligns the marginal distributions of the selected subset and the prior distributions of the unseen test set, and minimizes the upper bound of the generalization error. To validate the effectiveness and applicability of CRB, we conduct extensive experiments on the two benchmark 3D object detection datasets of KITTI and Waymo and examine both one-stage (i.e., Second) and two-stage 3D detector (i.e., PV-RCNN). Experiments evidence that the proposed approach outperforms existing active learning strategies and achieves fully supervised performance requiring 1% and 8% annotations of bounding boxes and point clouds, respectively.

Masked Frequency Modeling for Self-Supervised Visual Pre-Training
Jiahao Xie,Wei Li,Xiaohang Zhan,Ziwei Liu,Yew-Soon Ong,Chen Change Loy
We present Masked Frequency Modeling (MFM), a unified frequency-domain-based approach for self-supervised pre-training of visual models. Instead of randomly inserting mask tokens to the input embeddings in the spatial domain, in this paper, we shift the perspective to the frequency domain. Specifically, MFM first masks out a portion of frequency components of the input image and then predicts the missing frequencies on the frequency spectrum. Our key insight is that predicting masked components in the frequency domain is more ideal to reveal underlying image patterns rather than predicting masked patches in the spatial domain, due to the heavy spatial redundancy. Our findings suggest that with the right configuration of mask-and-predict strategy, both the structural information within high-frequency components and the low-level statistics among low-frequency counterparts are useful in learning good representations. For the first time, MFM demonstrates that, for both ViT and CNN, a simple non-Siamese framework can learn meaningful representations even using none of the following: (i) extra data, (ii) extra model, (iii) mask token. Experimental results on image classification and semantic segmentation, as well as several robustness benchmarks show the competitive performance and advanced robustness of MFM compared with recent masked image modeling approaches. Furthermore, we also comprehensively investigate the effectiveness of classical image restoration tasks for representation learning from a unified frequency perspective and reveal their intriguing relations with our MFM approach. Project page: https://www.mmlab-ntu.com/project/mfm/index.html.

Dynamic Prompt Learning via Policy Gradient for Semi-structured Mathematical Reasoning
Pan Lu,Liang Qiu,Kai-Wei Chang,Ying Nian Wu,Song-Chun Zhu,Tanmay Rajpurohit,Peter Clark,Ashwin Kalyan
Mathematical reasoning, a core ability of human intelligence, presents unique challenges for machines in abstract thinking and logical reasoning. Recent large pre-trained language models such as GPT-3 have achieved remarkable progress on mathematical reasoning tasks written in text form, such as math word problems (MWP). However, it is unknown if the models can handle more complex problems that involve math reasoning over heterogeneous information, such as tabular data. To fill the gap, we present Tabular Math Word Problems (TabMWP), a new dataset containing 38,431 open-domain grade-level problems that require mathematical reasoning on both textual and tabular data. Each question in TabMWP is aligned with a tabular context, which is presented as an image, semi-structured text, and a structured table. There are two types of questions: free-text and multi-choice, and each problem is annotated with gold solutions to reveal the multi-step reasoning process. We evaluate different pre-trained models on TabMWP, including the GPT-3 model in a few-shot setting. As earlier studies suggest, since few-shot GPT-3 re

lies on the selection of in-context examples, its performance is unstable and can degrade to near chance. The unstable issue is more severe when handling complex problems like TabMWP. To mitigate this, we further propose a novel approach, PromptPG, which utilizes policy gradient to learn to select in-context examples from a small amount of training data and then constructs the corresponding prompt for the test example. Experimental results show that our method outperforms the best baseline by 5.31% on the accuracy metric and reduces the prediction variance significantly compared to random selection, which verifies its effectiveness in selecting in-context examples. The data and code are available at https://promptpg.github.io.

Lottery Aware Sparsity Hunting: Enabling Federated Learning on Resource-Limited Edge

Sara Babakniya,Souvik Kundu,Saurav Prakash,Yue Niu,Salman Avestimehr

Limited computation and communication capabilities of clients pose significant challenges in federated learning (FL) over resource-limited edge nodes. A potential solution to this problem is to deploy off-the-shelf sparse learning algorithms that train a binary sparse mask on each client with the expectation of training a consistent sparse server mask yielding sparse weight tensors. However, as we investigate in this paper, such naive deployments result in a significant drop in accuracy compared to FL with dense models, especially for clients with limited resource budgets. In particular, our investigations reveal a serious lack of consensus among the trained sparsity masks on clients, which prevents convergence for the server mask and potentially leads to a substantial drop in model performance. Based on such key observations, we propose federated lottery aware sparsity hunting (FLASH), a unified sparse learning framework to make the server win a lottery in terms of yielding a sparse sub-model, able to maintain classification performance under highly resource-limited client settings. Moreover, to support FL on different devices requiring different parameter density, we leverage our findings to present hetero-FLASH, where clients can have different target sparsity budgets based on their device resource limits. Experimental evaluations with multiple models on various datasets (both IID and non-IID) show superiority of our models in closing the gap with unpruned baseline while yielding up to ~10.1% improved accuracy with ~10.26x fewer communication costs, compared to existing alternatives, at similar hyperparameter settings.

Neuro-Symbolic Procedural Planning with Commonsense Prompting

Yujie Lu,Weixi Feng,Wanrong Zhu,Wenda Xu,Xin Eric Wang,Miguel Eckstein,William Yang Wang

Procedural planning aims to implement complex high-level goals by decomposition into simpler low-level steps. Although procedural planning is a basic skill set for humans in daily life, it remains a challenge for large language models (LLMs) that lack a deep understanding of the cause-effect relations in procedures. Previous methods require manual exemplars to acquire procedural planning knowledge from LLMs in the zero-shot setting. However, such elicited pre-trained knowledge in LLMs induces spurious correlations between goals and steps, which impair the model generalization to unseen tasks. In contrast, this paper proposes a neuro-symbolic procedural PLANner (PLAN) that elicits procedural planning knowledge from the LLMs with commonsense-infused prompting. To mitigate spurious goal-step correlations, we use symbolic program executors on the latent procedural representations to formalize prompts from commonsense knowledge bases as a causal intervention toward the Structural Causal Model. Both automatic and human evaluations on WikiHow and RobotHow show the superiority of PLAN on procedural planning without further training or manual exemplars.

Learning Object-Language Alignments for Open-Vocabulary Object Detection

Chuang Lin,Peize Sun,Yi Jiang,Ping Luo,Lizhen Qu,Gholamreza Haffari,Zehuan Yuan,Jianfei Cai

Existing object detection methods are bounded in a fixed-set vocabulary by costly labeled data. When dealing with novel categories, the model has to be retraine d with more bounding box annotations. Natural language supervision is an attractive alternative for its annotation-free attributes and broader object concepts. However, learning open-vocabulary object detection from language is challenging since image-text pairs do not contain fine-grained object-language alignments. Previous solutions rely on either expensive grounding annotations or distilling classification-oriented vision models. In this paper, we propose a novel open-vocabulary object detection framework directly learning from image-text pair data. We formulate object-language alignment as a set matching problem between a set of image region features and a set of word embeddings. It enables us to train an open-vocabulary object detector on image-text pairs in a much simple and effective way. Extensive experiments on two benchmark datasets, COCO and LVIS, demonstrate our superior performance over the competing approaches on novel categories, e.g. achieving 32.0% mAP on COCO and 21.7% mask mAP on LVIS. Code will be released.

Phase transition for detecting a small community in a large network

Jiashun Jin,Tracy Ke,Paxton Turner,Anru Zhang

How to detect a small community in a large network is an interesting problem, including clique detection as a special case, where a naive degree-based χ^2-test was shown to be powerful in the presence of an Erdös-Renyi (ER) background. Using Sinkhorn's theorem, we show that the signal captured by the χ^2-test may be a modeling artifact, and it may disappear once we replace the Erdös-Renyi model by a broader network model. We show that the recent SgnQ test is more appropriate for such a setting. The test is optimal in detecting communities with sizes comparable to the whole network, but has never been studied for our setting, which is substantially different and more challenging. Using a degree-corrected block model (DCBM), we establish phase transitions of this testing problem concerning the size of the small community and the edge densities in small and large communities. When the size of the small community is larger than $\sqrt{n}$, the SgnQ test is optimal for it attains the computational lower bound (CLB), the information lower bound for methods allowing polynomial computation time. When the size of the small community is smaller than $\sqrt{n}$, we establish the parameter regime where the SgnQ test has full power and make some conjectures of the CLB. We also study the classical information lower bound (LB) and show that there is always a gap between the CLB and LB in our range of interest. ■

On the Word Boundaries of Emergent Languages Based on Harris's Articulation Scheme

Ryo Ueda,Taiga Ishii,Yusuke Miyao

This paper shows that emergent languages in signaling games lack meaningful word boundaries in terms of Harris's Articulation Scheme (HAS), a universal property of natural language. Emergent Languages are artificial communication protocols arising among agents. However, it is not obvious whether such a simulated language would have the same properties as natural language. In this paper, we test if they satisfy HAS. HAS states that word boundaries can be obtained solely from phonemes in natural language. We adopt HAS-based word segmentation and verify whether emergent languages have meaningful word segments. The experiment suggested they do not have, although they meet some preconditions for HAS. We discovered a gap between emergent and natural languages to be bridged, indicating that the standard signaling game satisfies prerequisites but is still missing some necessary ingredients.

TempCLR: Temporal Alignment Representation with Contrastive Learning

Yuncong Yang,Jiawei Ma,Shiyuan Huang,Long Chen,Xudong Lin,Guangxing Han,Shih-Fu Chang

Video representation learning has been successful in video-text pre-training for zero-shot transfer, where each sentence is trained to be close to the paired video clips in a common feature space. For long videos, given a paragraph of description where the sentences describe different segments of the video, by matching all sentence-clip pairs, the paragraph and the full video are aligned implicit ly. However, such unit-level similarity measure may ignore the global temporal context over a long time span, which inevitably limits the generalization ability. In this paper, we propose a contrastive learning framework TempCLR to compare the full video and the paragraph explicitly. As the video/paragraph is formulated as a sequence of clips/sentences, under the constraint of their temporal order, we use dynamic time warping to compute the minimum cumulative cost over sentence-clip pairs as the sequence-level distance. To explore the temporal dynamics, we break the consistency of temporal order by shuffling the video clips or sentences according to the temporal granularity. In this way, we obtain the representations for clips/sentences, which perceive the temporal information and thus facilitate the sequence alignment. In addition to pre-training on the video and paragraph, our approach can also generalize on the matching between different video instances. We evaluate our approach on video retrieval, action step localization, and few-shot action recognition, and achieve consistent performance gain over all three tasks. Detailed ablation studies are provided to justify the approach design.

Generative Augmented Flow Networks

Ling Pan,Dinghuai Zhang,Aaron Courville,Longbo Huang,Yoshua Bengio

The Generative Flow Network is a probabilistic framework where an agent learns a stochastic policy for object generation, such that the probability of generating an object is proportional to a given reward function. Its effectiveness has been shown in discovering high-quality and diverse solutions, compared to reward-maximizing reinforcement learning-based methods. Nonetheless, GFlowNets only learn from rewards of the terminal states, which can limit its applicability. Indeed, intermediate rewards play a critical role in learning, for example from intrinsic motivation to provide intermediate feedback even in particularly challenging sparse reward tasks. Inspired by this, we propose Generative Augmented Flow Networks (GAFlowNets), a novel learning framework to incorporate intermediate rewards into GFlowNets. We specify intermediate rewards by intrinsic motivation to tackle the exploration problem in sparse reward environments. GAFlowNets can leverage edge-based and state-based intrinsic rewards in a joint way to improve exploration. Based on extensive experiments on the GridWorld task, we demonstrate the effectiveness and efficiency of GAFlowNet in terms of convergence, performance, and diversity of solutions. We further show that GAFlowNet is scalable to a more complex and large-scale molecule generation domain, where it achieves consistent and significant performance improvement.

Inferring Fluid Dynamics via Inverse Rendering

Jinxian Liu,Ye Chen,Bingbing Ni,Jiyao Mao,Zhenbo Yu

Humans have a strong intuitive understanding of physical processes such as fluid falling by just a glimpse of such a scene picture, i.e., quickly derived from our immersive visual experiences in memory. This work achieves such a photo-to-fluid-dynamics reconstruction functionality learned from unannotated videos, without any supervision of ground-truth fluid dynamics. In a nutshell, a differentiable Euler simulator modeled with a ConvNet-based pressure projection solver, is integrated with a volumetric renderer, supporting end-to-end/coherent differentiable dynamic simulation and rendering. By endowing each sampled point with a fluid volume value, we derive a NeRF-like differentiable renderer dedicated from fluid data; and thanks to this volume-augmented representation, fluid dynamics could be inversely inferred from error signal between the rendered result and ground-truth video frame (i.e., inverse rendering). Experiments on our generated Fluid Fall datasets and DPI Dam Break dataset are conducted to demonstrate both effectiveness and generalization ability of our method.

How Does Value Distribution in Distributional Reinforcement Learning Help Optimization?

Ke Sun,Bei Jiang,Linglong Kong

We consider the problem of learning a set of probability distributions from the Bellman dynamics in distributional reinforcement learning~(RL) that learns the w hole return distribution compared with only its expectation in classical RL. Despite its success to obtain superior performance, we still have a poor understanding of how the value distribution in distributional RL works. In this study, we analyze the optimization benefits of distributional RL by leverage of additional value distribution information over classical RL in the Neural Fitted Z-Iteration~(Neural FZI) framework. To begin with, we demonstrate that the distribution loss of distributional RL has desirable smoothness characteristics and hence enjoys stable gradients, which is in line with its tendency to promote optimization stability. Furthermore, the acceleration effect of distributional RL is revealed by decomposing the return distribution. It turns out that distributional RL can perform favorably if the value distribution approximation is appropriate, measured by the variance of gradient estimates in each environment for any specific distributional RL algorithm. Rigorous experiments validate the stable optimization behaviors of distributional RL, contributing to its acceleration effects compared to classical RL. The findings of our research illuminate how the value distribution in distributional RL algorithms helps the optimization.

Bort: Towards Explainable Neural Networks with Bounded Orthogonal Constraint

Borui Zhang,Wenzhao Zheng,Jie Zhou,Jiwen Lu

Deep learning has revolutionized human society, yet the black-box nature of deep neural networks hinders further application to reliability-demanded industries. In the attempt to unpack them, many works observe or impact internal variables to improve the comprehensibility and invertibility of the black-box models. However, existing methods rely on intuitive assumptions and lack mathematical guarantees. To bridge this gap, we introduce Bort, an optimizer for improving model explainability with boundedness and orthogonality constraints on model parameters, derived from the sufficient conditions of model comprehensibility and invertibility. We perform reconstruction and backtracking on the model representations optimized by Bort and observe a clear improvement in model explainability. Based on Bort, we are able to synthesize explainable adversarial samples without additional parameters and training. Surprisingly, we find Bort constantly improves the classification accuracy of various architectures including ResNet and DeiT on MNIST, CIFAR-10, and ImageNet. Code: https://github.com/zbr17/Bort.

Interpreting Distributional Reinforcement Learning: A Regularization Perspective

Ke Sun,Yingnan Zhao,Yi Liu,Enze Shi,Yafei Wang,Xiaodong Yan,Bei Jiang,Linglong Kong

Distributional reinforcement learning~(RL) is a class of state-of-the-art algorithms that estimate the entire distribution of the total return rather than its expected value alone. The theoretical advantages of distributional RL over expectation-based RL remain elusive, despite the remarkable performance of distributional RL. Our work attributes the superiority of distributional RL to its regularization effect stemming from the value distribution information regardless of only its expectation. We decompose the value distribution into its expectation and the remaining distribution part using a variant of the gross error model in robust statistics. Hence, distributional RL has an additional benefit over expectation-based RL thanks to the impact of a \textit{risk-sensitive entropy regularization} within the Neural Fitted Z-Iteration framework. Meanwhile, we investigate the role of the resulting regularization in actor-critic algorithms by bridging the risk-sensitive entropy regularization of distributional RL and the vanilla entropy in maximum entropy RL. It reveals that distributional RL induces an augmented reward function, which promotes a risk-sensitive exploration against the intrinsic uncertainty of the environment. Finally, extensive experiments verify the importance of the regularization effect in distributional RL, as well as the mutual impacts of different entropy regularizations. Our study paves the way towards a better understanding of distributional RL, especially when looked at through a regularization lens.

The Power of Regularization in Solving Extensive-Form Games

Mingyang Liu,Asuman E. Ozdaglar,Tiancheng Yu,Kaiqing Zhang

In this paper, we investigate the power of {\it regularization}, a common technique in reinforcement learning and optimization, in solving extensive-form games (EFGs). We propose a series of new algorithms based on regularizing the payoff functions of the game, and establish a set of convergence results that strictly improve over the existing ones, with either weaker assumptions or stronger convergence guarantees. In particular, we first show that dilated optimistic mirror descent (DOMD), an efficient variant of OMD for solving EFGs, with adaptive regularization can achieve a fast $\tilde O(1/T)$ last-iterate convergence in terms of duality gap and distance to the set of Nash equilibrium (NE) without uniqueness assumption of the NE. Second, we show that regularized counterfactual regret minimization (\texttt{Reg-CFR}), with a variant of optimistic mirror descent algorithm as regret-minimizer, can achieve $O(1/T^{1/4})$ best-iterate, and $O(1/T^{3/4})$ average-iterate convergence rate for finding NE in EFGs. Finally, we show that \texttt{Reg-CFR} can achieve asymptotic last-iterate convergence, and optimal $O(1/T)$ average-iterate convergence rate, for finding the NE of perturbed EFGs, which is useful for finding approximate extensive-form perfect equilibria (EFPE). To the best of our knowledge, they constitute the first last-iterate convergence results for CFR-type algorithms, while matching the state-of-the-art average-iterate convergence rate in finding NE for non-perturbed EFGs. We also provide numerical results to corroborate the advantages of our algorithms.

Neural Topic Modeling with Embedding Clustering Regularization
Xiaobao Wu,Xinshuai Dong,Thong Thanh Nguyen,Anh Tuan Luu

Topic models have been prevalent for decades with various applications like automatic text analysis due to their effectiveness and interpretability. However, existing topic models commonly suffer from the notorious topic collapsing issue: the discovered topics semantically collapse towards each other, leading to highly repetitive topics, insufficient topic discovery, and damaged model interpretability. In this paper, we propose a new neural topic model, Embedding Clustering Regularization Topic Model (ECRTM), to solve the topic collapsing issue. In addition to the reconstruction error of existing work, we propose a novel Embedding Clustering Regularization (ECR), which forces each topic embedding to be the center of a separately aggregated word embedding cluster in the semantic space. Instead of collapsing together, this makes topic embeddings away from each other and cover different semantics of word embeddings. Thus our ECR enables each produced topic to contain distinct word semantics, which alleviates topic collapsing. Through jointly optimizing our ECR objective and the neural topic modeling objective, ECRTM generates diverse and coherent topics together with high-quality topic distributions of documents. Extensive experiments on benchmark datasets demonstrate that ECRTM effectively addresses the topic collapsing issue and consistently surpasses state-of-the-art baselines in terms of topic quality, topic distributions of documents, and downstream classification tasks.

Distributional Reinforcement Learning via Sinkhorn Iterations
Ke Sun,Yingnan Zhao,Yi Liu,Wulong Liu,Bei Jiang,Linglong Kong

Distributional reinforcement learning~(RL) is a class of state-of-the-art algorithms that estimate the entire distribution of the total return rather than only its expectation. The empirical success of distributional RL is determined by the representation of return distributions and the choice of distribution divergence. In this paper, we propose a new class of \textit{Sinkhorn distributional RL~(SinkhornDRL)} algorithm that learns a finite set of statistics, i.e., deterministic samples, from each return distribution and then uses Sinkhorn iterations to evaluate the Sinkhorn distance between the current and target Bellmen distributions. Sinkhorn divergence features as the interpolation between the Wasserstein distance and Maximum Mean Discrepancy~(MMD). SinkhornDRL finds a sweet spot by taking advantage of the geometry of optimal transport-based distance and the unbiased gradient estimate property of MMD. Finally, compared to state-of-the-art algorithms, SinkhornDRL's competitive performance is demonstrated on the suit of 55 Atari games.

Contextual Symbolic Policy For Meta-Reinforcement Learning

Jiaming Guo,Rui Zhang,Shaohui Peng,Qi Yi,Xing Hu,Ruizhi Chen,Kehan Long,Zidong Du,Xishan Zhang,Ling Li,Qi Guo,Yunji Chen

Context-based Meta-Reinforcement Learning (Meta-RL), which conditions the RL agent on the context variables, is a powerful method for learning a generalizable agent.

Current context-based Meta-RL methods often construct their contextual policy with a neural network (NN) and directly take the context variables as a part of the input. However, the NN-based policy contains tremendous parameters which possibly result in overfitting, the difficulty of deployment and poor interpretability.

To improve the generation ability, efficiency and interpretability, we propose a novel Contextual Symbolic Policy (CSP) framework, which generates contextual policy with a symbolic form based on the context variables for unseen tasks in meta-RL. Our key insight is that the symbolic expression is capable of capturing complex relationships by composing various operators and has a compact form that helps strip out irrelevant information. Thus, the CSP learns to produce symbolic policy for meta-RL tasks and extract the essential common knowledge to achieve higher generalization ability. Besides, the symbolic policies with a compact form are efficient to be deployed and easier to understand.

In the implementation, we construct CSP as a gradient-based framework to learn the symbolic policy from scratch in an end-to-end and differentiable way. The symbolic policy is represented by a symbolic network composed of various symbolic operators. We also employ a path selector to decide the proper symbolic form of the policy and a parameter generator to produce the coefficients of the symbolic policy. Empirically, we evaluate the proposed CSP method on several Meta-RL tasks and demonstrate that the contextual symbolic policy achieves higher performance and efficiency and shows the potential to be interpretable.

MLPInit: Embarrassingly Simple GNN Training Acceleration with MLP Initialization

Xiaotian Han,Tong Zhao,Yozen Liu,Xia Hu,Neil Shah

Training graph neural networks (GNNs) on large graphs is complex and extremely time consuming. This is attributed to overheads caused by sparse matrix multiplication, which are sidestepped when training multi-layer perceptrons (MLPs) with only node features. MLPs, by ignoring graph context, are simple and faster for graph data, however they usually sacrifice prediction accuracy, limiting their applications for graph data. We observe that for most message passing-based GNNs, we can trivially derive an analog MLP (we call this a PeerMLP) with an equivalent weight space, by setting the trainable parameters with the same shapes, making us curious about how do GNNs using weights from a fully trained PeerMLP perform? Surprisingly, we find that GNNs initialized with such weights significantly outperform their PeerMLPs, motivating us to use PeerMLP training as a precursor, initialization step to GNN training. To this end, we propose an embarrassingly simple, yet hugely effective initialization method for GNN training acceleration, called \mlpinit. Our extensive experiments on multiple large-scale graph datasets with diverse GNN architectures validate that MLPInit can accelerate the training of GNNs (up to 33× speedup on OGB-Products) and often improve prediction performance (e.g., up to 7.97% improvement for GraphSAGE across 7 datasets for node classification, and up to 17.81% improvement across 4 datasets for link prediction on metric Hits@10). The code is available at https://github.com/snap-research/MLPInit-for-GNNs.

Progressively Compressed Auto-Encoder for Self-supervised Representation Learning

Jin Li,Yaoming Wang,XIAOPENG ZHANG,Yabo Chen,Dongsheng Jiang,Wenrui Dai,Chenglin Li,Hongkai Xiong,Qi Tian

As a typical self-supervised learning strategy, Masked Image Modeling (MIM) is driven by recovering all masked patches from visible ones. However, patches from the same image are highly correlated and it is redundant to reconstruct all the masked patches. We find that this redundancy is neglected by existing MIM based methods and causes non-negligible overheads in computation that do not necessarily benefit self-supervised representation. In this paper, we present a novel approach named PCAE, short for Progressively Compressed AutoEncoder, to address the redundant reconstruction issue by progressively compacting tokens and only retaining necessary information for forward propagation and reconstruction. In particular, we identify those redundant tokens in an image via a simple yet effective similarity metric between each token with the mean of the token sequence. Those redundant tokens that other ones can probably represent are progressively dropped accordingly during the forward propagation, and importantly, we only focus on reconstructing these retained tokens. As a result, we are able to achieve a better trade-off between performance and efficiency for pre-training. Besides, benefitting from the flexible strategy, PCAE can be also directly employed for downstream fine-tuning tasks and enable scalable deployment. Experiments show that PCAE achieves comparable performance to MAE with only 1/8 GPU days. The code is available at https://github.com/caddyless/PCAE/.

ConBaT: Control Barrier Transformer for Safety-Critical Policy Learning

Yue Meng,Sai Vemprala,Rogerio Bonatti,Chuchu Fan,Ashish Kapoor

Large-scale self-supervised models have recently revolutionized our ability to perform a variety of tasks within the vision and language domains. However, using such models for autonomous systems is challenging because of safety requirements: besides executing correct actions, an autonomous agent needs to also avoid high cost and potentially fatal critical mistakes. Traditionally, self-supervised training mostly focuses on imitating previously observed behaviors, and the training demonstrations carry no notion of which behaviors should be explicitly avoided. In this work, we propose Control Barrier Transformer (ConBaT), an approach that learns safe behaviors from demonstrations in a self-supervised fashion. ConBaT is inspired by the concept of control barrier functions in control theory and uses a causal transformer that learns to predict safe robot actions autoregressively using a critic that requires minimal safety data labeling. During deployment, we employ a lightweight online optimization to find actions that can ensure future states lie within the safe set. We apply our approach to different simulated control tasks and show that our method results in safer control policies compared to other classical and learning-based methods.

****

Robust Transfer Learning Based on Minimax Principle

Xinyi Tong,Xiangxiang Xu,Shao-Lun Huang,Lizhong Zheng

The similarity between target and source tasks is a crucial quantity for theoretical analyses and algorithm designs in transfer learning studies. However, this quantity is often difficult to be precisely captured. To address this issue, we make a boundedness assumption on the task similarity and then propose a mathematical framework based on the minimax principle, which minimizes the worst-case expected population risk under this assumption. Furthermore, our proposed minimax problem can be solved analytically, which provides a guideline for designing robust transfer learning models. According to the analytical expression, we interpret the influences of sample sizes, task distances, and the model dimensionality in knowledge transferring. Then, practical algorithms are developed based on the theoretical results. Finally, experiments conducted on image classification tasks show that our approaches can achieve robust and competitive accuracies under random selections of training sets.

Interpreting Neural Networks Through the Lens of Heat Flow

Rui Xia,Fan Yang,Liang Sun

Machine learning models are often developed in a way that prioritizes task-specific performance but defers the understanding of how they actually work. This is especially true nowadays for deep neural networks. In this paper, we step back and consider the basic problem of understanding a learned model represented as a smooth scalar-valued function. We introduce HeatFlow, a framework based upon the heat diffusion process for interpreting the multi-scale behavior of the model a round a test point. At its core, our approach looks into the heat flow initialized at the function of interest, which generates a family of functions with increasing smoothness. By applying differential operators to these smoothed functions, summary statistics (i.e., explanations) characterizing the original model on different scales can be drawn. We place an emphasis on studying the heat flow on data manifold, where the model is trained and expected to be well behaved. Numeric approximation procedures for implementing the proposed method in practice are discussed and demonstrated on image recognition tasks.

****

Efficient Surrogate Gradients for Training Spiking Neural Networks

Hao Lin,Shikuang Deng,Shi Gu

Spiking Neural Network (SNN) is widely regarded as one of the next-generation neural network infrastructures, yet it suffers from an inherent non-differentiable problem that makes the traditional backpropagation (BP) method infeasible. Surrogate gradients (SG), which are an approximation to the shape of the Dirac's δ-function, can help alleviate this issue to some extent. To our knowledge, the majority of research, however, keep a fixed surrogate gradient for all layers, ignorant of the fact that there exists a trade-off between the approximation to the delta function and the effective domain of gradients under the given dataset, hence limiting the efficiency of surrogate gradients and impairing the overall model performance. To guide the shape optimization in applying surrogate gradients for training SNN, we propose an indicator χ, which represents the proportion of parameters with non-zero gradients in backpropagation. Further we present a novel χ-based training pipeline that adaptively makes trade-offs between the surrogate gradients' shapes and its effective domain, followed by a series of ablation experiments for verification. Our algorithm achieves 69.09\% accuracy on the ImageNet dataset using SEW-ResNet34 - a 2.05\% absolute improvement from baseline. Moreover, our method only requires extremely low external cost and can be simply integrated into the existing training procedure.

The Trade-off between Universality and Label Efficiency of Representations from Contrastive Learning

Zhenmei Shi,Jiefeng Chen,Kunyang Li,Jayaram Raghuram,Xi Wu,Yingyu Liang,Somesh Jha

Pre-training representations (a.k.a. foundation models) has recently become a prevalent learning paradigm, where one first pre-trains a representation using large-scale unlabeled data, and then learns simple predictors on top of the representation using small labeled data from the downstream tasks. There are two key desiderata for the representation: label efficiency (the ability to learn an accurate classifier on top of the representation with a small amount of labeled data) and universality (usefulness across a wide range of downstream tasks). In this paper, we focus on one of the most popular instantiations of this paradigm: contrastive learning with linear probing, i.e., learning a linear predictor on the representation pre-trained by contrastive learning. We show that there exists a trade-off between the two desiderata so that one may not be able to achieve both simultaneously.

Specifically, we provide analysis using a theoretical data model and show that, while more diverse pre-training data result in more diverse features for different tasks (improving universality), it puts less emphasis on task-specific features, giving rise to larger sample complexity for down-stream supervised tasks, and thus worse prediction performance. Guided by this analysis, we propose a contrastive regularization method to improve the trade-off. We validate our analysis and method empirically with systematic experiments using real-world datasets and foundation models.

****

S-NeRF: Neural Radiance Fields for Street Views

Ziyang Xie,Junge Zhang,Wenye Li,Feihu Zhang,Li Zhang

Neural Radiance Fields (NeRFs) aim to synthesize novel views of objects and scenes, given the object-centric camera views with large overlaps. However, we conjugate that this paradigm does not fit the nature of the street views that are col lected by many self-driving cars from the large-scale unbounded scenes. Also, the onboard cameras perceive scenes without much overlapping. Thus, existing NeRFs often produce blurs, "floaters" and other artifacts on street-view synthesis. In this paper, we propose a new street-view NeRF (S-NeRF) that considers novel view synthesis of both the large-scale background scenes and the foreground moving vehicles jointly. Specifically, we improve the scene parameterization function and the camera poses for learning better neural representations from street views. We also use the the noisy and sparse LiDAR points to boost the training and learn a robust geometry and reprojection based confidence to address the depth outliers.   Moreover, we extend our S-NeRF for reconstructing moving vehicles that is impracticable for conventional NeRFs. Thorough experiments on the large-scale driving datasets (e.g., nuScenes and Waymo) demonstrate that our method beats the state-of-the-art rivals by reducing 7■40% of the mean-squared error in the street-view synthesis and a 45% PSNR gain for the moving vehicles rendering.

****

Learning Visual Representation with Synthetic Images and Topologically-defined Labels

Shizuo Kaji,Yohsuke Watanabe

We propose a scheme for neural networks to learn visual representation with synthetic images and mathematically-defined labels that capture topological information. To verify that the model acquires a different visual representation than with the usual supervised learning with manually-defined labels, we show that the models pretrained with our scheme can be finetuned for image classification tasks to achieve an improved convergence compared to those trained from scratch.

Convolutional neural networks, built upon iterative local operations, are good at learning local features of the image, such as texture, whereas they tend to pay less attention to larger structures. Our method provides a simple way to encourage the model to learn global features through a specifically designed task based on topology. Furthermore, our method requires no real images nor manual labels; hence it sheds light on some of the lately concerned topics in computer vision, such as the cost and the fairness in data collection and annotation.

****

Cycle-consistent Masked AutoEncoder for Unsupervised Domain Generalization

Haiyang Yang,Xiaotong Li,SHIXIANG TANG,Feng Zhu,Yizhou Wang,Meilin Chen,LEI BAI,Rui Zhao,Wanli Ouyang

Self-supervised learning methods undergo undesirable performance drops when there exists a significant domain gap between training and testing scenarios. Therefore, unsupervised domain generalization (UDG) is proposed to tackle the problem, which requires the model to be trained on several different domains without supervision and generalize well on unseen test domains. Existing methods either rely on a cross-domain and semantically consistent image pair in contrastive methods or the reconstruction pair in generative methods, while the precious image pairs are not available without semantic labels. In this paper, we propose a cycle cross-domain reconstruction task for unsupervised domain generalization in the absence of paired images. The cycle cross-domain reconstruction task converts a masked image from one domain to another domain and then reconstructs the original image from the converted images. To preserve the divergent domain knowledge of decoders in the cycle reconstruction task, we propose a novel domain-contrastive loss to regularize the domain information in reconstructed images encoded with the desirable domain style. Qualitative results on extensive datasets illustrate our method improves the state-of-the-art unsupervised domain generalization methods by average $\textbf{+5.59\%}, \textbf{+4.52\%}, \textbf{+4.22\%}, \textbf{+7.02\%}$ on $1\%, 5\%, 10\%, 100\%$ PACS, and $\textbf{+5.08\%}, \textbf{+6.49\%}, \textbf{+1.79\%}, \textbf{+0.53\%}$ on $1\%, 5\%, 10\%, 100\%$ DomainNet, respectively.

CFlowNets: Continuous Control with Generative Flow Networks

Yinchuan Li,Shuang Luo,Haozhi Wang,Jianye HAO

Generative flow networks (GFlowNets), as an emerging technique, can be used as an alternative to reinforcement learning for exploratory control tasks. GFlowNets aims to sample actions with a probability proportional to the reward, similar to sampling different candidates in an active learning fashion. However, existing GFlowNets cannot adapt to continuous control tasks because GFlowNets need to form a DAG and compute the flow matching loss by traversing the inflows and outflows of each node in the trajectory. In this paper, we propose generative continuous flow networks (CFlowNets) that can be applied to continuous control tasks. First, we present the theoretical formulation of CFlowNets. Then, a training framework for CFlowNets is proposed, including the action selection process, the flow approximation algorithm, and the continuous flow matching loss function. Afterward, we theoretically prove the error bound of the flow approximation. The error decreases rapidly as the number of flow samples increases. Finally, experimental results on continuous control tasks demonstrate the performance advantages of CFlowNets compared to many reinforcement learning methods, especially regarding exploration ability.

Differentiable Gaussianization Layers for Inverse Problems Regularized by Deep Generative Models

Dongzhuo Li

Deep generative models such as GANs, normalizing flows, and diffusion models are powerful regularizers for inverse problems. They exhibit great potential for helping reduce ill-posedness and attain high-quality results. However, the latent tensors of such deep generative models can fall out of the desired high-dimensional standard Gaussian distribution during inversion, particularly in the presence of data noise and inaccurate forward models, leading to low-fidelity solutions. To address this issue, we propose to reparameterize and Gaussianize the latent tensors using novel differentiable data-dependent layers wherein custom operators are defined by solving optimization problems. These proposed layers constrain inverse problems to obtain high-fidelity in-distribution solutions. We validate our technique on three inversion tasks: compressive-sensing MRI, image deblurring, and eikonal tomography (a nonlinear PDE-constrained inverse problem) using two representative deep generative models: StyleGAN2 and Glow. Our approach achieves state-of-the-art performance in terms of accuracy and consistency.

****

DBQ-SSD: Dynamic Ball Query for Efficient 3D Object Detection

Jinrong Yang,Lin Song,Songtao Liu,Weixin Mao,Zeming Li,Xiaoping Li,Hongbin Sun,Jian Sun,Nanning Zheng

Many point-based 3D detectors adopt point-feature sampling strategies to drop some points for efficient inference. These strategies are typically based on fixed and handcrafted rules, making it difficult to handle complicated scenes. Different from them, we propose a Dynamic Ball Query (DBQ) network to adaptively select a subset of input points according to the input features, and assign the feature transform with a suitable receptive field for each selected point. It can be embedded into some state-of-the-art 3D detectors and trained in an end-to-end manner, which significantly reduces the computational cost. Extensive experiments demonstrate that our method can reduce latency by 30%-100% on KITTI, Waymo, and ONCE datasets. Specifically, the inference speed of our detector can reach 162 FPS on KITTI scene, and 30 FPS on Waymo and ONCE scenes without performance degradation. Due to skipping the redundant points, some evaluation metrics show significant improvements.

****

Exploring Low-Rank Property in Multiple Instance Learning for Whole Slide Image Classification

Jinxi Xiang,Jun Zhang

The classification of gigapixel-sized whole slide images (WSIs) with slide-level labels can be formulated as a multiple-instance-learning (MIL) problem. State-of-the-art models often consist of two decoupled parts: local feature embedding with a pre-trained model followed by a global feature aggregation network for classification. We leverage the properties of the apparent similarity in high-resolution WSIs, which essentially exhibit \textit{low-rank} structures in the data manifold, to develop a novel MIL with a boost in both feature embedding and featu re aggregation. We extend the contrastive learning with a pathology-specific Low-Rank Constraint (LRC) for feature embedding to pull together samples (i.e., patches) belonging to the same pathological tissue in the low-rank subspace and simultaneously push apart those from different latent subspaces. At the feature aggregation stage, we introduce an iterative low-rank attention MIL (ILRA-MIL) model to aggregate features with low-rank learnable latent vectors to model global interactions among all instances. We highlight the importance of instance correlation modeling but refrain from directly using the transformer encoder considering the $O(n^2)$ complexity. ILRA-MIL with LRC pre-trained features achieves strong empirical results across various benchmarks, including (i) 96.49\% AUC on the CAMELYON16 for binary metastasis classification, (ii) 97.63\% AUC on the TCGA-NSCLC for lung cancer subtyping, and (iii) 0.6562 kappa on the large-scale PANDA dataset for prostate cancer classification. The code is available at https://github.com/jinxixiang/low_rank_wsi.

Evaluating and Inducing Personality in Pre-trained Language Models

Guangyuan Jiang,Manjie Xu,Song-Chun Zhu,Wenjuan Han,Chi Zhang,Yixin Zhu

Originated as a philosophical quest, personality discerns how individuals differ from each other in terms of thinking, feeling, and behaving. Toward building social machines that work with humans on a daily basis, we are motivated to ask: (1) Do existing Large Language Models (LLMs) possess personalities, akin to their human counterparts? (2) If so, how can we evaluate them? (3) Further, given this evaluation framework, how can we induce a certain personality in a fully controllable fashion? To tackle these three questions, we propose the Machine Personality Inventory (MPI) dataset for evaluating the machine personality; MPI follows standardized personality tests, built upon the Big Five Personality Factors (Big Five) theory and personality assessment inventories. By evaluating models with MPI, we provide the first piece of evidence showing the existence of personality in LLMs. We further devise a Chain Prompting method to induce LLMs with a specific personality in a controllable manner, capable of producing diversified behaviors. We hope to shed light on future studies by adopting personality as the essential guide for various downstream tasks, building more human-like and in situ dialogue agents.

Node Classification Beyond Homophily: Towards a General Solution

Zhe Xu,Yuzhong Chen,Qinghai Zhou,Yuhang Wu,Menghai Pan,Hao Yang,Hanghang Tong

Graph neural networks (GNNs) have become core building blocks behind a myriad of graph learning tasks. The vast majority of the existing GNNs are built upon, either implicitly or explicitly, the homophily assumption, which is not always true and could heavily degrade the performance of learning tasks. In response, GNNs tailored for heterophilic graphs have been developed. However, most of the existing works are designed for the specific GNN models to address heterophily, which lacks generality. In this paper, we study the problem from the structure learning perspective and propose a family of general solutions named ALT. It can work hand in hand with most of the existing GNNs to decently handle graphs with either low or high homophily. The core of our method is learning to (1) decompose a given graph into two components, (2) extract complementary graph signals from these two components, and (3) adaptively merge the graph signals for node classification. Moreover, analysis based on graph signal processing shows that our framework can empower a broad range of existing GNNs to have adaptive filter characteristics and further modulate the input graph signals, which is critical for handling complex homophilic/heterophilic patterns. The proposed ALT brings significant and consistent performance improvement in node classification for a wide range of GNNs over a variety of real-world datasets.

Causal Balancing for Domain Generalization

Xinyi Wang,Michael Saxon,Jiachen Li,Hongyang Zhang,Kun Zhang,William Yang Wang

While machine learning models rapidly advance the state-of-the-art on various real-world tasks, out-of-domain (OOD) generalization remains a challenging problem given the vulnerability of these models to spurious correlations. We propose a balanced mini-batch sampling strategy to transform a biased data distribution into a spurious-free balanced distribution, based on the invariance of the underlying causal mechanisms for the data generation process. We argue that the Bayes optimal classifiers trained on such balanced distribution are minimax optimal across a diverse enough environment space. We also provide an identifiability guarantee of the latent variable model of the proposed data generation process, when utilizing enough train environments. Experiments are conducted on DomainBed, demonstrating empirically that our method obtains the best performance across 20 baselines reported on the benchmark.

Neural Radiance Fields with Geometric Consistency for Few-Shot Novel View Synthesis

Jiuhn Song,Min-Seop Kwak,Seungryong Kim

We present a novel method to regularizes neural radiance field (NeRF) in few-shot setting with geometry-based consistency regularization. The proposed approach leverages NeRF's rendered depth map to warp source images to unobserved viewpoints and impose them as pseudo ground truths to facilitate learning of detailed features. By encouraging consistency at feature-level instead of using pixel-level reconstruction loss, we regularize the network solely at semantic and structural levels while allowing view-dependent radiance to model freely after color variations. Our application of proposed consistency term for the network is twofold: between and observed and unobserved viewpoints, image rendered at unseen view is forced to model after the image warped from input observation, while between observed viewpoints the warped image undergoes optimization for geometry-specific regularization. We also demonstrate an effective method to filter out erroneous warped solutions, along with relevant techniques to stabilize training during optimization. We show that our model achieves competitive results compared to concurrent few-shot NeRF models.

Towards Addressing Label Skews in One-Shot Federated Learning

Yiqun Diao,Qinbin Li,Bingsheng He

Federated learning (FL) has been a popular research area, where multiple clients collaboratively train a model without sharing their local raw data. Among existing FL solutions, one-shot FL is a promising and challenging direction, where the clients conduct FL training with a single communication round. However, while label skew is a common real-world scenario where some clients may have few or no data of some classes, existing one-shot FL approaches that conduct voting on the local models are not able to produce effective global models. Due to the limited number of classes in each party, the local models misclassify the data from unseen classes into seen classes, which leads to very ineffective global models from voting. To address the label skew issue in one-shot FL, we propose a novel approach named FedOV which generates diverse outliers and introduces them as an additional unknown class in local training to improve the voting performance. Specifically, based on open-set recognition, we propose novel outlier generation approaches by corrupting the original features and further develop adversarial learning to enhance the outliers. Our extensive experiments show that FedOV can significantly improve the test accuracy compared to state-of-the-art approaches in various label skew settings.

****

Breaking Correlation Shift via Conditional Invariant Regularizer

Mingyang Yi,Ruoyu Wang,Jiacheng Sun,Zhenguo Li,Zhi-Ming Ma

Recently, generalization on out-of-distribution (OOD) data with correlation shift has attracted great attentions. The correlation shift is caused by the spurious attributes that correlate to the class label, as the correlation between them may vary in training and test data. For such a problem, we show that given the class label, the models that are conditionally independent of spurious attributes are OOD generalizable. Based on this, a metric Conditional Spurious Variation (CSV) which controls the OOD generalization error, is proposed to measure such conditional independence. To improve the OOD generalization, we regularize the training process with the proposed CSV. Under mild assumptions, our training object ive can be formulated as a nonconvex-concave mini-max problem. An algorithm with a provable convergence rate is proposed to solve the problem. Extensive empirical results verify our algorithm's efficacy in improving OOD generalization.

CROM: Continuous Reduced-Order Modeling of PDEs Using Implicit Neural Representations

Peter Yichen Chen,Jinxu Xiang,Dong Heon Cho,Yue Chang,G A Pershing,Henrique Teles Maia,Maurizio M Chiaramonte,Kevin Thomas Carlberg,Eitan Grinspun

The long runtime of high-fidelity partial differential equation (PDE) solvers makes them unsuitable for time-critical applications. We propose to accelerate PDE solvers using reduced-order modeling (ROM). Whereas prior ROM approaches reduce the dimensionality of discretized vector fields, our continuous reduced-order modeling (CROM) approach builds a low-dimensional embedding of the continuous vector fields themselves, not their discretization. We represent this reduced manifold using continuously differentiable neural fields, which may train on any and all available numerical solutions of the continuous system, even when they are obtained using diverse methods or discretizations. We validate our approach on an extensive range of PDEs with training data from voxel grids, meshes, and point clouds. Compared to prior discretization-dependent ROM methods, such as linear subspace proper orthogonal decomposition (POD) and nonlinear manifold neural-network-based autoencoders, CROM features higher accuracy, lower memory consumption, dynamically adaptive resolutions, and applicability to any discretization. For equal latent space dimension, CROM exhibits 79$\times$ and 49$\times$ better accuracy, and 39$\times$ and 132$\times$ smaller memory footprint, than POD and autoencoder methods, respectively. Experiments demonstrate 109$\times$ and 89$\times$ wall-clock speedups over unreduced models on CPUs and GPUs, respectively. Videos and codes are available on the project page: https://crom-pde.github.io

Towards One-shot Neural Combinatorial Solvers: Theoretical and Empirical Notes on the Cardinality-Constrained Case

Runzhong Wang,Li Shen,Yiting Chen,Xiaokang Yang,Dacheng Tao,Junchi Yan

One-shot non-autoregressive neural networks, different from RL-based ones, have been actively adopted for solving combinatorial optimization (CO) problems, which can be trained by the objective score in a self-supervised manner. Such methods have shown their superiority in efficiency (e.g. by parallelization) and potential for tackling predictive CO problems for decision-making under uncertainty. While the discrete constraints often become a bottleneck for gradient-based neural solvers, as currently handled in three typical ways: 1) adding a soft penalty in the objective, where a bounded violation of the constraints cannot be guaranteed, being critical to many constraint-sensitive scenarios; 2) perturbing the input to generate an approximate gradient in a black-box manner, though the constraints are exactly obeyed while the approximate gradients can hurt the performance on the objective score; 3) a compromise by developing soft algorithms whereby the output of neural networks obeys a relaxed constraint, and there can still occur an arbitrary degree of constraint-violation. Towards the ultimate goal of establishing a general framework for neural CO solver with the ability to control an arbitrary-small degree of constraint violation, in this paper, we focus on a more achievable and common setting: the cardinality constraints, which in fact can be readily encoded by a differentiable optimal transport (OT) layer. Based on this observation, we propose OT-based cardinality constraint encoding for end-to-end CO problem learning with two variants: Sinkhorn and Gumbel-Sinkhorn, whereby their violation of the constraints can be exactly characterized and bounded by our theoretical results. On synthetic and real-world CO problem instances, our methods surpass the state-of-the-art CO network and are comparable to (if not superior to) the commercial solver Gurobi. In particular, we further showcase a case study of applying our approach to the predictive portfolio optimization task on real-world asset price data, improving the Sharpe ratio from 1.1 to 2.0 of a strong LSTM+Gurobi baseline under the classic predict-then-optimize paradigm.

Block and Subword-Scaling Floating-Point (BSFP) : An Efficient Non-Uniform Quant ization For Low Precision Inference

Yun-Chen Lo,Tse-Kuang Lee,Ren-Shuo Liu

In this paper, we propose Block and Subword-Scaling Floating-Point (BSFP), a non-uniform quantization scheme for the skewed and non-uniform distribution of weight vectors in neural networks. By quantizing each weight vector as the superposition of multiple subword vectors (in two's complement) with scaling factors (in Low-bit Floating-Point, LBFP), BSFP can effectively fit the distribution of weight vectors while maintaining high computation efficiency. Furthermore, we present a grid search-based MSE-optimal quantization flow and a scaled serial processing engine to complete the quantization pipeline and the infrastructure.

The experimental results on the ImageNet classification task show that our proposed method outperforms state-of-the-art Microsoft Floating Point (MSFP) by up to 20.56% top-1 accuracy at the same weight precision and reduces up to 10.3% model size. Furthermore, BSFP outperforms MSFP by up to 2.0$\times$ computing throughput and up to 5.3$\times$ energy efficiency under the same silicon area budget.

Rethinking the Effect of Data Augmentation in Adversarial Contrastive Learning

Rundong Luo,Yifei Wang,Yisen Wang

Recent works have shown that self-supervised learning can achieve remarkable robustness when integrated with adversarial training (AT). However, the robustness gap between supervised AT (sup-AT) and self-supervised AT (self-AT) remains significant. Motivated by this observation, we revisit existing self-AT methods and discover an inherent dilemma that affects self-AT robustness: either strong or weak data augmentations are harmful to self-AT, and a medium strength is insufficient to bridge the gap. To resolve this dilemma, we propose a simple remedy named DYNACL (Dynamic Adversarial Contrastive Learning). In particular, we propose an augmentation schedule that gradually anneals from a strong augmentation to a weak one to benefit from both extreme cases. Besides, we adopt a fast post-processing stage for adapting it to downstream tasks. Through extensive experiments, we show that DYNACL can improve state-of-the-art self-AT robustness by 8.84% under Auto-Attack on the CIFAR-10 dataset, and can even outperform vanilla supervised adversarial training for the first time. Our code is available at \url{https://github.com/PKU-ML/DYNACL}.

Semi-supervised Community Detection via Structural Similarity Metrics

Yicong Jiang,Tracy Ke

Motivated by the interests of social network analysis and network-based recommendation systems, we consider a semi-supervised community detection problem, where the goal is to estimate the community label of a new node by leveraging on the network structure and partially observed community labels of existing nodes.

We model the network with a degree-corrected stochastic block model, which allows for severe degree heterogeneity and potentially non-assortative communities.

We propose a fast algorithm that computes a `structural similarity metric' between the new node and each of the K communities, aggregating information in labeled and unlabeled data. The estimated label of the new node is equal to the value of k that maximizes this similarity metric. Our method is computationally fast and compares favorably with existing semi-supervised algorithms on numerical performance. In theory, we derive explicit bounds for the misclassification error and show the efficiency of our method by comparing it with an ideal classifier. To our best knowledge, our results provide the first semi-supervised community detection algorithm with theoretical guarantees.

DDM^2: Self-Supervised Diffusion MRI Denoising with Generative Diffusion Models

Tiange Xiang,Mahmut Yurt,Ali B Syed,Kawin Setsompop,Akshay Chaudhari

Magnetic resonance imaging (MRI) is a common and life-saving medical imaging technique. However, acquiring high signal-to-noise ratio MRI scans requires long scan times, resulting in increased costs and patient discomfort, and decreased throughput. Thus, there is great interest in denoising MRI scans, especially for th e subtype of diffusion MRI scans that are severely SNR-limited. While most prior MRI denoising methods are supervised in nature, acquiring supervised training datasets for the multitude of anatomies, MRI scanners, and scan parameters proves impractical. Here, we propose Denoising Diffusion Models for Denoising Diffusion MRI (DDM^2), a self-supervised denoising method for MRI denoising using diffusion denoising generative models. Our three-stage framework integrates statistic-based denoising theory into diffusion models and performs denoising through conditional generation. During inference, we represent input noisy measurements as a sample from an intermediate posterior distribution within the diffusion Markov chain. We conduct experiments on 4 real-world in-vivo diffusion MRI datasets and show that our DDM^2 demonstrates superior denoising performances ascertained with clinically-relevant visual qualitative and quantitative metrics.

Multivariate Time-series Imputation with Disentangled Temporal Representations

SHUAI LIU,Xiucheng Li,Gao Cong,Yile Chen,YUE JIANG

Multivariate time series often faces the problem of missing value. Many time series imputation methods have been developed in the literature. However, these methods all rely on an entangled representation to model dynamics of time series, which may fail to fully exploit the multiple factors (e.g., periodic patterns) contained in the time series. Moreover, the entangled representation usually has no semantic meaning, and thus they often lack interpretability. In addition, many recent models are proposed to deal with the whole time series to capture cross-channel correlations and identify temporal dynamics, but they are not scalable to large-scale datasets. Different from existing approaches, we propose TIDER, a novel matrix factorization-based method with disentangled temporal representations that account for multiple factors, namely trend, seasonality, and local bias, to model complex dynamics. The learned disentanglement makes the imputation process more reliable and offers explainability for imputation results. Moreover, TIDER is scalable to large datasets. Empirical results show that our method not only outperforms existing approaches by notable margins on three real-world datasets, but also scales well to large datasets on which existing deep learning based methods struggle. Disentanglement validation experiments further demonstrate the robustness of our model in obtaining accurate and explainable disentangled components.

Knowledge-driven Scene Priors for Semantic Audio-Visual Embodied Navigation

Gyan Tatiya,Jonathan Francis,Luca Bondi,Ingrid Navarro,Eric Nyberg,Jivko Sinapov,Jean Oh

Generalisation to unseen contexts remains a challenge for embodied navigation agents. In the context of semantic audio-visual navigation (SAVi) tasks, generalisation includes both generalising to unseen indoor visual scenes as well as generalising to unheard sounding objects. Previous SAVi task definitions do not include evaluation conditions on truly novel sounding objects, resorting instead to evaluating agents on unheard sound clips of known objects; meanwhile, previous SAVi methods do not include explicit mechanisms for incorporating domain knowledge about object and region semantics. These weaknesses limit the development and assessment of models' abilities to generalise their learned experience. In this work, we introduce the use of knowledge-driven scene priors in the semantic audio-visual embodied navigation task: we combine semantic information from our novel knowledge graph that encodes object-region relations, spatial knowledge from dual Graph Encoder Networks, and background knowledge from a series of pre-training tasks---all within a reinforcement learning framework for audio-visual navigation. We define a new audio-visual navigation sub-task, where agents are evaluated on novel sounding objects, as opposed to unheard clips of known objects. We show improvements over strong baselines in generalisation to unseen regions and novel sounding objects, within the Habitat-Matterport3D simulation environment, under the SoundSpaces task. We release code, knowledge graphs, and dataset generation details in the supplementary material.

Socratic Models: Composing Zero-Shot Multimodal Reasoning with Language

Andy Zeng,Maria Attarian,brian ichter,Krzysztof Marcin Choromanski,Adrian Wong,Stefan Welker,Federico Tombari,Aveek Purohit,Michael S Ryoo,Vikas Sindhwani,Johnny Lee,Vincent Vanhoucke,Pete Florence

We investigate how multimodal prompt engineering can use language as the intermediate representation to combine complementary knowledge from different pretrained (potentially multimodal) language models for a variety of tasks. This approach is both distinct from and complementary to the dominant paradigm of joint multimodal training. It also recalls a traditional systems-building view as in classical NLP pipelines, but with prompting large pretrained multimodal models. We refer to these as Socratic Models (SMs): a modular class of systems in which multiple pretrained models may be composed zero-shot via multimodal-informed prompting to capture new multimodal capabilities, without additional finetuning. We show that these systems provide competitive state-of-the-art performance for zero-shot image captioning and video-to-text retrieval, and also enable new applications such as (i) answering free-form questions about egocentric video, (ii) engaging in multimodal assistive dialogue with people (e.g., for cooking recipes), and (iii) robot perception and planning. We hope this work provides (a) results for stronger zero-shot baseline performance with analysis also highlighting their limitations, (b) new perspectives for building multimodal systems powered by large pretrained models, and (c) practical application advantages in certain regimes limited by data scarcity, training compute, or model access.

CAST: Concurrent Recognition and Segmentation with Adaptive Segment Tokens

Tsung-Wei Ke,Jyh-Jing Hwang,Stella Yu

Recognizing an image and segmenting it into coherent regions are often treated as separate tasks. Human vision, however, has a general sense of segmentation hierarchy before recognition occurs. We are thus inspired to learn image recognition with hierarchical image segmentation based entirely on unlabeled images. Our insight is to learn fine-to-coarse features concurrently at superpixels, segments, and full image levels, enforcing consistency and goodness of feature induced segmentations while maximizing discrimination among image instances.

Our model innovates vision transformers on three aspects. 1) We use adaptive segment tokens instead of fixed-shape patch tokens. 2) We create a token hierarchy by inserting graph pooling between transformer blocks, naturally producing consistent multi-scale segmentations while increasing the segment size and reducing the number of tokens. 3) We produce hierarchical image segmentation for free {\it while} training for recognition by maximizing image-wise discrimination.

Our work delivers the first concurrent recognition and hierarchical segmentation model without any supervision.   Validated on ImageNet and PASCAL VOC, it achieves better recognition and segmentation with higher computational efficiency.

Multi-lingual Evaluation of Code Generation Models

Ben Athiwaratkun,Sanjay Krishna Gouda,Zijian Wang,Xiaopeng Li,Yuchen Tian,Ming Tan,Wasi Uddin Ahmad,Shiqi Wang,Qing Sun,Mingyue Shang,Sujan Kumar Gonugondla,Hantian Ding,Varun Kumar,Nathan Fulton,Arash Farahani,Siddhartha Jain,Robert Giaquinto,Haifeng Qian,Murali Krishna Ramanathan,Ramesh Nallapati,Baishakhi Ray,Parminder Bhatia,Sudipta Sengupta,Dan Roth,Bing Xiang

We present two new benchmarks, MBXP and Multilingual HumanEval, designed to evaluate code completion models in over 10 programming languages. These datasets are generated using a conversion framework that transpiles prompts and test cases from the original MBPP and HumanEval datasets into the corresponding data in the target language. By using these benchmarks, we are able to assess the performance of code generation models in a multi-lingual fashion, and discovered generalization ability of language models on out-of-domain languages, advantages of multi-lingual models over mono-lingual, the ability of few-shot prompting to teach the model new languages, and zero-shot translation abilities. In addition, we use our code generation model to perform large-scale bootstrapping to obtain synthetic canonical solutions in several languages, which can be used for other code-r elated evaluations such as code insertion, robustness, or summarization tasks.

****

GRACE-C: Generalized Rate Agnostic Causal Estimation via Constraints

Mohammadsajad Abavisani,David Danks,Sergey Plis

Graphical structures estimated by causal learning algorithms from time series data can provide highly misleading causal information if the causal timescale of the generating process fails to match the measurement timescale of the data. Existing algorithms provide limited resources to respond to this challenge, and so researchers must either use models that they know are likely misleading, or else forego causal learning entirely. Existing methods face up-to-four distinct shortfalls, as they might a) require that the difference between causal and measurement timescales is known; b) only handle very small number of random variables when the timescale difference is unknown; c) only apply to pairs of variables (albeit with fewer assumptions about prior knowledge); or d) be unable to find a solution given statistical noise in the data. This paper aims to address these challenges. We present an approach that combines constraint programming with both theoretical insights into the problem structure and prior information about admissible causal interactions to achieve speed up of multiple orders of magnitude. The resulting system scales to significantly larger sets of random variables (>100) without knowledge of the timescale difference while maintaining theoretical guarantees. This method is also robust to edge misidentification and can use parametric connection strengths, while optionally finding the optimal among many possible solutions.

How Powerful is Implicit Denoising in Graph Neural Networks

Songtao Liu,Zhitao Ying,Hanze Dong,Lu Lin,Jinghui Chen,Dinghao Wu

Graph Neural Networks (GNNs), which aggregate features from neighbors, are widely used for processing graph-structured data due to their powerful representation learning capabilities. It is generally believed that GNNs can implicitly remove feature noises. However, existing works have not rigorously analyzed the implicit denoising effect in graph neural networks. In this work, we conduct a comprehensive theoretical study and analyze when and why implicit denoising happens in GNNs. Our theoretical analysis suggests that the implicit denoising largely depends on the connectivity and size of the graph, as well as the GNN architectures. Motivated by adversarial machine learning in improving the robustness of neural networks, we propose the adversarial graph signal denoising (AGSD) problem. By solving such a problem, we derive a robust graph convolution, where the smoothness of the node representations and the implicit denoising effect can be enhanced. Extensive empirical evaluations verify our theoretical analyses and the effectiveness of our proposed model.

****

Unified Detoxifying and Debiasing in Language Generation via Inference-time Adaptive Optimization

Zonghan Yang,Xiaoyuan Yi,Peng Li,Yang Liu,Xing Xie

Recently pre-trained language models (PLMs) have prospered in various natural language generation (NLG) tasks due to their ability to generate fairly fluent text. Nevertheless, these models are observed to capture and reproduce harmful contents in training corpora, typically toxic language and social biases, raising severe moral issues. Prior works on ethical NLG tackle detoxifying and debiasing separately, which is problematic since we find debiased models still exhibit toxicity while detoxified ones even exacerbate biases. To address such a challenge, we propose the first unified framework of detoxifying and debiasing called UDDIA, which jointly formalizes these two problems as rectifying the output space. We theoretically interpret our framework as learning a text distribution mixing weighted attributes. Besides, UDDIA conducts adaptive optimization of only a few parameters during decoding based on a parameter-efficient tuning schema without any training data. This leads to minimal generation quality loss and improved rectification performance with acceptable computational cost. Experimental results demonstrate that compared to several strong baselines, UDDIA achieves debiasing and detoxifying simultaneously and better balances efficiency and effectiveness, taking a further step towards practical ethical NLG.

Distribution Aware Metrics for Conditional Natural Language Generation

David Chan,Yiming Ni,Sudheendra Vijayanarasimhan,David A Ross,Austin Myers,John Canny

Traditional automated metrics for evaluating conditional natural language generation use pairwise comparisons between a single generated text and the best-matching gold-standard ground truth text. When multiple ground truths are available, scores are aggregated using an average or max operation across references. While this approach works well when diversity in the ground truth data (i.e. dispersion of the distribution of conditional texts) can be ascribed to noise, such as in automated speech recognition, it does not allow for robust evaluation in the case where diversity in the ground truths represents signal for the model. In this work we argue that existing metrics are not appropriate for domains such as visual description or summarization where ground truths are semantically diverse, and where the diversity in those captions captures useful additional information about the context. We propose a novel paradigm for multi-candidate evaluation of conditional language generation models, and a new family of metrics that compare the {\em distributions} of reference and model-generated caption sets using small sample sets of each. We demonstrate the utility of our approach with a case study in visual description: where we show that existing models optimize for single-description quality over diversity, and gain some insights into how sampling methods and temperature impact description quality and diversity.

Recommender Transformers with Behavior Pathways

Zhiyu Yao,Xinyang Chen,Sinan Wang,Qinyan Dai,Yumeng Li,Tanchao Zhu,Mingsheng Long

Sequential recommendation requires the recommender to capture the evolving behavior characteristics from logged user behavior data for accurate recommendations. Nevertheless, user behavior sequences are viewed as a script with multiple ongoing threads intertwined. We find that only a small set of pivotal behaviors can be evolved into the user's future action. As a result, the future behavior of the user is hard to predict. We conclude this characteristic for sequential behaviors of each user as the \textit{behavior pathway}. Different users have their unique behavior pathways. Among existing sequential models, transformers have shown great capacity in capturing global-dependent characteristics. However, these models mainly provide a dense distribution over all previous behaviors using the self-attention mechanism, making the final predictions overwhelmed by the trivial behaviors not adjusted to each user. In this paper, we build the Recommender Transformer (RETR) with a novel Pathway Attention mechanism. RETR can dynamically plan the behavior pathway specified for each user, and sparingly activate the network through this behavior pathway to effectively capture evolving patterns useful for recommendation. The key design is a learned binary route to prevent the behavior pathway from being overwhelmed by trivial behaviors. Pathway attention is model-agnostic and can be applied to a series of transformer-based models for sequential recommendation. We empirically evaluate RETR on seven intra-domain benchmarks and RETR yields state-of-the-art performance. On another five cross-domain benchmarks, RETR can capture more domain-invariant representations for sequential recommendation.

Towards Discovering Neural Architectures from Scratch

Simon Schrodi,Danny Stoll,Binxin Ru,Rhea Sanjay Sukthanker,Thomas Brox,Frank Hutter

The discovery of neural architectures from scratch is the long-standing goal of Neural Architecture Search (NAS). Searching over a wide spectrum of neural architectures can facilitate the discovery of previously unconsidered but well-performing architectures. In this work, we take a large step towards discovering neural architectures from scratch by expressing architectures algebraically. This algebraic view leads to a more general method for designing search spaces, which allows us to compactly represent search spaces that are 100s of orders of magnitud e larger than common spaces from the literature. Further, we propose a Bayesian Optimization strategy to efficiently search over such huge spaces, and demonstrate empirically that both our search space design and our search strategy can be superior to existing baselines. We open source our algebraic NAS approach and provide APIs for PyTorch and TensorFlow.

Equiformer: Equivariant Graph Attention Transformer for 3D Atomistic Graphs

Yi-Lun Liao,Tess Smidt

Despite their widespread success in various domains, Transformer networks have yet to perform well across datasets in the domain of 3D atomistic graphs such as molecules even when 3D-related inductive biases like translational invariance and rotational equivariance are considered. In this paper, we demonstrate that Transformers can generalize well to 3D atomistic graphs and present Equiformer, a graph neural network leveraging the strength of Transformer architectures and incorporating SE(3)/E(3)-equivariant features based on irreducible representations (irreps). First, we propose a simple and effective architecture by only replacing original operations in Transformers with their equivariant counterparts and including tensor products. Using equivariant operations enables encoding equivariant information in channels of irreps features without complicating graph structures. With minimal modifications to Transformers, this architecture has already achieved strong empirical results. Second, we propose a novel attention mechanism called equivariant graph attention, which improves upon typical attention in Transformers through replacing dot product attention with multi-layer perceptron attention and including non-linear message passing. With these two innovations, Equiformer achieves competitive results to previous models on QM9, MD17 and OC20 datasets.

Automating Nearest Neighbor Search Configuration with Constrained Optimization

Philip Sun,Ruiqi Guo,Sanjiv Kumar

The approximate nearest neighbor (ANN) search problem is fundamental to efficiently serving many real-world machine learning applications. A number of techniques have been developed for ANN search that are efficient, accurate, and scalable. However, such techniques typically have a number of parameters that affect the speed-recall tradeoff, and exhibit poor performance when such parameters aren't properly set. Tuning these parameters has traditionally been a manual process, demanding in-depth knowledge of the underlying search algorithm. This is becoming an increasingly unrealistic demand as ANN search grows in popularity. To tackle this obstacle to ANN adoption, this work proposes a constrained optimization-based approach to tuning quantization-based ANN algorithms. Our technique takes just a desired search cost or recall as input, and then generates tunings that, empirically, are very close to the speed-recall Pareto frontier and give leading performance on standard benchmarks.

Truncated Diffusion Probabilistic Models and Diffusion-based Adversarial Auto-Encoders

Huangjie Zheng,Pengcheng He,Weizhu Chen,Mingyuan Zhou

Employing a forward diffusion chain to gradually map the data to a noise distribution, diffusion-based generative models learn how to generate the data by inferring a reverse diffusion chain. However, this approach is slow and costly because it needs many forward and reverse steps. We propose a faster and cheaper approach that adds noise not until the data become pure random noise, but until they reach a hidden noisy data distribution that we can confidently learn. Then, we use fewer reverse steps to generate data by starting from this hidden distribution that is made similar to the noisy data. We reveal that the proposed model can be cast as an adversarial auto-encoder empowered by both the diffusion process and a learnable implicit prior. Experimental results show even with a significantly smaller number of reverse diffusion steps, the proposed truncated diffusion probabilistic models can provide consistent improvements over the non-truncated ones in terms of performance in both unconditional and text-guided image generations.

****

NTK-SAP: Improving neural network pruning by aligning training dynamics

Yite Wang,Dawei Li,Ruoyu Sun

Pruning neural networks before training has received increasing interest due to its potential to reduce training time and memory. One popular method is to prune the connections based on a certain metric, but it is not entirely clear what metric is the best choice. Recent advances in neural tangent kernel (NTK) theory suggest that the training dynamics of large enough neural networks is closely related to the spectrum of the NTK. Motivated by this finding, we propose to prune the connections that have the least influence on the spectrum of the NTK. This method can help maintain the NTK spectrum, which may help align the training dynamics to that of its dense counterpart. However, one possible issue is that the fixed-weight-NTK corresponding to a given initial point can be very different from the NTK corresponding to later iterates during the training phase. We further propose to sample multiple realizations of random weights to estimate the NTK spectrum. Note that our approach is weight-agnostic, which is different from most existing methods that are weight-dependent. In addition, we use random inputs to compute the fixed-weight-NTK, making our method data-agnostic as well. We name our foresight pruning algorithm Neural Tangent Kernel Spectrum-Aware Pruning (NTK-SAP). Empirically, our method achieves better performance than all baselines on multiple datasets.

Towards Equivariant Graph Contrastive Learning via Cross-Graph Augmentation

Zhiyuan Liu,An Zhang,Yu Sun,Yicong Li,Yaorui Shi,Sihang Li,Xiang Wang,Xiangnan He,Tat-Seng Chua

Leading graph contrastive learning (GCL) frameworks conform to the invariance mechanism by encouraging insensitivity to different augmented views of the same graph. Despite the promising performance, invariance worsens representation when augmentations cause aggressive semantics shifts. For example, dropping the super-node can dramatically change a social network's topology. In this case, encouraging invariance to the original graph can bring together dissimilar patterns and hurt the task of instance discrimination. To resolve the problem, we get inspiration from equivariant self-supervised learning and propose Equivariant Graph Contrastive Learning (E-GCL) to encourage the sensitivity to global semantic shifts. Viewing each graph as a transformation to others, we ground the equivariance principle as a cross-graph augmentation -- graph interpolation -- to simulate global semantic shifts. Without using annotation, we supervise the representation of cross-graph augmented views by linearly combining the representations of their original samples. This simple but effective equivariance principle empowers E-GCL with the ability of cross-graph discrimination. It shows significant improvements over the state-of-the-art GCL models in unsupervised learning and transfer learning. Further experiments demonstrate E-GCL's generalization to various graph pre-training frameworks. Code is available at \url{https://anonymous.4open.science/r/E-GCL/}

Effective Self-supervised Pre-training on Low-compute Networks without Distillation

Fuwen Tan,Fatemeh Sadat Saleh,Brais Martinez

Despite the impressive progress of self-supervised learning (SSL), its applicability to low-compute networks has received limited attention. Reported performance has trailed behind standard supervised pre-training by a large margin, barring self-supervised learning from making an impact on models that are deployed on device. Most prior works attribute this poor performance to the capacity bottleneck of the low-compute networks and opt to bypass the problem through the use of knowledge distillation (KD). In this work, we revisit SSL for efficient neural networks, taking a closer at what are the detrimental factors causing the practical limitations, and whether they are intrinsic to the self-supervised low-compute setting. We find that, contrary to accepted knowledge, there is no intrinsic architectural bottleneck, we diagnose that the performance bottleneck is related to the model complexity vs regularization strength trade-off. In particular, we start by empirically observing that the use of local views can have a dramatic impact on the effectiveness of the SSL methods. This hints at view sampling being one of the performance bottlenecks for SSL on low-capacity networks. We hypothesize that the view sampling strategy for large neural networks, which requires matching views in very diverse spatial scales and contexts, is too demanding for low-capacity architectures. We systematize the design of the view sampling mechanism, leading to a new training methodology that consistently improves the performance across different SSL methods (e.g. MoCo-v2, SwAV or DINO), different low-size networks (convolution-based networks, e.g. MobileNetV2, ResNet18, ResNet34 and vision transformer, e.g. ViT-Ti), and different tasks (linear probe, object detection, instance segmentation and semi-supervised learning). Our best models establish new state-of-the-art for SSL methods on low-compute networks despite not using a KD loss term. Code is publicly available at github.com/saic-fi/SSLight.

Graph Neural Bandits

Yunzhe Qi,Yikun Ban,Jingrui He

Contextual bandits aim to choose the optimal arm with the highest reward out of a set of candidates based on their contextual information, and various bandit algorithms have been applied to personalized recommendation due to their ability of solving the exploitation-exploration dilemma. Motivated by online recommendation scenarios, in this paper, we propose a framework named Graph Neural Bandits (GNB) to leverage the collaborative nature among users empowered by graph neural networks (GNNs). Instead of estimating rigid user clusters, we model the "fine-grained'' collaborative effects through estimated user graphs in terms of exploitation and exploration individually. Then, to refine the recommendation strategy, we utilize separate GNN-based models on estimated user graphs for exploitation and adaptive exploration. Theoretical analysis and experimental results on multiple real data sets in comparison with state-of-the-art baselines are provided to demonstrate the effectiveness of our proposed framework.

CoRTX: Contrastive Framework for Real-time Explanation

Yu-Neng Chuang,Guanchu Wang,Fan Yang,Quan Zhou,Pushkar Tripathi,Xuanting Cai,Xia Hu

Recent advancements in explainable machine learning provide effective and faithful solutions for interpreting model behaviors. However, many explanation methods encounter efficiency issues, which largely limit their deployments in practical scenarios. Real-time explainer (RTX) frameworks have thus been proposed to accelerate the model explanation process by learning an one-feed-forward explainer. Existing RTX frameworks typically build the explainer under the supervised learning paradigm, which requires large amounts of explanation labels as the ground truth. Considering that accurate explanation labels are usually hard to obtain, due to constrained computational resources and limited human efforts, effective explainer training is still challenging in practice. In this work, we propose a COntrastive Real-Time eXplanation (CoRTX) framework to learn the explanation-oriented representation and relieve the intensive dependence of explainer training on explanation labels. Specifically, we design a synthetic strategy to select positive and negative instances for explanation representation learning. Theoretical analysis show that our selection strategy can benefit the contrastive learning process on explanation tasks. Experimental results on three real-world datasets further demonstrate the efficiency and efficacy of our proposed CoRTX framework.

MPCFORMER: FAST, PERFORMANT AND PRIVATE TRANSFORMER INFERENCE WITH MPC

Dacheng Li,Hongyi Wang,Rulin Shao,Han Guo,Eric Xing,Hao Zhang

Enabling private inference is crucial for many cloud inference services that are based on Transformer models. However, existing private inference solutions can increase the inference latency by more than 60$\times$ or significantly compromise the inference quality. In this paper, we design the framework MPCFORMER as a practical solution, using Secure Multi-Party Computation (MPC) and Knowledge Dis tillation (KD). Through extensive evaluations, we show that MPCFORMER significantly speeds up Transformer inference in MPC settings while achieving similar ML performance to the input model. On the IMDb dataset, it achieves similar performance to BERT_BASE, while being 5.3$\times$ faster. On the GLUE benchmark, it achieves 97% performance of BERT_BASE with a 2.2$\times$ speedup. MPCFORMER remains effective with different trained Transformer weights such as $\text{ROBERTA}_\text{BASE}$ and larger models including BERT_LARGE. Code is available at https://github.com/MccRee177/MPCFormer.

Discovering Distinctive ``Semantics'' in Super-Resolution Networks

Yihao Liu,Anran Liu,Jinjin Gu,Zhipeng Zhang,Wenhao Wu,Yu Qiao,Chao Dong

Image super-resolution (SR) is a representative low-level vision problem. Although deep SR networks have achieved extraordinary success, we are still unaware of their working mechanisms. Specifically, whether SR networks can learn semantic information, or just perform complex mapping function? What hinders SR networks from generalizing to real-world data? These questions not only raise our curiosity, but also influence SR network development. In this paper, we make the primary attempt to answer the above fundamental questions. After comprehensively analyzing the feature representations (via dimensionality reduction and visualization), we successfully discover the distinctive ``semantics'' in SR networks, i.e., deep degradation representations (DDR), which relate to image degradation instead of image content. We show that a well-trained deep SR network is naturally a good descriptor of degradation information. Our experiments also reveal two key factors (adversarial learning and global residual) that influence the extraction of such semantics. We further apply DDR in several interesting applications (such as distortion identification, blind SR and generalization evaluation) and achieve promising results, demonstrating the correctness and effectiveness of our findings.

Networks are Slacking Off: Understanding Generalization Problem in Image Deraining

Jinjin Gu,Xianzheng Ma,Xiangtao Kong,Yu Qiao,Chao Dong

Deep low-level networks are successful in laboratory benchmarks, but still suffer from severe generalization problems in real-world applications, especially for the deraining task. An ``acknowledgement'' of deep learning drives us to use the training data with higher complexity, expecting the network to learn richer knowledge to overcome generalization problems. Through extensive systematic experiments, we show that this approach fails to improve their generalization ability but instead makes the networks overfit to degradations even more. Our experiments establish that it is capable of training a deraining network with better generalization by reducing the training data complexity. Because the networks are slacking off during training, i.e. learn the less complex element in the image content and degradation to reduce the training loss. When the background image is less complex than the rain streak, the network will focus on the reconstruction of the background without overfitting the rain patterns, thus achieving a good generalization effect. Our research demonstrates excellent application potential and provides an indispensable perspective and research methodology for understanding the generalization problem of low-level vision.

Disparate Impact in Differential Privacy from Gradient Misalignment

Maria S. Esipova,Atiyeh Ashari Ghomi,Yaqiao Luo,Jesse C Cresswell

As machine learning becomes more widespread throughout society, aspects including data privacy and fairness must be carefully considered, and are crucial for deployment in highly regulated industries. Unfortunately, the application of privacy enhancing technologies can worsen unfair tendencies in models. In particular, one of the most widely used techniques for private model training, differentially private stochastic gradient descent (DPSGD), frequently intensifies disparate impact on groups within data. In this work we study the fine-grained causes of unfairness in DPSGD and identify gradient misalignment due to inequitable gradie nt clipping as the most significant source. This observation leads us to a new method for reducing unfairness by preventing gradient misalignment in DPSGD.

IDP: Iterative Differentiable Pruning based on Attention for Deep Neural Networks

Minsik Cho,Saurabh Adya,Devang Naik

Deep Neural network (DNN) pruning is an effective method to reduce the size of a model, improve the inference latency, and minimize the power consumption on DNN accelerators, at the risk of decreasing model accuracy. In this paper, we propose a novel differentiable pruning scheme, Iterative Differentiable Pruning or IDP which offers state-of-the-art qualities in model size, accuracy, and training cost. IDP creates attention-based pruning masks for a given sparsity target to achieve the state-of-the-art trade-offs between model accuracy and inference compute with negligible training overhead. We evaluated IDP on various computer vision and natural language processing tasks, and found that IDP delivers the state-of-the-art results. For MobileNet-v1 (which is a challenging DNN for pruning), IDP can achieve 68.2% top-1 ImageNet1k accuracy with 86.6% sparsity which is 2.3% higher accuracy than the latest state-of-the-art pruning algorithms. For ResNet18, IDP offers 69.5% top-1 ImageNet1k accuracy with 85.5% sparsity at the same training budget and 0.8% better top-1 accuracy than the state-of-the-art method. Also, IDP demonstrates over 83.1% accuracy on Multi-Genre Natural Language Inference with 90% sparsity for BERT, while the next best from the existing techniques shows 81.5% accuracy.

FADE: Enabling Large-Scale Federated Adversarial Training on Resource-Constrained Edge Devices

Minxue Tang,Jianyi Zhang,Mingyuan Ma,Louis DiValentin,Aolin Ding,Amin Hassanzadeh,Hai Li,Yiran Chen

Federated adversarial training can effectively complement adversarial robustness into the privacy-preserving federated learning systems. However, the high demand for memory capacity and computing power makes large-scale federated adversarial training infeasible on resource-constrained edge devices. Few previous studies in federated adversarial training have tried to tackle both memory and computational constraints at the same time. In this paper, we propose a new framework named Federated Adversarial Decoupled Learning (FADE) to enable AT on resource-constrained edge devices. FADE decouples the entire model into small modules to fit into the resource budget of each edge device respectively, and each device only needs to perform AT on a single module in each communication round. We also propose an auxiliary weight decay to alleviate objective inconsistency and achieve better accuracy-robustness balance in FADE. FADE offers a theoretical guarantee for convergence and adversarial robustness, and our experimental results show that FADE can significantly reduce the consumption of memory and computing power while maintaining accuracy and robustness.

Temporal Relevance Analysis for Video Action Models

Quanfu Fan,Donghyun Kim,Chun-Fu Chen,Stan Sclaroff,Kate Saenko,Sarah Adel Bargal

In this paper, we provide a deep analysis of temporal modeling for action recognition, an important but underexplored problem in
the literature. We first propose a new approach to quantify the temporal relationships between frames captured by CNN-based action models based on layer-wise relevance propagation. We then conduct comprehensive experiments and in-depth analysis to provide a better understanding of how temporal modeling is affected by various factors such as dataset, network architecture, and input frames. With this, we further study some important questions for action recognition that lead to interesting findings. Our analysis shows that there is no strong correlation between temporal relevance and model performance; and action models tend to capture local temporal information, but less long-range dependencies.

****

DeepPipe: Deep, Modular and Extendable Representations of Machine Learning Pipelines

Sebastian Pineda Arango,Josif Grabocka

Finding accurate Machine Learning pipelines is essential in achieving state-of-the-art AI predictive performance. Unfortunately, most existing Pipeline Optimization techniques rely on flavors of Bayesian Optimization that do not explore the deep interaction between pipeline stages/components (e.g. between hyperparameters of the deployed preprocessing algorithm and the hyperparameters of a classifier). In this paper, we are the first to capture the deep interaction between components of a Machine Learning pipeline. We propose embedding pipelines in a deep latent representation through a novel per-component encoder mechanism. Such pipeline embeddings are used with deep kernel Gaussian Process surrogates inside a Bayesian Optimization setup. Through extensive experiments on large-scale meta-datasets, we demonstrate that learning pipeline embeddings with Deep Neural Networks significantly advances the state-of-the-art in Pipeline Optimization.

****

OTOv2: Automatic, Generic, User-Friendly

Tianyi Chen,Luming Liang,Tianyu DING,Zhihui Zhu,Ilya Zharkov

The existing model compression methods via structured pruning typically require complicated multi-stage procedures. Each individual stage necessitates numerous engineering efforts and domain-knowledge from the end-users which prevent their wider applications onto broader scenarios. We propose the second generation of Only-Train-Once (OTOv2), which first automatically trains and compresses a general DNN only once from scratch to produce a more compact model with competitive performance without fine-tuning. OTOv2 is automatic and pluggable into various deep learning applications, and requires almost minimal engineering efforts from the users. Methodologically, OTOv2 proposes two major improvements: (i) Autonomy: automatically exploits the dependency of general DNNs, partitions the trainable variables into Zero-Invariant Groups (ZIGs), and constructs the compressed model; and (ii) Dual Half-Space Projected Gradient (DHSPG): a novel optimizer to more reliably solve structured-sparsity problems. Numerically, we demonstrate the generality and autonomy of OTOv2 on a variety of model architectures such as VGG, ResNet, CARN, ConvNeXt, DenseNet and StackedUnets, the majority of which cannot be handled by other methods without extensive handcrafting efforts. Together with benchmark datasets including CIFAR10/100, DIV2K, Fashion-MNIST, SVNH and ImageNet, its effectiveness is validated by performing competitively or even better than the state-of-the-arts. The source code is available at https://github.com/tianyic/only_train_once.

TabPFN: A Transformer That Solves Small Tabular Classification Problems in a Second

Noah Hollmann,Samuel Müller,Katharina Eggensperger,Frank Hutter

We present TabPFN, a trained Transformer that can do supervised classification for small tabular datasets in less than a second, needs no hyperparameter tuning and is competitive with state-of-the-art classification methods.

TabPFN is fully entailed in the weights of our network, which accepts training and test samples as a set-valued input and yields predictions for the entire test set in a single forward pass.

TabPFN is a Prior-Data Fitted Network (PFN) and is trained offline once, to approximate Bayesian inference on synthetic datasets drawn from our prior.

This prior incorporates ideas from causal reasoning: It entails a large space of structural causal models with a preference for simple structures.

On the 18 datasets in the OpenML-CC18 suite that contain up to 1000 training data points, up to 100 purely numerical features without missing values, and up to 10 classes, we show that our method clearly outperforms boosted trees and performs on par with complex state-of-the-art AutoML systems with up to $230\times$ speedup.

This increases to a $5\,700\times$ speedup when using a GPU. We also validate these results on an additional 67 small numerical datasets from OpenML.

We provide all our code, the trained TabPFN, an interactive browser demo and a Colab notebook at https://github.com/automl/TabPFN.

On the Importance of Architectures and Hyperparameters for Fairness in Face Recognition
Rhea Sanjay Sukthanker,Samuel Dooley,John P Dickerson,Colin White,Frank Hutter,Micah Goldblum
Face recognition systems are deployed across the world by government agencies and contractors for sensitive and impactful tasks, such as surveillance and database matching. Despite their widespread use, these systems are known to exhibit bias across a range of sociodemographic dimensions, such as gender and race. Nonetheless, an array of works proposing pre-processing, training, and post-processing methods have failed to close these gaps. Here, we take a very different approach to this problem, identifying that both architectures and hyperparameters of neural networks are instrumental in reducing bias. We first run a large-scale analysis of the impact of architectures and training hyperparameters on several common fairness metrics and show that the implicit convention of choosing high-accuracy architectures may be suboptimal for fairness. Motivated by our findings, we run the first neural architecture search for fairness, jointly with a search for hyperparameters. We output a suite of models which Pareto-dominate all other competitive architectures in terms of accuracy and fairness. Furthermore, we show that these models transfer well to other face recognition datasets with similar and distinct protected attributes. We release our code and raw result files so that researchers and practitioners can replace our fairness metrics with a bias measure of their choice.

Evaluating natural language processing models with generalization metrics that do not need access to any training or testing data
Yaoqing Yang,Ryan Theisen,Liam Hodgkinson,Joseph E. Gonzalez,Kannan Ramchandran,charles h martin,Michael W. Mahoney
The search for effective and robust metrics has been the focus of recent theoretical and empirical work on generalization of deep neural networks (NNs). In this paper, we discuss the performance of natural language processing (NLP) models, and we evaluate various existing and novel generalization metrics. Compared to prior studies, we (i) focus on NLP instead of computer vision (CV), (ii) focus on generalization metrics that predict test error instead of the generalization gap, (iii) focus on generalization metrics that do not need the access to data, and (iv) focus on the heavy-tail (HT) phenomenon that has received comparatively less attention in the study of deep neural networks. We extend recent HT-based work which focuses on power law (PL) distributions, and we study exponential (EXP) and exponentially truncated power law (E-TPL) fitting to the empirical spectral densities (ESDs) of weight matrices. Our empirical studies are carried on (i) hundreds of Transformers trained in different settings, in which we systematically vary the amount of data, the model size and the optimization hyperparameters, (ii) a total of 51 pretrained Transformers from eight families of Huggingface NLP models, including BERT, GPT2, ALBERT, etc., and (iii) a total of 28 existing and novel generalization metrics. From our detailed empirical analyses, we show that shape metrics, or the metrics obtained from fitting the shape of the ESDs, perform uniformly better at predicting generalization performance than scale metrics commonly studied in the literature, as measured by the average rank correlations with the generalization performance for all of our experiments. We also show that among the three HT distributions considered in our paper, the E-TPL fitting of ESDs performs the most robustly when the models are trained in experimental settings, while the PL fitting achieves the best performance on well-trained Huggingface models, and that both E-TPL and PL metrics (which are both shape metrics) outperform scale metrics.

Human Motion Diffusion Model
Guy Tevet,Sigal Raab,Brian Gordon,Yoni Shafir,Daniel Cohen-or,Amit Haim Bermano
Natural and expressive human motion generation is the holy grail of computer animation.
It is a challenging task, due to the diversity of possible motion, human perceptual sensitivity to it, and the difficulty of accurately describing it. Therefore

, current generative solutions are either low-quality or limited in expressiveness.
Diffusion models are promising candidates for the human motion domain since they have already shown remarkable generative capabilities in other domains, and their many-to-many nature.
In this paper, we introduce Motion Diffusion Model (MDM), a carefully adapted classifier-free diffusion-based generative model for human motion data. MDM is transformer-based, combining insights from motion generation literature.
A notable design-choice is that it predicts the sample itself rather than the noise in each step to facilitate the use of established geometric losses on the locations and velocities of the motion, such as the foot contact loss. As we demonstrate, MDM is a generic approach, enabling different modes of conditioning, and different generation tasks. We show that our model is trained with lightweight resources and yet achieves state-of-the-art results on leading benchmarks for text-to-motion, action-to-motion, and unconditioned motion generation.

****

Structure-based Drug Design with Equivariant Diffusion Models
Arne Schneuing,Yuanqi Du,Charles Harris,Arian Rokkum Jamasb,Ilia Igashov,weitao Du,Tom Leon Blundell,Pietro Lio,Carla P Gomes,Max Welling,Michael M. Bronstein,Bruno Correia
Structure-based drug design (SBDD) aims to design small-molecule ligands that bind with high affinity and specificity to pre-determined protein targets. Traditional SBDD pipelines start with large-scale docking of compound libraries from public databases, thus limiting the exploration of chemical space to existent previously studied regions.
Recent machine learning methods approached this problem using an atom-by-atom generation approach, which is computationally expensive.
In this paper, we formulate SBDD as a 3D-conditional generation problem and present DiffSBDD, an E(3)-equivariant 3D-conditional diffusion model that generates novel ligands conditioned on protein pockets.
Furthermore, we curate a new dataset of experimentally determined binding complex data from Binding MOAD to provide realistic binding scenario rather than the synthetic CrossDocked dataset. Comprehensive in silico experiments demonstrate the efficiency of DiffSBDD in generating novel and diverse drug-like ligands that engage protein pockets with high binding energies as predicted by in silico docking.

****

Deep reinforced active learning for multi-class image classification
Emma Slade,Kim Branson
High accuracy medical image classification can be limited by the costs of acquiring more data as well as the time and expertise needed to label existing images. In this paper, we apply active learning to medical image classification, a method which aims to maximise model performance on a minimal subset from a larger pool of data. We present a new active learning framework, based on deep reinforcement learning, to learn an active learning query strategy to label images based on predictions from a convolutional neural network. Our framework modifies the deep-Q network formulation, allowing us to pick data based additionally on geometric arguments in the latent space of the classifier, allowing for high accuracy multi-class classification in a batch-based active learning setting, enabling the agent to label datapoints that are both diverse and about which it is most uncertain. We apply our framework to two medical imaging datasets and compare with standard query strategies as well as the most recent reinforcement learning based active learning approach for image classification.

****

A UNIFIED VIEW OF FINDING AND TRANSFORMING WINNING LOTTERY TICKETS
Kun Wang,Yuxuan Liang,Pengkun Wang,Pengfei Gu,Zhengyang Zhou,Chao Huang,Yang Wang
While over-parameterized deep neural networks obtain prominent results on various machine learning tasks, their superfluous parameters usually make model training and inference notoriously inefficient. Lottery Ticket Hypothesis (LTH) addres

ses this issue from a novel perspective: it articulates that there always exist sparse and admirable subnetworks in a randomly initialized dense network, which can be realized by an iterative pruning strategy. Dual Lottery Ticket Hypothesis (DLTH) further investigates sparse network training from a complementary view. Concretely, it introduces a gradually increased regularization term to transform a dense network to an ultra-light subnetwork without sacrificing learning capacity. After revisiting the success of LTH and DLTH, we unify these two research lines by coupling the stability of iterative pruning and the excellent performance of increased regularization, resulting in two new algorithms (UniLTH and UniDLTH) for finding and transforming winning tickets, respectively. Unlike either LTH without regularization or DLTH which applies regularization across the training, our methods first train the network without any regularization force until the model reaches a certain point (i.e., the validation loss does not decrease for several epochs), and then employ increased regularization for information extrusion and iteratively perform magnitude pruning till the end. We theoretically prove that the early stopping mechanism acts analogously as regularization and can help the optimization trajectory stop at a particularly better point in space than regularization. This not only prevent the parameters from being excessively skewed to the training distribution (over-fitting), but also better stimulate the network potential to obtain more powerful subnetworks. Extensive experiments are conducted to show the superiority of our methods in terms of accuracy and sparsity.

Filter-Recovery Network for Multi-Speaker Audio-Visual Speech Separation

Haoyue Cheng,Zhaoyang Liu,Wayne Wu,Limin Wang

In this paper, we systematically study the audio-visual speech separation task in a multi-speaker scenario. Given the facial information of each speaker, the goal of this task is to separate the corresponding speech from the mixed speech. The existing works are designed for speech separation in a controlled setting with a fixed number of speakers (mostly 2 or 3 speakers), which seems to be impractical for real applications. As a result, we try to utilize a single model to separate the voices with a variable number of speakers. Based on the observation, there are two prominent issues for multi-speaker separation: 1) There are some noisy voice pieces belonging to other speakers in the separation results; 2) Part of the target speech is missing after separation. Accordingly, we propose \textbf{BFRNet}, including a {\bf B}asic audio-visual speech separator and a Filter-Recovery Network (\textbf{FRNet}). FRNet can refine the coarse audio separated by basic audio-visual speech separator. To have fair comparisons, we build a comprehensive benchmark for multi-speaker audio-visual speech separation to verify the performance of various methods. Experimental results show that our method is able to achieve the state-of-the-art performance. Furthermore, we also find that FRNet can boost the performance of other off-the-shelf speech separators, which exhibits its ability of generalization.

****

Probing into the Fine-grained Manifestation in Multi-modal Image Synthesis

Qianyu Feng,Peike Li,Yulei Sui,Hongyu Zhang

The ever-growing development of multi-modal image synthesis brings unprecedented realism to generation tasks. In practice, it is straightforward to judge the visual quality and reality of an image. However, it is labor-consuming to verify the correctness of semantic consistency in the auto-generation, which requires a comprehensive understanding and mapping of different modalities. The results of existing models are sorted and displayed largely relying on the global visual-text similarity. However, this coarse-grained approach does not capture the fine-grained semantic alignment between image regions and text spans. To address this issue, we first present a new method to evaluate the cross-modal consistency by inspecting the decomposed semantic concepts. We then introduce a new metric, called MIS-Score, which is designed to measure the fine-grained semantic alignment between a prompt and its generation quantitatively. Moreover, we have also developed an automated robustness testing technique with referential transforms to test and measure the robustness of multi-modal synthesis models. We have conducte d comprehensive experiments to evaluate the performance of recent popular models for text-to-image generation. Our study demonstrates that the proposed metric MIS-Score represents better evaluation criteria than existing coarse-grained ones (e.g., CLIP) to understand the semantic consistency of the synthesized results. Our robustness testing method also proves the existence of biases embedded in the models, hence uncovering their limitations in real applications.

Can discrete information extraction prompts generalize across language models?

Nathanaël Carraz Rakotonirina,Roberto Dessi,Fabio Petroni,Sebastian Riedel,Marco Baroni

We study whether automatically-induced prompts that effectively extract information from a language model can also be used, out-of-the-box, to probe other language models for the same information. After confirming that discrete prompts induced with the AutoPrompt algorithm outperform manual and semi-manual prompts on the slot-filling task, we demonstrate a drop in performance for AutoPrompt prompts learned on a model and tested on another. We introduce a way to induce prompts by mixing language models at training time that results in prompts that generalize well across models. We conduct an extensive analysis of the induced prompts, finding that the more general prompts include a larger proportion of existing English words and have a less order-dependent and more uniform distribution of information across their component tokens. Our work provides preliminary evidence that it's possible to generate discrete prompts that can be induced once and used with a number of different models, and gives insights on the properties characterizing such prompts.

Deep Power Laws for Hyperparameter Optimization

Arlind Kadra,Maciej Janowski,Martin Wistuba,Josif Grabocka

Hyperparameter optimization is an important subfield of machine learning that focuses on tuning the hyperparameters of a chosen algorithm to achieve peak performance. Recently, there has been a stream of methods that tackle the issue of hyperparameter optimization, however, most of the methods do not exploit the scaling law property of learning curves. In this work, we propose Deep Power Law (DPL), a neural network model conditioned to yield predictions that follow a power-law scaling pattern. Our model dynamically decides which configurations to pause and train incrementally by making use of multi-fidelity estimation. We compare our method against 7 state-of-the-art competitors on 3 benchmarks related to tabular, image, and NLP datasets covering 59 diverse search spaces. Our method achieves the best results across all benchmarks by obtaining the best any-time results compared to all competitors.

****

A view of mini-batch SGD via generating functions: conditions of convergence, phase transitions, benefit from negative momenta.

Maksim Velikanov,Denis Kuznedelev,Dmitry Yarotsky

Mini-batch SGD with momentum is a fundamental algorithm for learning large predictive models. In this paper we develop a new analytic framework to analyze noise-averaged properties of mini-batch SGD for linear models at constant learning rates, momenta and sizes of batches. Our key idea is to consider the dynamics of the second moments of model parameters for a special family of "Spectrally Expressible" approximations. This allows to obtain an explicit expression for the generating function of the sequence of loss values. By analyzing this generating function, we find, in particular, that 1) the SGD dynamics exhibits several convergent and divergent regimes depending on the spectral distributions of the problem; 2) the convergent regimes admit explicit stability conditions, and explicit loss asymptotics in the case of power-law spectral distributions; 3) the optimal convergence rate can be achieved at negative momenta. We verify our theoretical predictions by extensive experiments with MNIST and synthetic problems, and find a good quantitative agreement.

****

Curiosity-Driven Unsupervised Data Collection for Offline Reinforcement Learning

Chenyu Sun,Hangwei Qian,Chunyan Miao

In offline reinforcement learning (RL), while the majority of efforts are focusing on engineering sophisticated learning algorithms given a fixed dataset, very few works have been carried out to improve the dataset quality itself. More importantly, it is even challenging to collect a task-agnostic dataset such that the offline RL agent can learn multiple skills from it. In this paper, we propose a Curiosity-driven Unsupervised Data Collection (CUDC) method to improve the data collection process. Specifically, we quantify the agent's internal belief to estimate the probability of the k-step future states being reachable from the current states. Different from existing approaches that implicitly assume limited feature space with fixed environment steps, CUDC is capable of adapting the number of environment steps to explore. Thus, the feature representation can be substantially diversified with the dynamics information. With this adaptive reachability mechanism in place, the agent can navigate itself to collect higher-quality data with curiosity. Empirically, CUDC surpasses existing unsupervised methods in sample efficiency and learning performance in various downstream offline RL tasks of the DeepMind control suite.

Big Learning: A Universal Machine Learning Paradigm?

Yulai Cong,Miaoyun Zhao

Recent breakthroughs based on big/foundation models reveal a vague avenue for AI, that is, \emph{big data, big/foundation models, big learning, $\cdots$}. Following that avenue, here we elaborate on our newly introduced big learning. Specifically, big learning exhaustively exploits the information/tasks inherent in its large-scale \emph{complete/incomplete} training data, by learning to simultaneously model many/all joint/conditional/marginal data distributions (thus named big learning) with one universal foundation model. We reveal that big learning is what existing foundation models are implicitly doing; accordingly, our big learning provides high-level guidance for flexible design and improvements of foundation models. Besides, big learning (i) is equipped with great flexibilities for complete/incomplete training data and for customizing trustworthy data tasks; (ii) potentially delivers all joint/conditional/marginal data capabilities after training; (iii) significantly reduces the training-test gap with improved model generalization; and (iv) potentially unifies conventional machine learning paradigms and enables their flexible cooperations, manifested as a universal learning paradigm. Preliminary experiments verified the effectiveness of the presented big learning.

Bridging the Gap between ANNs and SNNs by Calibrating Offset Spikes

Zecheng Hao,Jianhao Ding,Tong Bu,Tiejun Huang,Zhaofei Yu

Spiking Neural Networks (SNNs) have attracted great attention due to their distinctive characteristics of low power consumption and temporal information processing. ANN-SNN conversion, as the most commonly used training method for applying SNNs, can ensure that converted SNNs achieve comparable performance to ANNs on large-scale datasets. However, the performance degrades severely under low quantities of time-steps, which hampers the practical applications of SNNs to neuromorphic chips.

In this paper, instead of evaluating different conversion errors and then eliminating these errors, we define an offset spike to measure the degree of deviation between actual and desired SNN firing rates. We perform a detailed analysis of offset spike and note that the firing of one additional (or one less) spike is the main cause of conversion errors. Based on this, we propose an optimization strategy based on shifting the initial membrane potential and we theoretically prove the corresponding optimal shifting distance for calibrating the spike. In addition, we also note that our method has a unique iterative property that enables further reduction of conversion errors. The experimental results show that our proposed method achieves state-of-the-art performance on CIFAR-10, CIFAR-100, and ImageNet datasets. For example, we reach a top-1 accuracy of 67.12% on ImageNet when using 6 time-steps. To the best of our knowledge, this is the first time an ANN-SNN conversion has been shown to simultaneously achieve high accuracy and ultralow latency on complex datasets. Code is available at https://github.com/hzc1208/ANN2SNN_COS.

MIA: A Framework for Certified Robustness of Time-Series Classification and Forecasting Against Temporally-Localized Perturbations

Ruoxin Chen,Ruizhe Zhong,Jiawei Sun,Jie LI,Chentao Wu,Junchi Yan

Recent literature demonstrates that times-series forecasting/classification are sensitive to input perturbations. However, the defenses for time-series models are relatively under-explored. In this paper, we propose \textbf{M}asking \textbf{I}mputing \textbf{A}ggregation (MIA), a plug-and-play framework to provide an arbitrary deterministic time-series model with certified robustness against temporally-localized perturbations (also known as ℓ_0-norm localized perturbations), which is to our knowledge the first ℓ_0-norm defense for time-series models. Our main insight is to let an occluding mask move across the input series, guaranteeing that, for an arbitrary localized perturbation there must exist at least a mask that completely remove out the perturbation, so that our prediction on this masked series is uninfluenced. Remarkably, MIA is high-availability as it still works even if we only have query access to the pretrained model. Furthermore, as there is no dedicated defense against ℓ_0-norm perturbations for time-series models, we specifically adapt two matrix-based defenses to time-series models for comparison. Extensive experiments show that MIA yields stronger robustness as well as practicality.

Offline RL with No OOD Actions: In-Sample Learning via Implicit Value Regularization

Haoran Xu,Li Jiang,Jianxiong Li,Zhuoran Yang,Zhaoran Wang,Victor Wai Kin Chan,Xianyuan Zhan

Most offline reinforcement learning (RL) methods suffer from the trade-off between improving the policy to surpass the behavior policy and constraining the policy to limit the deviation from the behavior policy as computing Q-values using out-of-distribution (OOD) actions will suffer from errors due to distributional shift. The recent proposed \textit{In-sample Learning} paradigm (i.e., IQL), which improves the policy by quantile regression using only data samples, shows great promise because it learns an optimal policy without querying the value function of any unseen actions. However, it remains unclear how this type of method handles the distributional shift in learning the value function. In this work, we make a key finding that the in-sample learning paradigm arises under the \textit{Implicit Value Regularization} (IVR) framework. This gives a deeper understanding of why the in-sample learning paradigm works, i.e., it applies implicit value regularization to the policy. Based on the IVR framework, we further propose two practical algorithms, Sparse Q-learning (SQL) and Exponential Q-learning (EQL), which adopt the same value regularization used in existing works, but in a complete in-sample manner. Compared with IQL, we find that our algorithms introduce sparsity in learning the value function, making them more robust in noisy data regimes. We also verify the effectiveness of SQL and EQL on D4RL benchmark datasets and show the benefits of in-sample learning by comparing them with CQL in small data regimes. Code is available at \url{https://github.com/ryanxhr/SQL}.

Eliminating Catastrophic Overfitting Via Abnormal Adversarial Examples Regularization

Runqi Lin,Chaojian Yu,Tongliang Liu

Single-step adversarial training (SSAT) is shown to be able to defend against iterative-step adversarial attacks to achieve both efficiency and robustness. However, SSAT suffers from catastrophic overfitting (CO) with strong adversaries, showing that the classifier decision boundaries are highly distorted and robust accuracy against iterative-step adversarial attacks suddenly drops from peak to nearly 0% in a few epochs. In this work, we find that some adversarial examples generated on the network trained by SSAT exhibit anomalous behaviour, that is, although the training data is generated by the inner maximization process, the loss of some adversarial examples decreases instead, which we called abnormal adversarial examples. Furthermore, network optimization on these abnormal adversarial examples will further accelerate the model decision boundaries distortion, and correspondingly, the number of abnormal adversarial examples will sharply increase with CO. These observations motivate us to prevent CO by hindering the generation of abnormal adversarial examples. Specifically, we design a novel method, Abnormal Adversarial Examples Regularization (AAER), which explicitly regularizes the number and logits variation of abnormal adversarial examples to hinder the model from generating abnormal adversarial examples. Extensive experiments demonstrate that our method can prevent CO and further boost adversarial robustness with strong adversaries.

TIB: Detecting Unknown Objects via Two-Stream Information Bottleneck

Aming WU,Cheng Deng

Detecting diverse objects, including ones never-seen-before during model training, is critical for the safe application of object detectors. To this end, a task of unsupervised out-of-distribution object detection (OOD-OD) is proposed to detect unknown objects without the reliance on an auxiliary dataset. For this task, it is important to reduce the impact of lacking unknown data for supervision and leverage in-distribution (ID) data to improve the model's discrimination ability. In this paper, we propose a method of Two-Stream Information Bottleneck (TIB), which consists of a standard Information Bottleneck and a dedicated Reverse Information Bottleneck (RIB). Specifically, after extracting the features of an ID image, we first define a standard IB network to disentangle instance representations that are beneficial for localizing and recognizing objects. Meanwhile, we present RIB to obtain simulative OOD features to alleviate the impact of lacking unknown data. Different from standard IB aiming to extract task-relevant compact representations, RIB is to obtain task-irrelevant representations by reversing the optimization objective of the standard IB. Next, to further enhance the discrimination ability, a mixture of information bottlenecks is designed to sufficiently capture object-related information. In the experiments, our method is evaluated on OOD-OD and incremental object detection. The significant performance gains over baselines show the superiorities of our method.

Win: Weight-Decay-Integrated Nesterov Acceleration for Adaptive Gradient Algorithms

Pan Zhou,Xingyu Xie,Shuicheng YAN

Training deep networks on large-scale datasets is computationally challenging. In this work, we explore the problem of ``\textit{how to accelerate adaptive gradient algorithms in a general manner}", and aim to provide practical efficiency-boosting insights.   To this end, we   propose an effective and general   {Weight-decay-Integrated Nesterov acceleration} (Win) to accelerate adaptive algorithms. Taking AdamW and Adam as examples, we minimize a dynamical   loss per iteration which combines the vanilla training loss and a dynamic regularizer inspired by proximal point method (PPM) to improve the convexity of the problem. To introduce Nesterov-alike-acceleration into AdamW and Adam, we respectively use the first- and second-order Taylor approximations of vanilla loss to update the variable twice. In this way, we arrive at our Win acceleration for AdamW and Adam that uses a conservative step and a reckless step to update twice and then linearly combines these two updates for acceleration. Next, we extend Win acceleration to LAMB and SGD. Our transparent acceleration derivation could provide insights for other accelerated methods and their integration into adaptive algorithms. Besides, we prove the convergence of Win-accelerated adaptive algorithms and justify their convergence superiority over their non-accelerated counterparts by taking AdamW and Adam as examples. Experimental results testify to the faster convergence speed and superior performance of our Win-accelerated AdamW, Adam, LAMB and SGD over their non-accelerated counterparts on vision classification tasks and language modeling tasks with both CNN and Transforme r backbones. We hope Win shall be a default acceleration option for popular optimizers in deep learning community to improve the training efficiency. Code will be released at \url{https://github.com/sail-sg/win}.

Towards Understanding Convergence and Generalization of AdamW

Pan Zhou,Xingyu Xie,Shuicheng YAN

AdamW modifies vanilla Adam by decaying network weights per training iteration, and shows remarkable generalization superiority over Adam and its ℓ_2-regularized variant. In context of adaptive gradient algorithms (\eg~Adam), the decoupled weight decay in AdamW differs from the widely used ℓ_2-regularizer, since the former does not affect optimization steps, while the latter changes the first- and second-order gradient moments and thus the optimization steps. Despite its great success on both vision transformers and CNNs, for AdamW, its convergence behavior and its generalization improvement over (ℓ_2-regularized) Adam remain absent yet. To solve this issue, we prove the convergence of AdamW and justify its generalization advantages over Adam and its ℓ_2-regularized version. Specifically, AdamW can provably converge but minimizes a dynamically regularized loss that combines a vanilla loss and a dynamical regularization induced by the decoupled weight decay, thus leading to its different behaviors compared with Adam and its ℓ_2-regularized version. Moreover, on both general nonconvex problems and P\L-conditioned problems, we establish the stochastic gradient complexity of AdamW to find a stationary point. Such complexity is also applicable to Adam and its ℓ_{2}-regularized variant, and indeed improves their previously known complexity, especially for modern over-parametrized networks. Besides, we theoretically show that AdamW often enjoys smaller generalization error bound than both Adam and its ℓ_2-regularized variant from the Bayesian posterior aspect. This result, for the first time, explicitly reveals the benefits of the unique decoupled weight decay in AdamW. We hope the theoretical results in this work could motivate researchers to propose novel optimizers with faster convergence and better generalization. Experimental results testify our theoretical implications.

GeoVeX: Geospatial Vectors with Hexagonal Convolutional Autoencoders

Daniele Donghi,Anne Morvan

We introduce a new geospatial representation model called GeoVeX to learn global vectors for all geographical locations on Earth land cover (200+ million embeddings). GeoVeX is built on a novel model architecture named Hexagonal Convolutional Autoencoders (HCAE) combined with a Zero-Inflated Poisson (ZIP) reconstruction layer, applied to a grid of Uber's H3 hexagons, each one described by the histogram of OpenStreetMap (OSM) geographical tags occurrences. GeoVeX is novel on three aspects: 1) it produces the first geospatial vectors trained on worldwide open data, enabling wide adoption on every downstream tasks which may benefit from enriched geographical information, requiring only location coordinates; 2) it represents the first use of hexagonal convolutions within autoencoder architectures, to learn latent representations of an hexagonal grid; and 3) it introduces a spatial-contextual Poisson reconstruction loss function for autoencoder architectures suitable for training on sparse geographical count data. Experiments demonstrate that GeoVeX embeddings can improve upon state-of-the-art geospatial location representations on two different downstream tasks: price prediction in the travel industry and hyperlocal interpolation of climate data from weather stations.

Split and Merge Proxy: pre-training protein-protein contact prediction by mining rich information from monomer data

Hao Du,Yuchen Ren,Yan Lu,He Huang,Yating Liu,Zhendong Mao,Xinqi Gong,Wanli Ouyang

Protein-protein contact prediction is a key intelligent biology computation technology for complex multimer protein function analysis but still sufferers from low accuracy. An important problem is that the number of training data cannot meet the requirements of deep-learning-based methods due to the expensive cost of c apturing structure information of multimer data. In this paper, we solve this data volume bottleneck in a cheap way, borrowing rich information from monomer data. To utilize monomer (single chain) data in this multimer (multiple chains) problem, we propose a simple but effective pre-training method called Split and Merger Proxy (SMP), which utilizes monomer data to construct a proxy task for model pre-training. This proxy task cuts monomer data into two sub-parts, called pseudo multimer, and pre-trains the model to merge them back together by predicting their pseudo contacts. The pre-trained model is then used to initialize for our target – protein-protein contact prediction. Because of the consistency between this proxy task and the final target, the whole method brings a stronger pre-trained model for subsequent fine-tuning, leading to significant performance gains. Extensive experiments validate the effectiveness of our method and show the model performs better than the state of the art by 11.40% and 2.97% on the P@ L/10 metric for bounded benchmarks DIPS-Plus and CASP-CAPRI, respectively. Further, the model also achieves almost 1.5 times performance superiority to the state of the art on the harder unbounded benchmark DB5. The code, model, and pre-training data will be released after this paper is accepted.

ESD: Expected Squared Difference as a Tuning-Free Trainable Calibration Measure

Hee Suk Yoon,Joshua Tian Jin Tee,Eunseop Yoon,Sunjae Yoon,Gwangsu Kim,Yingzhen Li,Chang D. Yoo

Studies have shown that modern neural networks tend to be poorly calibrated due to over-confident predictions. Traditionally, post-processing methods have been used to calibrate the model after training. In recent years, various trainable calibration measures have been proposed to incorporate them directly into the training process. However, these methods all incorporate internal hyperparameters, and the performance of these calibration objectives relies on tuning these hyperparameters, incurring more computational costs as the size of neural networks and datasets become larger. As such, we present Expected Squared Difference (ESD), a tuning-free (i.e., hyperparameter-free) trainable calibration objective loss, where we view the calibration error from the perspective of the squared difference between the two expectations. With extensive experiments on several architectures (CNNs, Transformers) and datasets, we demonstrate that (1) incorporating ESD into the training improves model calibration in various batch size settings without the need for internal hyperparameter tuning, (2) ESD yields the best-calibrated results compared with previous approaches, and (3) ESD drastically improves the computational costs required for calibration during training due to the absence of internal hyperparameter. The code is publicly accessible at https://github.com/hee-suk-yoon/ESD.

Interactive Portrait Harmonization

Jeya Maria Jose Valanarasu,HE Zhang,Jianming Zhang,Yilin Wang,Zhe Lin,Jose Echevarria,Yinglan Ma,Zijun Wei,Kalyan Sunkavalli,Vishal Patel

Current image harmonization methods consider the entire background as the guidance for harmonization. However, this may limit the capability for user to choose any specific object/person in the background to guide the harmonization. To enable flexible interaction between user and harmonization, we introduce interactive harmonization, a new setting where the harmonization is performed with respect to a selected region in the reference image instead of the entire background. A new flexible framework that allows users to pick certain regions of the background image and use it to guide the harmonization is proposed. Inspired by professional portrait harmonization users, we also introduce a new luminance matching loss to optimally match the color/luminance conditions between the composite foreground and select reference region. This framework provides more control to the image harmonization pipeline achieving visually pleasing portrait edits. Furthermore, we also introduce a new dataset carefully curated for validating portrait harmonization. Extensive experiments on both synthetic and real-world datasets show that the proposed approach is efficient and robust compared to previous harmonization baselines, especially for portraits.

Self-Distillation for Further Pre-training of Transformers
Seanie Lee,Minki Kang,Juho Lee,Sung Ju Hwang,Kenji Kawaguchi
Pre-training a large transformer model on a massive amount of unlabeled data and fine-tuning it on labeled datasets for diverse downstream tasks has proven to be a successful strategy, for a variety of vision and natural language processing tasks. However, direct fine-tuning of the pre-trained model may be suboptimal if there exist large discrepancies across data domains for pre-training and fine-tuning. To tackle this issue, several previous studies have proposed further pre-training strategies, where we continue to pre-train the model on the target unlabeled dataset before fine-tuning. However, all of them solely focus on language models and we empirically find that a Vision Transformer is vulnerable to overfitting as we continue to pretrain the model on target unlabeled data. In order to tackle this limitation, we propose self-distillation as a regularization for a further pre-training stage. Specifically, we first further pre-train the initial pre-trained model on the target unlabeled data and then consider it as a teacher for self-distillation. Then we take the same initial pre-trained model as a student and enforce its hidden representations to be close to those of the teacher while optimizing the student with a masked auto-encoding objective. We empirically validate the efficacy of self-distillation on a variety of benchmark datasets for image and text classification tasks. Experimentally, we show that our proposed method outperforms all the relevant baselines. Theoretically, we analyze the proposed method with a simplified model to understand how self-distillation for further pre-training can potentially help improve the performance of the downstream tasks.

Iterative Relaxing Gradient Projection for Continual Learning
Zeyuan Yang,Zonghan Yang,Peng Li,Yang Liu
A critical capability for intelligent systems is to continually learn given a sequence of tasks. An ideal continual learner should be able to avoid catastrophic forgetting and effectively leverage past learned experiences to master new knowledge. Among different continual learning algorithms, gradient projection approaches impose hard constraints on the optimization space for new tasks to minimize task interference, yet hinder forward knowledge transfer at the same time. Recent methods use expansion-based techniques to relax the constraints, but a growing network can be computationally expensive. Therefore, it remains a challenge whether we can improve forward knowledge transfer for gradient projection approaches \textit{using a fixed network architecture}. In this work, we propose the Iterative Relaxing Gradient Projection (IRGP) framework. The basic idea is to iteratively search for the parameter subspaces most related to the current task and relax these parameters, then reuse the frozen spaces to facilitate forward knowledge transfer while consolidating previous knowledge. Our framework requires neither memory buffers nor extra parameters. Extensive experiments have demonstrated the superiority of our framework over several strong baselines. We also provide theoretical guarantees for our iterative relaxing strategies.

Adversarial Counterfactual Environment Model Learning
Xiong-Hui Chen,Yang Yu,Zhengmao Zhu,ZhiHua Yu,Chen Zhenjun,Chenghe Wang,Yinan Wu,Hongqiu Wu,Rong-Jun Qin,Ruijin Ding,Huang Fangsheng
A good model for action-effect prediction, i.e., the environment model, is essential for sample-efficient policy learning, in which the agent can take numerous free trials to find good policies. Currently, the model is commonly learned by fitting historical transition data through empirical risk minimization (ERM). However, we discover that simple data fitting can lead to a model that will be totally wrong in guiding policy learning due to the selection bias in offline dataset collection. In this work, we introduce weighted empirical risk minimization (WERM) to handle this problem in model learning. A typical WERM method utilizes inverse propensity scores to re-weight the training data to approximate the target distribution. However, during the policy training, the data distributions of the candidate policies can be various and unknown. Thus, we propose an adversarial weighted empirical risk minimization (AWRM) objective that learns the model wi

th respect to the worst case of the target distributions. We implement AWRM in a sequential decision structure, resulting in the GALILEO model learning algorithm. We also discover that GALILEO is closely related to adversarial model learning, explaining the empirical effectiveness of the latter. We apply GALILEO in synthetic tasks and verify that GALILEO makes accurate predictions on counterfactual data. We finally applied GALILEO in real-world offline policy learning tasks and found that GALILEO significantly improves policy performance in real-world testing.

Admeta: A Novel Double Exponential Moving Average to Adaptive and Non-adaptive Momentum Optimizers with Bidirectional Looking

Yineng Chen,Zuchao Li,Lefei Zhang,Bo Du,hai zhao

Optimizer is an essential component for the success of deep learning, which guides the neural network to update the parameters according to the loss on the training set. SGD and Adam are two classical and effective optimizers on which researchers have proposed many variants, such as SGDM and RAdam. In this paper, we innovatively combine the backward-looking and forward-looking aspects of the optimizer algorithm and propose a novel \textsc{Admeta} (\textbf{A} \textbf{D}ouble exponential \textbf{M}oving averag\textbf{E} \textbf{T}o \textbf{A}daptive and non-adaptive momentum) optimizer framework. For backward-looking part, we propose a DEMA variant scheme, which is motivated by a metric in the stock market, to replace the common exponential moving average scheme. While in the forward-looking part, we present a dynamic lookahead strategy which asymptotically approaching a set value, maintaining its speed at early stage and high convergence performance at final stage. Based on this idea, we provide two optimizer implementations, \textsc{AdmetaR} and \textsc{AdmetaS}, the former based on RAdam and the latter based on SGDM. Through extensive experiments on diverse tasks, we find that the proposed \textsc{Admeta} optimizer outperforms our base optimizers and shows advantages over recently proposed competitive optimizers. We also provide theoretical proof of these two algorithms, which verifies the convergence of our proposed \textsc{Admeta}.

Learning from Interval-valued Data

Guangzhi Ma,Jie Lu,Zhen Fang,Feng Liu,Guangquan Zhang

The classification problem concerning crisp-valued data has been well resolved. However, interval-valued data, where all of the observations’ features are described by intervals, is also a common type of data in real-world scenarios. For example, the data extracted by many measuring devices are not exact numbers but intervals. In this paper, we focus on a highly challenging problem called learning from interval-valued data (LIND), where we aim to learn a classifier with high performance on interval-valued observations. First, we obtain the estimation error bound of the LIND problem based on Rademacher complexity. Then, we give the theoretical analysis to show the strengths of multi-view learning on classification problems, which inspires us to construct a new framework called multi-view interval information extraction (Mv-IIE) approach for improving classification accuracy on interval-valued data. The experiment comparisons with several baselines on both synthetic and real-world datasets illustrate the superiority of the proposed framework in handling interval-valued data. Moreover, we describe an application of the Mv-IIE framework that we can prevent data privacy leakage by transforming crisp-valued (raw) data into interval-valued data.

Efficient Hyperdimensional Computing

Zhanglu Yan,Shida Wang,Kaiwen Tang,Weng-Fai Wong

Hyperdimensional computing (HDC) uses binary vectors of high dimensions to perform classification. Due to its simplicity and massive parallelism, HDC can be highly energy-efficient and well-suited for resource-constrained platforms. However, in trading off orthogonality with efficiency, hypervectors may use tens of thousands of dimensions. In this paper, we will examine the necessity for such high dimensions. In particular, we give a detailed theoretical analysis of the relationship among dimensions of hypervectors, accuracy, and orthogonality. The main conclusion of this study is that a much lower dimension, typically less than 100, can also achieve similar or even higher detecting accuracy compared with other state-of-the-art HDC models. Based on this insight, we propose a suite of novel techniques to build HDC models that use binary hypervectors of dimensions that are orders of magnitude smaller than those found in the state-of-the-art HDC models, yet yield equivalent or even improved accuracy and efficiency. For image classification, we achieved an HDC accuracy of 96.88\% with a dimension of only 32 on the MNIST dataset. We further explore our methods on more complex datasets like CIFAR-10 and show the limits of HDC computing.

****

Contextual Convolutional Networks

Shuxian Liang,Xu Shen,Tongliang Liu,Xian-Sheng Hua

This paper presents a new Convolutional Neural Network, named Contextual Convolutional Network, that capably serves as a general-purpose backbone for visual recognition. Most existing convolutional backbones follow the representation-to-classification paradigm, where representations of the input are firstly generated by category-agnostic convolutional operations, and then fed into classifiers for specific perceptual tasks (e.g., classification and segmentation). In this paper, we deviate from this classic paradigm and propose to augment potential category memberships as contextual priors in the convolution for contextualized representation learning. Specifically, top-k likely classes from the preceding stage are encoded as a contextual prior vector. Based on this vector and the preceding features, offsets for spatial sampling locations and kernel weights are generated to modulate the convolution operations. The new convolutions can readily replace their plain counterparts in existing CNNs and can be easily trained end-to-end by standard back-propagation without additional supervision. The qualities of Contextual Convolutional Networks make it compatible with a broad range of vision tasks and boost the state-of-the-art architecture ConvNeXt-Tiny by 1.8% on top-1 accuracy of ImageNet classification. The superiority of the proposed model reveals the potential of contextualized representation learning for vision tasks. Code is available at: \url{https://github.com/liang4sx/contextual_cnn}.

Factor Learning Portfolio Optimization Informed by Continuous-Time Finance Models

Sinong Geng,houssam nassif,Zhaobin Kuang,Anders Max Reppen,K. Ronnie Sircar

We study financial portfolio optimization in the presence of unknown and uncontrolled system variables referred to as stochastic factors. Existing work falls into two distinct categories: (i) reinforcement learning employs end-to-end policy learning with flexible factor representation, but does not precisely model the dynamics of asset prices or factors; (ii) continuous-time finance methods, in contrast, take advantage of explicitly modeled dynamics but pre-specify, rather than learn, factor representation. We propose FaLPO (factor learning portfolio optimization), a framework that interpolates between these two approaches. Specifically, FaLPO hinges on deep policy gradient to learn a performant investment policy that takes advantage of flexible representation for stochastic factors. Meanwhile, FaLPO also incorporates continuous-time finance models when modeling the dynamics. It uses the optimal policy functional form derived from such models and optimizes an objective that combines policy learning and model calibration. We prove the convergence of FaLPO, and provide performance guarantees via a finite-sample bound. On both synthetic and real-world portfolio optimization tasks, we observe that FaLPO outperforms five leading methods. Finally, we show that FaLPO can be extended to other decision-making problems with stochastic factors.

****

An Incremental Learning Approach for Sustainable Regional Isolation and Integration

Ziyi Wu,Hongge Yao,Jiaojiao Ma

Humans are capable of acquiring new knowledge on a constant basis, while integrating and optimizing old knowledge without forgetting them. This is mainly attributed to the human brain’s ability of partitioned learning and memory replay. In this paper, we simulate this ability and propose an incremental learning network of Sustainable Regional Isolation and Integration (SRII). SRII consists of two phases, regional isolation and regional integration, which are iterated to achieve continuous incremental class learning. Regional isolation isolates new learning processes to avoid interfering with existing knowledge, while regional integration introduces knowledge distillation and margin loss regularization term, knowledge distillation to transfer replay knowledge for alleviating catastrophic forgetting, margin loss regularization term to clarify the boundaries of new and old knowledge for alleviating recency bias. Experimental results on the CIFAR100 and miniImageNet datasets demonstrate that SRII outperforms the state-of-the-arts to avoid catastrophic forgetting. In all 5-stage and 10-stage incremental settings, SRII outperforms the baseline and achieves at least $5.27\%+$ average accuracy improvement. Our source code is available at https://github.com/Wuziyi123/SRII.

GraphPNAS: Learning Distribution of Good Neural Architectures via Deep Graph Generative Models

Muchen Li,Jeffrey Yunfan Liu,Leonid Sigal,Renjie Liao

Neural architectures can be naturally viewed as computational graphs. Motivated by this perspective, we, in this paper, study neural architecture search (NAS) through the lens of learning random graph models. In contrast to existing NAS methods which largely focus on searching for a single best architecture, i.e, point estimation, we propose GraphPNAS a deep graph generative model that learns a distribution of well-performing architectures. Relying on graph neural networks (GNNs), our GraphPNAS can better capture topologies of good neural architectures and relations between operators therein. Moreover, our graph generator leads to a learnable probabilistic search method that is more flexible and efficient than the commonly used RNN generator and random search methods. Finally, we learn our generator via an efficient reinforcement learning formulation for NAS. To assess the effectiveness of our GraphPNAS, we conduct extensive experiments on three search spaces, including the challenging RandWire on TinyImageNet, ENAS on CIFAR10, and NAS-Bench-101. The complexity of RandWire is significantly larger than other search spaces in the literature. We show that our proposed graph generator consistently outperforms RNN-based one and achieves better or comparable performances than state-of-the-art NAS methods.

Private GANs, Revisited

Alex Bie,Gautam Kamath,Guojun Zhang

We show that with improved training, the standard approach for differentially private GANs -- updating the discriminator with noisy gradients -- achieves or competes with state-of-the-art results for private image synthesis. Existing instantiations of this approach neglect to consider how adding noise only to discriminator updates disrupts the careful balance between generator and discriminator necessary for successful GAN training. We show that a simple fix restores parity: taking more discriminator steps between generator steps. Finally, with the goal of restoring parity between generator and discriminator, we experiment with further modifications to improve discriminator training and see further improvements. For MNIST at $\eps=10$, our private GANs improve the record FID from 48.4 to 13.0, as well as downstream classifier accuracy from 83.2\% to 95.0\%.

****

Hidden Poison: Machine unlearning enables camouflaged poisoning attacks

Jimmy Z. Di,Jack Douglas,Jayadev Acharya,Gautam Kamath,Ayush Sekhari

We introduce camouflaged data poisoning attacks, a new attack vector that arises in the context of machine unlearning and other settings when model retraining may be induced. An adversary first adds a few carefully crafted points to the training dataset such that the impact on the model's predictions is minimal. The adversary subsequently triggers a request to remove a subset of the introduced points at which point the attack is unleashed and the model's predictions are negatively affected. In particular, we consider clean-label targeted attacks (in which the goal is to cause the model to misclassify a specific test point) on datase ts including CIFAR-10, Imagenette, and Imagewoof. This attack is realized by constructing camouflage datapoints that mask the effect of a poisoned dataset.

Statistical Inference for Fisher Market Equilibrium

Luofeng Liao,Yuan Gao,Christian Kroer

Statistical inference under market equilibrium effects has attracted increasing attention recently. In this paper we focus on the specific case of linear Fisher markets. They have been widely use in fair resource allocation of food/blood donations and budget management in large-scale Internet ad auctions. In resource allocation, it is crucial to quantify the variability of the resource received by the agents (such as blood banks and food banks) in addition to fairness and efficiency properties of the systems. For ad auction markets, it is important to establish statistical properties of the platform's revenues in addition to their expected values. To this end, we propose a statistical framework based on the concept of infinite-dimensional Fisher markets. In our framework, we observe a market formed by a finite number of items sampled from an underlying distribution (the ``observed market'') and aim to infer several important equilibrium quantities of the underlying long-run market. These equilibrium quantities include individual utilities, social welfare, and pacing multipliers. Through the lens of sample average approximation (SSA), we derive a collection of statistical results and show that the observed market provides useful statistical information of the long-run market. In other words, the equilibrium quantities of the observed market converge to the true ones of the long-run market with strong statistical guarantees. These include consistency, finite sample bounds, asymptotics, and confidence. As an extension, we discuss revenue inference in quasilinear Fisher markets.

Auxiliary task discovery through generate and test

Banafsheh Rafiee,Sina Ghiassian,Jun Jin,Richard S. Sutton,Jun Luo,Adam White

In this paper, we explore an approach to auxiliary task discovery in reinforcement learning based on ideas from representation learning. Auxiliary tasks tend to improve data efficiency by forcing the agent to learn auxiliary prediction and control objectives in addition to the main task of maximizing reward, and thus producing better representations. Typically these tasks are designed by people. Meta-learning offers a promising avenue for automatic task discovery; however, these methods are computationally expensive and challenging to tune in practice. In this paper, we explore a complementary approach to the auxiliary task discovery: continually generating new auxiliary tasks and preserving only those with high utility. We also introduce a new measure of auxiliary tasks' usefulness based on how useful the features induced by them are for the main task. Our discovery algorithm significantly outperforms random tasks, hand-designed tasks, and learning without auxiliary tasks across a suite of environments.

MMTSA: Multi-Modal Temporal Segment Attention Network for Efficient Human Activity Recognition

Ziqi Gao,Jianguo Chen,Xin Liu,Yuntao Wang,Yuanchun Shi

Multimodal sensors (e.g., visual, non-visual, and wearable) provide complementary information to develop robust perception systems for recognizing activities. However, most existing algorithms use dense sampling and heterogeneous sub-network to extract unimodal features and fuse them at the end of their framework, which causes data redundancy, lack of multimodal complementary information and high computational cost. In this paper, we propose a new novel multi-modal neural architecture based on RGB and IMU wearable sensors (e.g., accelerometer, gyroscope) for human activity recognition called Multimodal Temporal Segment Attention Network (MMTSA). MMTSA first employs a multimodal data isomorphism mechanism based on Gramian Angular Field (GAF) and then applies a novel multimodal sparse sampling method to reduce redundancy. Moreover, we propose an inter-segment attention module in MMTSA to fuse multimodal features effectively and efficiently. We demonstrate the importance of imu data imaging and attention mechanism in human activity recognition by rigours evaluation on three public datasets, and achieved s uperior improvements (11.13% on the MMAct dataset) than the previous state-of-the-art methods.

Scenario-based Question Answering with Interacting Contextual Properties
Haitian Sun,William W. Cohen,Ruslan Salakhutdinov

In the scenario-based Question Answering (QA) task, models are asked to find answers that are appropriate to the user scenarios associated with the question and identify information that is missing from the scenarios but is necessary for the answers to hold. Scenarios commonly include multiple properties of users, such as age, employment status, and income level for the question “How much can I claim from this benefit”. The properties relevant to a potential answer are given in a document, which will state conditions necessary for the answer to hold. Documents also may specify how conditions interact with each other, e.g. with text like “one of the conditions below must apply”. Although understanding the relationship between conditions is crucial for solving this challenging QA task, limited work has been done so far in modeling this. In this paper, we propose the T-Reasoner model, which solves this problem with three jointly learned modules: an entailment module which checks whether a condition has been satisfied by the scenario, a decoding module which locates eligible answers from documents, and a reasoning module which infers the relationship between conditions and performs a reasoning step to determine the logically consistent answers and identify missing conditions. T-Reasoner outperforms strong baselines on a synthetic scenario-based QA dataset and achieves a new state-of-the-art on two scenario-based QA benchmarks, outperforming the prior best models by 3-10 points.

Easy Differentially Private Linear Regression
Kareem Amin,Matthew Joseph,Mónica Ribero,Sergei Vassilvitskii

Linear regression is a fundamental tool for statistical analysis. This has motivated the development of linear regression methods that also satisfy differential privacy and thus guarantee that the learned model reveals little about any one data point used to construct it. However, existing differentially private solutions assume that the end user can easily specify good data bounds and hyperparameters. Both present significant practical obstacles. In this paper, we study an algorithm which uses the exponential mechanism to select a model with high Tukey depth from a collection of non-private regression models. Given n samples of d-dimensional data used to train m models, we construct an efficient analogue using an approximate Tukey depth that runs in time $O(d^2n + dm\log(m))$. We find that this algorithm obtains strong empirical performance in the data-rich setting with no data bounds or hyperparameter selection required.

PointDP: Diffusion-driven Purification against 3D Adversarial Point Clouds
Jiachen Sun,Jiongxiao Wang,Weili Nie,Zhiding Yu,Zhuoqing Mao,Chaowei Xiao

3D Point cloud is a critical data representation in many real-world applications, such as autonomous driving, robotics, and medical imaging. Although the success of deep learning further accelerates the adoption of 3D point clouds in the physical world, deep learning is notoriously vulnerable to adversarial attacks. Various defense solutions have been proposed to build robust models against adversarial attacks. In this work, we identify that the state-of-the-art empirical defense, adversarial training, has a major limitation in 3D point cloud models due to gradient obfuscation, resulting in significant degradation of robustness against strong attacks. To bridge the gap, we propose PointDP, a purification strategy that leverages diffusion models to defend against 3D adversarial attacks. Since PointDP does not rely on predefined adversarial examples for training, it can defend against diverse threats. We extensively evaluate PointDP on six representative 3D point cloud architectures and leverage sixteen strong and adaptive attacks to demonstrate its lower-bound robustness. Our evaluation shows that PointDP achieves significantly better (i.e., 12.6\%-40.3\%) adversarial robustness than state-of-the-art methods under strong attacks bounded by different ℓ_p norms.

Visual Recognition with Deep Nearest Centroids

Wenguan Wang,Cheng Han,Tianfei Zhou,Dongfang Liu

We devise deep nearest centroids (DNC), a conceptually elegant yet surprisingly effective network for large-scale visual recognition, by revisiting Nearest Centroids, one of the most classic and simple classifiers. Current deep models learn the classifier in a fully parametric manner, ignoring the latent data structure and lacking simplicity and explainability. DNC instead conducts nonparametric, case-based reasoning; it utilizes sub-centroids of training samples to describe class distributions and clearly explains the classification as the proximity of test data and the class sub-centroids in the feature space. Due to the distance-based nature, the network output dimensionality is flexible, and all the learnable parameters are only for data embedding. That means all the knowledge learnt for ImageNet classification can be completely transferred for pixel recognition learning, under the ‘pre-training and fine-tuning’ paradigm. Apart from its nested simplicity and intuitive decision-making mechanism, DNC can even possess ad-hoc explainability when the sub-centroids are selected as actual training images that humans can view and inspect. Compared with parametric counterparts, DNC performs better on image classification (CIFAR-10, ImageNet) and greatly boots pixel recognition (ADE20K, Cityscapes), with improved transparency and fewer learnable parameters, using various network architectures (ResNet, Swin) and segmentation models (FCN, DeepLabV3, Swin). We feel this work brings fundamental insights into related fields. Our code is available at https://github.com/ChengHan111/DNC.

Closing the Gap Between SVRG and TD-SVRG with Gradient Splitting

Arsenii Mustafin,Ioannis Paschalidis,Alex Olshevsky

Temporal difference (TD) learning is a simple algorithm for policy evaluation in reinforcement learning. The performance of TD learning is affected by high variance and it can be naturally enhanced with variance reduction techniques, such as the Stochastic Variance Reduced Gradient (SVRG) method. Recently, multiple works have sought to fuse TD learning with SVRG to obtain a policy evaluation method with a linear rate of convergence. However, the resulting convergence rate is significantly weaker than what is achieved by SVRG in the setting of convex optimization. In this work we utilize a recent interpretation of TD-learning as the splitting of the gradient of an appropriately chosen function, thus simplifying the algorithm and fusing TD with SVRG. We prove a linear convergence bound that is identical to the convergence bound available for SVRG in the convex setting.

****

Rethinking Backdoor Data Poisoning Attacks in the Context of Semi-Supervised Learning

Marissa Catherine Connor,Vincent Emanuele

Semi-supervised learning methods can train high-accuracy machine learning models with a fraction of the labeled training samples required for traditional supervised learning. Such methods do not typically involve close review of the unlabeled training samples, making them tempting targets for data poisoning attacks. In this paper we investigate the vulnerabilities of semi-supervised learning methods to backdoor data poisoning attacks on the unlabeled samples. We show that a simple poisoning attack using adversarially perturbed samples is highly effective - achieving an average attack success rate of 93.6%. We introduce a generalized attack framework targeting semi-supervised learning methods to better understand and exploit their limitations and to motivate future defense strategies.

****

LPT: Long-tailed Prompt Tuning for Image Classification

Bowen Dong,Pan Zhou,Shuicheng Yan,Wangmeng Zuo

For long-tailed classification tasks, most works often pretrain a big model on a large-scale (unlabeled) dataset, and then fine-tune the whole pretrained model for adapting to long-tailed data. Though promising, fine-tuning the whole pret rained model tends to suffer from high cost in computation and deployment of different models for different tasks, as well as weakened generalization capability for overfitting to certain features of long-tailed data. To alleviate these issues, we propose an effective Long-tailed Prompt Tuning (LPT) method for long-tailed classification tasks. LPT introduces several trainable prompts into a frozen pretrained model to adapt it to long-tailed data. For better effectiveness, we divide prompts into two groups: 1) a shared prompt for the whole long-tailed dataset to learn general features and to adapt a pretrained model into the target long-tailed domain; and 2) group-specific prompts to gather group-specific features for the samples which have similar features and also to empower the pretrained model with fine-grained discrimination ability. Then we design a two-phase training paradigm to learn these prompts. In the first phase, we train the shared prompt via conventional supervised prompt tuning to adapt a pretrained model to the desired long-tailed domain. In the second phase, we use the learnt shared prompt as query to select a small best matched set for a group of similar samples from the group-specific prompt set to dig the common features of these similar samples, and then optimize these prompts with a dual sampling strategy and the asymmetric Gaussian Clouded Logit loss. By only fine-tuning a few prompts while fixing the pretrained model, LPT can reduce training cost and deployment cost by storing a few prompts, and enjoys a strong generalization ability of the pretrained model. Experiments show that on various long-tailed benchmarks, with only $\sim$1.1\% extra trainable parameters, LPT achieves comparable or higher performance than previous whole model fine-tuning methods, and is more robust to domain-shift.

****

Interpretable Out-of-Distribution Detection using Pattern Identification

Romain Xu-Darme,Julien Girard-Satabin,Darryl Hond,Gabriele Incorvaia,Zakaria Chihani

Out-of-distribution (OoD) detection for data-based programs is a goal of paramount importance. Common approaches in the literature tend to train binary classifiers requiring inside-of-distribution (IoD) and OoD validation samples, and/or implement confidence metrics that are often abstract and therefore difficult to interpret. In this work, we propose to use the PARTICUL pattern identification algorithm in order to build more interpretable and robust OoD detectors for visual classifiers. Crucially, this approach does not require retraining the classifier and is tuned directly to the IoD dataset, making it applicable to domains where OoD does not have a clear definition. Moreover, pattern identification allows us to provide images from the IoD dataset as reference points to better explain our confidence scores. We illustrate the generalization abilities of our approach through an extensive benchmark across four datasets and two definitions of OoD. Our experiments show that the robustness of all metrics under test does not solely depend on the nature of the IoD dataset or the OoD definition, but also on the architecture of the classifier, which stresses the need for thorough experimentations for future work in OoD detection.

TopoZero: Digging into Topology Alignment on Zero-Shot Learning

Yang Liu,Fei Wang,Jiankang Deng,Chen WeiTao,Lei Shang,Baigui Sun,Xuansong Xie

Common space learning, associating semantic and visual domains in a common latent space, is essential to transfer knowledge from seen classes to unseen ones on Zero-Shot Learning (ZSL) realm. Existing methods for common space learning rely heavily on structure alignment due to the heterogeneous nature between semantic and visual domains, but the existing design is sub-optimal. In this paper, we utilize persistent homology to investigate geometry structure alignment, and observe two following issues: (i) The sampled mini-batch data points present a distinct structure gap compared to global data points, thus the learned structure alignment space inevitably neglects abundant and accurate global structure information. (ii) The latent visual and semantic space fail to preserve multiple

dimensional geometry structure, especially high dimensional structure information.
To address the first issue, we propose a Topology-guided Sampling Strategy (TGSS) to mitigate the gap between sampled and global data points. Both theoretical analyses and empirical results guarantee the effectiveness of the TGSS.
To solve the second issue, we introduce a Topology Alignment Module (TAM) to preserve multi-dimensional geometry structure in latent visual and semantic space, respectively. The proposed method is dubbed TopoZero. Empirically, our TopoZero achieves superior performance on three authoritative ZSL benchmark datasets.

DamoFD: Digging into Backbone Design on Face Detection

Yang Liu,Jiankang Deng,Fei Wang,Lei Shang,Xuansong Xie,Baigui Sun

Face detection (FD) has achieved remarkable success over the past few years, yet, these leaps often arrive when consuming enormous computation costs. Moreover, when considering a realistic situation, i.e., building a lightweight face detector under a computation-scarce scenario, such heavy computation cost limits the application of the face detector. To remedy this, several pioneering works design tiny face detectors through off-the-shelf neural architecture search (NAS) technologies, which are usually applied to the classification task. Thus, the searched architectures are sub-optimal for the face detection task since some design criteria between detection and classification task are different. As a representative, the face detection backbone design needs to guarantee the stage-level detection ability while it is not required for the classification backbone. Furthermore, the detection backbone consumes a vast body of inference budgets in the whole detection framework.
Considering the intrinsic design requirement and the virtual importance role of the face detection backbone, we thus ask a critical question: How to employ NAS to search FD-friendly backbone architecture? To cope with this question, we propose a distribution-dependent stage-aware ranking score (DDSAR-Score) to explicitly characterize the stage-level expressivity and identify the individual importance of each stage, thus satisfying the aforementioned design criterion of the FD backbone. Based on our proposed DDSAR-Score, we conduct comprehensive experiments on the challenging Wider Face benchmark dataset and achieve dominant performance across a wide range of compute regimes. In particular, compared to the tiniest face detector SCRFD-0.5GF, our method is +2.5 % better in Average Precision (AP) score when using the same amount of FLOPs. The code is avaliable at https://github.com/ly19965/EasyFace/tree/master/face_project/face_detection/DamoFD.

Towards Stable Test-time Adaptation in Dynamic Wild World

Shuaicheng Niu,Jiaxiang Wu,Yifan Zhang,Zhiquan Wen,Yaofo Chen,Peilin Zhao,Mingkui Tan

Test-time adaptation (TTA) has shown to be effective at tackling distribution shifts between training and testing data by adapting a given model on test samples. However, the online model updating of TTA may be unstable and this is often a key obstacle preventing existing TTA methods from being deployed in the real world. Specifically, TTA may fail to improve or even harm the model performance when test data have: 1) mixed distribution shifts, 2) small batch sizes, and 3) online imbalanced label distribution shifts, which are quite common in practice. In this paper, we investigate the unstable reasons and find that the batch norm layer is a crucial factor hindering TTA stability. Conversely, TTA can perform more stably with batch-agnostic norm layers, i.e., group or layer norm. However, we observe that TTA with group and layer norms does not always succeed and still suffers many failure cases. By digging into the failure cases, we find that certain noisy test samples with large gradients may disturb the model adaption and result in collapsed trivial solutions, i.e., assigning the same class label for all samples. To address the above collapse issue, we propose a sharpness-aware and reliable entropy minimization method, called SAR, for further stabilizing TTA from two aspects: 1) remove partial noisy samples with large gradients, 2) encourage model weights to go to a flat minimum so that the model is robust to the remaining noisy samples. Promising results demonstrate that SAR performs more stably than prior methods and is computationally efficient under the above wild test scenarios.

Sorted eigenvalue comparison d_{Eig}: A simple alternative to d_{FID}

Jiqing Wu,Viktor Koelzer

For $i = 1, 2$, let $\mathbf{S}_i$ be the sample covariance of $\mathbf{Z}_i$ with n_i p-dimensional vectors. First, we theoretically justify an improved Fréchet Inception Distance (d_{FID}) algorithm that replaces np.trace(sqrtm($\mathbf{S}_1 \mathbf{S}_2$)) with np.sqrt(eigvals($\mathbf{S}_1 \mathbf{S}_2$)).sum(). With the appearance of unsorted eigenvalues in the improved d_{FID}, we are then motivated to propose sorted eigenvalue comparison (d_{Eig}) as a simple alternative: $d_{\mathsf{Eig}}(\mathbf{S}_1, \mathbf{S}_2)^2=\sum_{j=1}^p (\sqrt{\lambda_j^1} - \sqrt{\lambda_j^2})^2$, and λ_j^i is the j-th largest eigenvalue of $\mathbf{S}_i$. Second, we present two main takeaways for the improved d_{FID} and proposed d_{Eig} . (i) d_{FID}: The error bound for computing non-negative eigenvalues of diagonalizable $\mathbf S_1 \mathbf S_2$ is reduced to $\mathcal{O}(\varepsilon) \|\mathbf S_1 \| \|\mathbf S_1 \mathbf S_2 \|$, along with reducing the run time by $\sim25\%$. (ii) d_{Eig}: The error bound for computing non-negative eigenvalues of sample covariance $\mathbf S_i$ is further tightened to $\mathcal{O}(\varepsilon) \|\mathbf S_i \|$, with reducing $\sim90\%$ run time. Taking a statistical viewpoint (random matrix theory) on S_i, we illustrate the asymptotic stability of its largest eigenvalues, i.e., rigidity estimates of $\mathcal{O}(n_i^{-\frac{1}{2}+\alpha})$. Last, we discuss limitations and future work for d_{Eig}.

Towards Smooth Video Composition

Qihang Zhang,Ceyuan Yang,Yujun Shen,Yinghao Xu,Bolei Zhou

Video generation, with the purpose of producing a sequence of frames, requires synthesizing consistent and persistent dynamic contents over time. This work investigates how to model the temporal relations for composing a video with arbitrary number of frames, from a few to even infinite, using generative adversarial networks (GANs). First, towards composing adjacent frames, we show that the alias-free operation for single image generation, together with adequately pre-learned knowledge, bring a smooth frame transition without harming the per-frame quality. Second, through incorporating a temporal shift module (TSM), which is originally designed for video understanding, into the discriminator, we manage to advance the generator in synthesizing more reasonable dynamics. Third, we develop a novel B-Spline based motion representation to ensure the temporal smoothness, and hence achieve infinite-length video generation, going beyond the frame number used in training. We evaluate our approach on a range of datasets and show substantial improvements over baselines on video generation. Code and models are publicly available at \url{https://genforce.github.io/StyleSV}.

Deep Dynamic AutoEncoder for Vision BERT Pretraining

Honghao Chen,Xiangwen Kong,Xiangyu Zhang,Xin Zhao,Kaiqi Huang

Recently, masked image modeling (MIM) has demonstrated promising prospects in se lf-supervised representation learning. However, existing MIM frameworks recover all masked patches equivalently, ignoring that the reconstruction difficulty of different patches can vary sharply due to their diverse distance from visible patches. In this paper, we propose Deep Dynamic AutoEncoder (DDAE), a novel MIM framework that dynamically focuses on patch reconstructions with different degrees of difficulty at different pretraining phases and depths of the model. In addition to raw pixel regression, DDAE performs dynamic feature self-distillation for intermediate layers to learn semantic information. Our methodology provides more locality inductive bias for ViTs, especially in deep layers, which inherently makes up for the absence of local prior for self-attention mechanism. Moreover, our core design deep dynamic supervision can be migrated into existing MIM methods (e.g., MAE, BEiT-v2) seamlessly. The Experimental results demonstrate the effectiveness of our approach. As a tokenizer-free framework, the base-size DDAE can achieve 83.5% top-1 accuracy with only 100 epochs pretraining, surpassing MAE and BEiT pretrained for 800 epochs. For a longer pretraining schedule, DDAE achieves 84.3% top-1 accuracy on Imagenet-1K, and 49.3% mIoU on ADE20K for semantic segmentation.

Continuous PDE Dynamics Forecasting with Implicit Neural Representations

Yuan Yin,Matthieu Kirchmeyer,Jean-Yves Franceschi,Alain Rakotomamonjy,patrick gallinari

Effective data-driven PDE forecasting methods often rely on fixed spatial and / or temporal discretizations. This raises limitations in real-world applications like weather prediction where flexible extrapolation at arbitrary spatiotemporal locations is required. We address this problem by introducing a new data-driven approach, DINo, that models a PDE's flow with continuous-time dynamics of spatially continuous functions. This is achieved by embedding spatial observations independently of their discretization via Implicit Neural Representations in a small latent space temporally driven by a learned ODE. This separate and flexible treatment of time and space makes DINo the first data-driven model to combine the following advantages. It extrapolates at arbitrary spatial and temporal locations; it can learn from sparse irregular grids or manifolds; at test time, it generalizes to new grids or resolutions. DINo outperforms alternative neural PDE forecasters in a variety of challenging generalization scenarios on representative PDE systems.

Adversarial Collaborative Learning on Non-IID Features

Qinbin Li,Bingsheng He,Dawn Song

Federated Learning (FL) has been a popular approach to enable collaborative learning on multiple parties without exchanging raw data. However, the model performance of FL may degrade a lot due to non-IID data. While many FL algorithms focus on non-IID labels, FL on non-IID features has largely been overlooked. Different from typical FL approaches, the paper proposes a new learning concept called ADCOL (Adversarial Collaborative Learning) for non-IID features. Instead of adopting the widely used model-averaging scheme, ADCOL conducts training in an adversarial way: the server aims to train a discriminator to distinguish the representations of the parties, while the parties aim to generate a common representation distribution. Our experiments on three tasks show that ADCOL achieves better performance than state-of-the-art FL algorithms on non-IID features.

DiffMimic: Efficient Motion Mimicking with Differentiable Physics

Jiawei Ren,Cunjun Yu,Siwei Chen,Xiao Ma,Liang Pan,Ziwei Liu

Motion mimicking is a foundational task in physics-based character animation. However, most existing motion mimicking methods are built upon reinforcement learning (RL) and suffer from heavy reward engineering, high variance, and slow convergence with hard explorations. Specifically, they usually take tens of hours or even days of training to mimic a simple motion sequence, resulting in poor scalability. In this work, we leverage differentiable physics simulators (DPS) and propose an efficient motion mimicking method dubbed $\textbf{DiffMimic}$. Our key insight is that DPS casts a complex policy learning task to a much simpler state matching problem. In particular, DPS learns a stable policy by analytical gradients with ground-truth physical priors hence leading to significantly faster and stabler convergence than RL-based methods. Moreover, to escape from local optima, we utilize an \textit{Demonstration Replay} mechanism to enable stable gradient backpropagation in a long horizon. Extensive experiments on standard benchmarks show that DiffMimic has a better sample efficiency and time efficiency than existing methods (e.g., DeepMimic). Notably, DiffMimic allows a physically simulated character to learn back-flip after 10 minutes of training and be able to cycle it after 3 hours of training, while DeepMimic requires about a day of training to cycle back-flip. More importantly, we hope DiffMimic can benefit more differentiable animation systems with techniques like differentiable clothes simulation in future research. Our code is available at https://github.com/diffmimic/diffmimic. Qualitative results can be viewed at https://diffmimic-demo-main-g7h0i8.streamlitapp.com.

Towards Inferential Reproducibility of Machine Learning Research

Michael Hagmann,Philipp Meier,Stefan Riezler

Reliability of machine learning evaluation --- the consistency of observed evaluation scores across replicated model training runs --- is affected by several sources of nondeterminism which can be regarded as measurement noise. Current tendencies to remove noise in order to enforce reproducibility of research results neglect inherent nondeterminism at the implementation level and disregard crucial interaction effects between algorithmic noise factors and data properties. This limits the scope of conclusions that can be drawn from such experiments. Instead of removing noise, we propose to incorporate several sources of variance, including their interaction with data properties, into an analysis of significance and reliability of machine learning evaluation, with the aim to draw inferences beyond particular instances of trained models. We show how to use linear mixed effects models (LMEMs) to analyze performance evaluation scores, and to conduct statistical inference with a generalized likelihood ratio test (GLRT). This allows us to incorporate arbitrary sources of noise like meta-parameter variations into statistical significance testing, and to assess performance differences conditional on data properties. Furthermore, a variance component analysis (VCA) enables the analysis of the contribution of noise sources to overall variance and the computation of a reliability coefficient by the ratio of substantial to total variance.

Knowledge Distillation based Degradation Estimation for Blind Super-Resolution

Bin Xia,Yulun Zhang,Yitong Wang,Yapeng Tian,Wenming Yang,Radu Timofte,Luc Van Gool

Blind image super-resolution (Blind-SR) aims to recover a high-resolution (HR) image from its corresponding low-resolution (LR) input image with unknown degradations. Most of the existing works design an explicit degradation estimator for each degradation to guide SR. However, it is infeasible to provide concrete labels of multiple degradation combinations (\eg, blur, noise, jpeg compression) to supervise the degradation estimator training. In addition, these special designs for certain degradation, such as blur, impedes the models from being generalized to handle different degradations. To this end, it is necessary to design an implicit degradation estimator that can extract discriminative degradation representation for all degradations without relying on the supervision of degradation ground-truth. In this paper, we propose a Knowledge Distillation based Blind-SR network (KDSR). It consists of a knowledge distillation based implicit degradation estimator network (KD-IDE) and an efficient SR network. To learn the KDSR model, we first train a teacher network: KD-IDE$_{T}$. It takes paired HR and LR patches as inputs and is optimized with the SR network jointly. Then, we further train a student network KD-IDE$_{S}$, which only takes LR images as input and learns to extract the same implicit degradation representation (IDR) as KD-IDE$_{T}$. In addition, to fully use extracted IDR, we design a simple, strong, and efficient IDR based dynamic convolution residual block (IDR-DCRB) to build an SR network. We conduct extensive experiments under classic and real-world degradation se ttings. The results show that KDSR achieves SOTA performance and can generalize to various degradation processes. The source codes and pre-trained models will be released.

Very Large Scale Multi-Agent Reinforcement Learning with Graph Attention Mean Field

Qianyue Hao

With recent advances in reinforcement learning, we have witnessed countless successes of intelligent agents in various domains. Especially, multi-agent reinforcement learning (MARL) is suitable for many real-world scenarios and has vast potential applications. However, typical MARL methods can only handle tens of agents, leaving scenarios with up to hundreds or even thousands of agents almost unexplored. There exist two key challenges in scaling up the number of agents: (1) agent-agent interactions are critical in multi-agent systems while the number of interactions grows quadratically with the number of agents, causing great computational complexity and difficulty in strategies-learning; (2) the strengths of interactions vary among agents and over time, making it difficult to precisely model such interactions. In this paper, we propose the Graph Attention Mean Field (GAT-MF) method, where we convert agent-agent interactions into interactions between each agent and a weighted mean field, greatly reducing the computational complexity. We mathematically prove the correctness of this conversion. We design a graph attention mechanism to automatically capture the different and time-varying strengths of interactions, ensuring the ability of our method to precisely model interactions among the agents. We conduct extensive experiments in both manual and real-world scenarios with up to more than 3000 agents, demonstrating that comparing existing MARL methods, our method reaches superior performance and 9.4 times computational efficiency.

Graph Contrastive Learning for Skeleton-based Action Recognition

Xiaohu Huang,Hao Zhou,Jian Wang,Haocheng Feng,Junyu Han,Errui Ding,Jingdong Wang,Xinggang Wang,Wenyu Liu,Bin Feng

In the field of skeleton-based action recognition, current top-performing graph convolutional networks (GCNs) exploit intra-sequence context to construct adaptive graphs for feature aggregation. However, we argue that such context is still $\textit{local}$ since the rich cross-sequence relations have not been explicitly investigated. In this paper, we propose a graph contrastive learning framework for skeleton-based action recognition ($\textit{SkeletonGCL}$) to explore the $\textit{global}$ context across all sequences. In specific, SkeletonGCL associates graph learning across sequences by enforcing graphs to be class-discriminative, i.e., intra-class compact and inter-class dispersed, which improves the GCN capacity to distinguish various action patterns. Besides, two memory banks are designed to enrich cross-sequence context from two complementary levels, i.e., instance and semantic levels, enabling graph contrastive learning in multiple context scales. Consequently, SkeletonGCL establishes a new training paradigm, and it can be seamlessly incorporated into current GCNs. Without loss of generality, we combine SkeletonGCL with three GCNs (2S-ACGN, CTR-GCN, and InfoGCN), and achieve consistent improvements on NTU60, NTU120, and NW-UCLA benchmarks.

Explicit Box Detection Unifies End-to-End Multi-Person Pose Estimation

Jie Yang,Ailing Zeng,Shilong Liu,Feng Li,Ruimao Zhang,Lei Zhang

This paper presents a novel end-to-end framework with Explicit box Detection for multi-person Pose estimation, called ED-Pose, where it unifies the contextual learning between human-level (global) and keypoint-level (local) information. Different from previous one-stage methods, ED-Pose re-considers this task as two explicit box detection processes with a unified representation and regression supervision. First, we introduce a human detection decoder from encoded tokens to extract global features. It can provide a good initialization for the latter keypoint detection, making the training process converge fast. Second, to bring in contextual information near keypoints, we regard pose estimation as a keypoint box detection problem to learn both box positions and contents for each keypoint. A human-to-keypoint detection decoder adopts an interactive learning strategy between human and keypoint features to further enhance global and local feature aggregation. In general, ED-Pose is conceptually simple without post-processing and dense heatmap supervision. It demonstrates its effectiveness and efficiency compared with both two-stage and one-stage methods. Notably, explicit box detection boosts the pose estimation performance by 4.5 AP on COCO and 9.9 AP on CrowdPose. For the first time, as a fully end-to-end framework with a L1 regression loss, ED-Pose surpasses heatmap-based Top-down methods under the same backbone by 1.2 AP on COCO and achieves the state-of-the-art with 76.6 AP on CrowdPose without bells and whistles. Code is available at https://github.com/IDEA-Research/ED-Pose.

Expected Perturbation Scores for Adversarial Detection

Shuhai Zhang,Feng Liu,Jiahao Yang,Yifan Yang,Bo Han,Mingkui Tan

Adversarial detection aims to determine whether a given sample is an adversarial one based on the discrepancy between natural and adversarial distributions. Unfortunately, estimating or comparing two data distributions is extremely difficult, especially in the high-dimension space. Recently, the gradients of log probability density (a.k.a., score) w.r.t. samples is used as an alternative statistic to compute. However, we find that the score is sensitive in identifying adversarial samples due to insufficient information with one sample only. In this paper, we propose a new statistic called expected perturbation score (EPS), which is essentially the expected score of a sample after various perturbations. Specifically, to obtain adequate information regarding one sample, we can perturb it by adding various noises to capture its multi-view observations. We theoretically prove that EPS is a proper statistic to compute the discrepancy between two distributions under mild conditions. In practice, we can use a pre-trained diffusion model to estimate EPS for each sample. Last, we propose an EPS-based adversarial detection (EPS-AD) method, in which we develop EPS-based maximum mean discrepancy (MMD) as a metric to measure the discrepancy between the test sample and natural samples. To verify the validity of our proposed method, we also prove that the EPS-based MMD between natural and adversarial samples is larger than that among natural samples. Empirical studies on CIFAR-10 and ImageNet across different network architectures including ResNet, WideResNet, and ViT show the superior adversarial detection performance of EPS-AD compared to existing methods.

Look Back When Surprised: Stabilizing Reverse Experience Replay for Neural Approximation

Ramnath Kumar,Dheeraj Mysore Nagaraj

Experience replay-based sampling techniques are essential to several reinforcement learning (RL) algorithms since they aid in convergence by breaking spurious correlations. The most popular techniques, such as uniform experience replay(UER) and prioritized experience replay (PER), seem to suffer from sub-optimal convergence and significant bias error, respectively. To alleviate this, we introduce a new experience replay method for reinforcement learning, called Introspective Experience Replay (IER). IER picks batches corresponding to data points consecutively before the ‘surprising’ points. Our proposed approach is based on the theoretically rigorous reverse experience replay (RER), which can be shown to remove bias in the linear approximation setting but can be sub-optimal with neural approximation. We show empirically that IER is stable with neural function approximation and has a superior performance compared to the state-of-the-art techniques like uniform experience replay (UER), prioritized experience replay(PER), and hindsight experience replay (HER) on the majority of tasks.

BQ-NCO: Bisimulation Quotienting for Generalizable Neural Combinatorial Optimization

Darko Drakulic,Sofia Michel,Florian Mai,Arnaud Sors,Jean-Marc Andreoli

Despite the success of Neural Combinatorial Optimization methods for end-to-end heuristic learning, out-of-distribution generalization remains a challenge.
In this paper, we present a novel formulation of combinatorial optimization (CO)

problems as Markov Decision Processes (MDPs) that effectively leverages symmetries of the CO problems to improve out-of-distribution robustness.
Starting from the standard MDP formulation of constructive heuristics, we introduce a generic transformation based on bisimulation quotienting (BQ) in MDPs.
This transformation allows to reduce the state space by accounting for the intrinsic symmetries of the CO problem and facilitates the MDP solving.
We illustrate our approach on the Traveling Salesman and Capacitated Vehicle Routing Problems. We present a BQ reformulation of these problems and introduce a simple attention-based policy network that we train by imitation of (near) optimal solutions for small instances from a single distribution.
We obtain new state-of-the-art generalization results for instances with up to 1000 nodes from synthetic and realistic benchmarks that vary both in size and node distributions.
****

CoGANs: Collaborative Generative Adversarial Networks

Omkar Joglekar,Goren Gordon

In complex creative scenarios, co-creativity by multiple agents offer great advantages. Each agent has a specific skill set and a set of abilities, which is sometimes not enough to perform a general, large and complex task single-handed. These kinds of tasks benefit substantially from collaboration. In deep learning applications, data generation is an example of such a complex, potentially multi-modal task. Previous Generative Adversarial Networks (GANs) focused on using a single generator to generate multi-modal datasets, which is sometimes known to face issues such as mode-collapse and failure to converge. The multi-generator based works such as MGAN, MMGAN, MADGAN and AdaGAN either require training a classifier online, the use of complex mixture models or sequentially adding generators, which is computationally complex.

In this work, we present a simple, novel approach of training collaborative GANs (CoGAN), with multiple generators and a single critic/discriminator, without introducing external complexities such as a classifier model. We show that this method of workload division meets the state-of-the-art quality metrics, and makes GAN training robust. We present a proof-of-concept on the MNIST dataset, which has 10 modes of data. The individual generators learn to generate different digits from the distribution, and together learn to generate the whole distribution. We introduce a new component to the generator loss during GAN training, based on the Total Variation Distance (TVD) and show that it significantly improves stability during training and performance over state-of-the-art single generator GANs.

Multiscale Neural Operator: Learning Fast and Grid-independent PDE Solvers

Björn Lütjens,Catherine H. Crawford,Campbell D Watson,Christopher Hill,Dava Newman

Numerical simulations in climate, chemistry, or astrophysics are computationally too expensive for uncertainty quantification or parameter-exploration at high-resolution. Reduced-order or surrogate models are multiple orders of magnitude faster, but traditional surrogates are inflexible or inaccurate and pure machine learning (ML)-based surrogates too data-hungry. We propose a hybrid, flexible surrogate model that exploits known physics for simulating large-scale dynamics and limits learning to the hard-to-model term, which is called parametrization or closure and captures the effect of fine- onto large-scale dynamics. Leveraging neural operators, we are the first to learn grid-independent, non-local, and flexible parametrizations. Our \textit{multiscale neural operator} is motivated by a rich literature in multiscale modeling, has quasilinear runtime complexity, is more accurate or flexible than state-of-the-art parametrizations and demonstrated on the chaotic equation multiscale Lorenz96.

Out-of-distribution Detection with Diffusion-based Neighborhood

Luping Liu,Yi Ren,Xize Cheng,Zhou Zhao

Out-of-distribution (OOD) detection is an important task to ensure the reliability and safety of deep learning and the discriminator models outperform others fo r now. However, the feature extraction of such models must compress the data and lose certain information, leaving room for bad cases and malicious attacks. However, despite effectively fitting the data distribution and producing high-quality samples, generative models lack suitable indicator scores to match with discriminator models in the OOD detection tasks. In this paper, we find that these two kinds of models can be combined to solve each other's problems. We introduce diffusion models (DMs), a kind of powerful generative model, into OOD detection and find that the denoising process of DMs also functions as a novel form of asymmetric interpolation. This property establishes a diffusion-based neighborhood for each input data. Then, we perform discriminator-based OOD detection based on the diffusion-based neighborhood instead of isolated data. In this combination, the discriminator models provide detection metrics for generation models and the diffusion-based neighborhood reduces the information loss of feature extraction. According to our experiments on CIFAR10 and CIFAR100, our new methods successfully outperform state-of-the-art methods. Our implementation is put in the supplementary materials.

Never Revisit: Continuous Exploration in Multi-Agent Reinforcement Learning
Chenghao Li,Tonghan Wang,Xiaoran Wu,Jun Yang,Qianchuan Zhao,Chongjie Zhang
Recently, intrinsic motivations are wildly used for exploration in multi-agent reinforcement learning. We discover that coming with intrinsic rewards is the issue of revisitation -- the relative values of intrinsic rewards fluctuate, causing a sub-space visited before becomes attractive after a period of exploration to other areas. Consequently, agents risk exploring some sub-spaces repeatedly. In this paper, we formally define the concept of revisitation, based on which we propose an observation-distribution matching approach to detect the appearance of revisitation. To avoid it, we add branches to agents' local Q-networks and the mixing network to separate sub-spaces which have already been revisited. Furthermore, to prevent adding branches excessively, we design intrinsic rewards to reduce the probability of and penalize the occurrence of revisitation. By virtue of these advances, our method achieves superior performance on three challenging Google Research Football (GRF) scenarios with sparse rewards.

Do Not Train It: A Linear Neural Architecture Search of Graph Neural Networks
Peng XU,Lin Zhang,Xuanzhou Liu,Jiaqi Sun,Yue Zhao,Haiqin Yang,Bei Yu
Neural architecture search (NAS) for Graph neural networks (GNNs), called NAS-GNNs, has achieved significant performance over manually designed GNN architectures. However, these methods inherit issues from the conventional NAS methods, such as high computational cost and optimization difficulty. More importantly, previous NAS methods have ignored the uniqueness of GNNs, where the non-linearity has limited effect. Based on this, we are the first to theoretically prove that a GNN fixed with random weights can obtain optimal outputs under mild conditions. With the randomly-initialized weights, we can then seek the optimal architecture parameters via the sparse coding objective and derive a novel NAS-GNNs method, namely neural architecture coding (NAC). Consequently, our NAC holds a no-update scheme on GNNs and can efficiently compute in linear time. Empirical evaluations on multiple GNN benchmark datasets demonstrate that our approach leads to state-of-the-art performance, which is up to $200\times$ faster and 18.8% more accurate than the strong baselines.

Rethinking the Explanation of Graph Neural Network via Non-parametric Subgraph Matching
Fang Wu,Lirong Wu,Siyuan Li,Dragomir Radev,Wenbing Huang
The great success in graph neural networks (GNNs) provokes the question about explainability: ``Which fraction of the input graph is the most determinant to the prediction?'' However, current approaches usually resort to a black-box to decipher another black-box (i.e., GNN), making it difficult to understand how the explanation is made. Based on the observation that graphs typically share some joint motif patterns, we propose a novel subgraph matching framework named MatchExplainer to explore explanatory subgraphs.

It couples the target graph with other counterpart instances and identifies the most crucial joint substructure by minimizing the node corresponding-based distance between them. After that, an external graph ranking is followed to select the most informative substructure from all subgraph candidates. Thus, MatchExplainer is entirely non-parametric.

Moreover, present graph sampling or node dropping methods usually suffer from the false positive sampling problem. To ameliorate that issue, we take advantage of MatchExplainer to fix the most informative portion of the graph and merely operate graph augmentations on the rest less informative part, which is dubbed as MatchDrop.

We conduct extensive experiments on both synthetic and real-world datasets, showing the effectiveness of our MatchExplainer by outperforming all parametric baselines with large margins. Additional results also demonstrate that our MatchDrop is a general paradigm to be equipped with GNNs for enhanced performance.

Spikformer: When Spiking Neural Network Meets Transformer

Zhaokun Zhou,Yuesheng Zhu,Chao He,Yaowei Wang,Shuicheng YAN,Yonghong Tian,Li Yuan

We consider two biologically plausible structures, the Spiking Neural Network (SNN) and the self-attention mechanism. The former offers an energy-efficient and event-driven paradigm for deep learning, while the latter has the ability to capture feature dependencies, enabling Transformer to achieve good performance. It is intuitively promising to explore the marriage between them. In this paper, we consider leveraging both self-attention capability and biological properties of SNNs, and propose a novel Spiking Self Attention (SSA) as well as a powerful framework, named Spiking Transformer (Spikformer). The SSA mechanism in Spikformer models the sparse visual feature by using spike-form Query, Key, and Value without softmax. Since its computation is sparse and avoids multiplication, SSA is efficient and has low computational energy consumption. It is shown that Spikformer with SSA can outperform the state-of-the-art SNNs-like frameworks in image classification on both neuromorphic and static datasets. Spikformer (66.3M parameters) with comparable size to SEW-ResNet-152 (60.2M,69.26%) can achieve 74.81% top1 accuracy on ImageNet using 4 time steps, which is the state-of-the-art in directly trained SNNs models. Code is avaiable at https://github.com/ZK-Zhou/spikformer.

DeSCo: Towards Scalable Deep Subgraph Counting

Tianyu Fu,Yu Wang,Zhitao Ying

Subgraph counting is the problem of determining the number of a given query graph in a large targe graph. Despite being a #P problem, subgraph counting is a crucial graph analysis method in domains ranging from biology and social science to risk management and software analysis. However, existing exact counting methods take combinatorially long runtime as target and query sizes increase. Existing approximate heuristic methods and neural approaches fall short in accuracy due to high label dynamic range, limited model expressive power, and inability to predict the distribution of subgraph counts in the target graph. Here we propose DeSCo, a neural deep subgraph counting framework, which aims to accurately predict the count and distribution of query graphs on any given target graph. DeSCo uses canonical partition to divide the large target graph into small neighborhood graphs and predict the canonical count objective on each neighborhood. The proposed partition method avoids missing or double-counting any patterns of the target graph. A novel subgraph-based heterogeneous graph neural network is then used to improve the expressive power. Finally, gossip correction improves counting accuracy via prediction propagation with learnable weights. Compared with state-of-the-art approximate heuristic and neural methods. DeSCo achieves 437x improvement in the mean squared error of count prediction and benefits from the polynomial runtime complexity.

On a Built-in Conflict between Deep Learning and Systematic Generalization

Yuanpeng Li
Out-of-distribution or systematic generalization is a desirable property that most deep learning algorithms lack. In this paper, we hypothesize that internal function sharing is one of the reasons to weaken systematic generalization in deep learning for classification tasks. Under equivalent prediction, a model partitions an input space into multiple parts separated by boundaries. The function sharing prefers to reuse boundaries, leading to fewer parts for new outputs, which conflicts with systematic generalization. We show such phenomena in standard deep learning models, such as fully connected, convolutional, residual networks, LSTMs, and (Vision) Transformers. We hope this study provides novel insights and forms a basis for new research directions to improve systematic generalization.
****
Consistent and Truthful Interpretation with Fourier Analysis
Yifan Zhang,Haowei He,Yang Yuan
For many interdisciplinary fields,
ML interpretations need to be consistent with \emph{what-if} scenarios related to the current case, i.e., if one factor changes, how does the model react?
Although the attribution methods are supported by the elegant axiomatic systems, they mainly focus on individual inputs,
and are generally inconsistent.
To support what-if scenarios, we introduce a new objective of consistency based on a notion called truthful interpretation. Towards this objective,
we apply Fourier analysis of Boolean functions to get
consistency guarantees.
Experimental results show that
for neighborhoods with various radii,
our method achieves 2x - 50x lower inconsistency compared with the other methods.
****
D2Match: Leveraging Deep Learning and Degeneracy for Subgraph Matching
Xuanzhou Liu,Lin Zhang,Jiaqi Sun,Yujiu Yang,Haiqin Yang
Subgraph matching is a fundamental building block for many graph-based applications and is challenging due to its high-order combinatorial nature. However, previous methods usually tackle it by combinatorial optimization or representation learning and suffer from exponential computational cost or matching without theoretical guarantees. In this paper, we develop D2Match by leveraging the efficiency of Deep learning and Degeneracy for subgraph matching. More specifically, we prove that subgraph matching can degenerate to subtree matching, and subsequently is equivalent to finding a perfect matching on a bipartite graph. This matching procedure can be implemented by the built-in tree-structured aggregation mechanism on graph neural networks, which yields linear time complexity. Moreover, circle structures, abstracted as {\em supernodes}, and node attributes can be easily incorporated in D2Match to boost the matching. Finally, we conduct extensive experiments to show the superior performance of our D2Match and confirm that our D2Match indeed tries to exploit the subtrees and differs from existing learning-based subgraph matching methods that depend on memorizing the data distribution divergence.

Multimodal Analogical Reasoning over Knowledge Graphs
Ningyu Zhang,Lei Li,Xiang Chen,Xiaozhuan Liang,Shumin Deng,Huajun Chen
Analogical reasoning is fundamental to human cognition and holds an important place in various fields. However, previous studies mainly focus on single-modal analogical reasoning and ignore taking advantage of structure knowledge. Notably, the research in cognitive psychology has demonstrated that information from multimodal sources always brings more powerful cognitive transfer than single modality sources. To this end, we introduce the new task of multimodal analogical reasoning over knowledge graphs, which requires multimodal reasoning ability with the help of background knowledge. Specifically, we construct a Multimodal Analogical Reasoning dataSet (MARS) and a multimodal knowledge graph MarKG. We evaluate with multimodal knowledge graph embedding and pre-trained Transformer baselines,

illustrating the potential challenges of the proposed task. We further propose a novel model-agnostic Multimodal analogical reasoning framework with Transformer (MarT) motivated by the structure mapping theory, which can obtain better performance. We hope our work can deliver benefits and inspire future research. Code and datasets are available in https://github.com/zjunlp/MKG_Analogy.

GAIN: Enhancing Byzantine Robustness in Federated Learning with Gradient Decomposition

Yuchen Liu,Chen Chen,Lingjuan Lyu,Fangzhao Wu,Tianlei Hu,Sai Wu,Gang Chen

Federated learning provides a privacy-aware learning framework by enabling participants to jointly train models without exposing their private data. However, federated learning has exhibited vulnerabilities to Byzantine attacks, where the adversary aims to destroy the convergence and performance of the global model. Meanwhile, we observe that most existing robust AGgregation Rules (AGRs) fail to stop the aggregated gradient deviating from the optimal gradient (the average of honest gradients) in the non-IID setting. We attribute the reason of the failure of these AGRs to two newly proposed concepts: identification failure and integrity failure. The identification failure mainly comes from the exacerbated curse of dimensionality in the non-IID setting. The integrity failure is a combined result of conservative filtering strategy and gradient heterogeneity. In order to address both failures, we propose GAIN, a gradient decomposition scheme that can help adapt existing robust algorithms to heterogeneous datasets. We theoretically show that integrating exisiting robust AGRs into our GAIN can mitigate the deviation of aggregated gradient, thus improve the performance. Experiments on various real-world datasets verify the efficacy of our proposed GAIN

****

Temporary feature collapse phenomenon in early learning of MLPs

Dongrui Liu,Shaobo Wang,Jie Ren,Kangrui Wang,Sheng Yin,Huiqi Deng,Quanshi Zhang

In this paper, we focus on a typical two-phase phenomenon in the learning of multi-layer perceptrons (MLPs). We discover and explain the reason for the feature collapse phenomenon in the first phase, i.e., the diversity of features over different samples keeps decreasing in the first phase, until samples of different categories share almost the same feature, which hurts the optimization of MLPs. We explain such a phenomenon in terms of the learning dynamics of MLPs. Furthermore, we theoretically analyze the reason why four typical operations can alleviate the feature collapse. The code has been attached with the submission.

MECTA: Memory-Economic Continual Test-Time Model Adaptation

Junyuan Hong,Lingjuan Lyu,Jiayu Zhou,Michael Spranger

Continual Test-time Adaptation (CTA) is a promising art to secure accuracy gains in continually-changing environments. The state-of-the-art adaptations improve out-of-distribution model accuracy via computation-efficient online test-time gradient descents but meanwhile cost about times of memory versus the inference, even if only a small portion of parameters are updated. Such high memory consumption of CTA substantially impedes wide applications of advanced CTA on memory-constrained devices. In this paper, we provide a novel solution, dubbed MECTA, to drastically improve the memory efficiency of gradient-based CTA. Our profiling shows that the major memory overhead comes from the intermediate cache for back-propagation, which scales by the batch size, channel, and layer number. Therefore, we propose to reduce batch sizes, adopt an adaptive normalization layer to maintain stable and accurate predictions, and stop the back-propagation caching heuristically. On the other hand, we prune the networks to reduce the computation and memory overheads in optimization and recover the parameters afterward to avoid forgetting. The proposed MECTA is efficient and can be seamlessly plugged into state-of-the-art CTA algorithms at negligible overhead on computation and memory. On three datasets, CIFAR10, CIFAR100, and ImageNet, MECTA improves the accuracy by at least 6% with constrained memory and significantly reduces the memory costs of ResNet50 on ImageNet by at least 70% with comparable accuracy. Our codes can be accessed at https://github.com/SonyAI/MECTA.

MocoSFL: enabling cross-client collaborative self-supervised learning

Jingtao Li,Lingjuan Lyu,Daisuke Iso,Chaitali Chakrabarti,Michael Spranger

Existing collaborative self-supervised learning (SSL) schemes are not suitable for cross-client applications because of their expensive computation and large local data requirements. To address these issues, we propose MocoSFL, a collaborative SSL framework based on Split Federated Learning (SFL) and Momentum Contrast (MoCo). In MocoSFL, the large backbone model is split into a small client-side model and a large server-side model, and only the small client-side model is processed locally on the client's local devices. MocoSFL has three key components: (i) vector concatenation which enables the use of small batch size and reduces computation and memory requirements by orders of magnitude; (ii) feature sharing that helps achieve high accuracy regardless of the quality and volume of local data; (iii) frequent synchronization that helps achieve better non-IID performance because of smaller local model divergence. For a 1,000-client case with non-IID data (each client only has data from 2 random classes of CIFAR-10), MocoSFL can achieve over 84% accuracy with ResNet-18 model. Next we present TAResSFL module that significantly improves the resistance to privacy threats and communication overhead with small sacrifice in accuracy for a MocoSFL system. On a Raspberry Pi 4B device, the MocoSFL-based scheme requires less than 1MB of memory and less than 40MB of communication, and consumes less than 5W power. The code is available at https://github.com/SonyAI/MocoSFL.

Block-level Stiffness Analysis of Residual Networks

Eliska Kloberdanz,Wei Le

Residual Networks (ResNets) can be interpreted as dynamic systems, which are systems whose state changes over time and can be described with ordinary differential equations (ODEs). Specifically, the dynamic systems interpretation views individual residual blocks as ODEs. The solution to an ODE is an approximation; and therefore contains an error term. If an ODE is stiff it is likely that this error is amplified and becomes dominating in the solution calculations, which negatively affects the accuracy of the approximated solution. Therefore, stiff ODEs are often numerically unstable. In this paper we leverage the dynamic systems interpretation to perform a novel theoretical analysis of ResNets by leveraging findings and tools from numerical analysis of ODEs. Specifically, we perform block level stiffness analysis of ResNets. We find that residual blocks towards the end of ResNet models exhibit increased stiffness and that there is a significant correlation between stiffness and model accuracy and loss. Based on these findings, we propose that ResNets behave as stiff numerically unstable ODEs.

Q-Match: Self-Supervised Learning For Tabular Data by Matching Distributions Induced by a Queue

Thomas Mulc,Debidatta Dwibedi

In semi-supervised learning, student-teacher distribution matching has been successful in improving performance of models using unlabeled data in conjunction with few labeled samples. In this paper, we aim to replicate that success in the self-supervised setup where we do not have access to any labeled data during pre-training. We show it is possible to induce the student-teacher distributions without any knowledge of downstream classes by using a queue of embeddings of samples from the unlabeled dataset. We show that Q-Match outperforms previous self-supervised learning techniques on tabular datasets when measuring downstream classification performance. Furthermore, we show that our method is sample efficient, both in terms of labels required for both downstream task training and amount of unlabeled data required for pre-training.

****

Supervised Contrastive Regression

Kaiwen Zha,Peng Cao,Yuzhe Yang,Dina Katabi

Deep regression models typically learn in an end-to-end fashion and do not explicitly try to learn a regression-aware representation. Their representations tend to be fragmented and fail to capture the continuous nature of regression tasks. In this paper, we propose Supervised Contrastive Regression (SupCR), a framewor

k that learns a regression-aware representation by contrasting samples against each other based on their target distance. SupCR is orthogonal to existing regression models, and can be used in combination with such models to improve performance. Extensive experiments using five real-world regression datasets that span computer vision, human-computer interaction, and healthcare show that using SupCR achieves the state-of-the-art performance and consistently improves prior regression baselines on all datasets, tasks, and input modalities. SupCR also improves robustness to data corruptions, resilience to reduced training data, performance on transfer learning, and generalization to unseen targets.
****

SELF-SUPERVISED PRETRAINING FOR DIFFERENTIALLY PRIVATE LEARNING
Arash Asadian,Evan Weidner,Lei Jiang

We demonstrate self-supervised pretraining (SSP) is a scalable solution to deep learning with differential privacy (DP) regardless of the size of available public datasets in image classification. When facing the lack of public datasets, we show the features generated by SSP on only one single image enable a private classifier to obtain a much better utility than the non-learned handcrafted features under the same privacy budget. When a moderate or large size public dataset is available, the features produced by SSP greatly outperform the features trained with labels on various complex private datasets under the same private budget. We also compared multiple DP-enabled training frameworks to train a private classifier on the features generated by SSP.

Explainable Artificial Intelligence: Reaping the Fruits of Decision Trees
Ralf Peter Riedel,Aviv Segev

The recent push for explainable artificial intelligence (XAI) has given rise to extensive work toward understanding the inner workings of neural networks. Much of that work, however, has focused on manipulating input data feeding the network to assess their effect on network output. It is shown in this study that XAI can benefit from investigating the network node, the most fundamental unit of neural networks. Whereas studies on XAI have mostly benefited from a focus on manipulating input data, assessing patterns in node weights may prove equally beneficial, if not more significant, especially when realizing that weight values may not be as random as previously thought. A manipulated, a contrived, and a real dataset were used in this study. Datasets were run on convolutional and deep neural network models. Node rank stability was the central construct to investigate neuronal patterns in this study. Rank stability was defined as the number of epochs wherein nodes held their rank in terms of weight value compared to their rank at the last epoch, when the model reached convergence, or stability (defined in this study as accuracy $\geq$ 0.90). Findings indicated that neural networks behaved like a decision tree, in that rank stability increased as weight absolute values increased. Decision tree behavior may assist in more efficient pruning algorithms, which may produce distilled models simpler to explain to technical and non-technical audiences.

Interpretability with full complexity by constraining feature information
Kieran A Murphy,Danielle Bassett

Interpretability is a pressing issue for machine learning. Common approaches to interpretable machine learning constrain interactions between features of the input, sacrificing model complexity in order to render more comprehensible the effects of those features on the model's output. We approach interpretability from a new angle: constrain the information about the features without restricting the complexity of the model. We use the Distributed Information Bottleneck to optimally compress each feature so as to maximally preserve information about the output. The learned information allocation, by feature and by feature value, provides rich opportunities for interpretation, particularly in problems with many features and complex feature interactions. The central object of analysis is not a single trained model, but rather a spectrum of models serving as approximations that leverage variable amounts of information about the inputs. Information is allocated to features by their relevance to the output, thereby solving the prob lem of feature selection by constructing a learned continuum of feature inclusion-to-exclusion. The optimal compression of each feature---at every stage of approximation---allows fine-grained inspection of the distinctions among feature values that are most impactful for prediction. We develop a framework for extracting insight from the spectrum of approximate models and demonstrate its utility on a range of tabular datasets.

Revisiting Group Robustness: Class-specific Scaling is All You Need

Seonguk Seo,Bohyung Han

Group distributionally robust optimization, which aims to improve robust accuracies such as worst-group or unbiased accuracy, is one of the mainstream algorithms to mitigate spurious correlation and reduce dataset bias. While existing approaches have apparently gained performance in robust accuracy, these improvements mainly come from a trade-off at the expense of average accuracy. To address the challenges, we first propose a simple class-specific scaling strategy to control the trade-off between robust and average accuracies flexibly and efficiently, which is directly applicable to existing debiasing algorithms without additional training; it reveals that a naive ERM baseline matches or even outperforms the recent debiasing approaches by adopting the class-specific scaling. Then, we employ this technique to 1) evaluate the performance of existing algorithms in a comprehensive manner by introducing a novel unified metric that summarizes the trade-off between the two accuracies as a scalar value and 2) develop an instance-wise adaptive scaling technique for overcoming the trade-off and improving the performance even further in terms of both accuracies. Experimental results verify the effectiveness of the proposed frameworks in both tasks.

Provable Benefits of Representational Transfer in Reinforcement Learning

Alekh Agarwal,Yuda Song,Wen Sun,Kaiwen Wang,Mengdi Wang,Xuezhou Zhang

We study the problem of representational transfer in RL, where an agent first pretrains in a number of source tasks to discover a shared representation, which is subsequently used to learn a good policy in a target task. We propose a new notion of task relatedness between source and target tasks, and develop a novel approach for representational transfer under this assumption. Concretely, we show that given a generative access to source tasks, we can discover a representation, using which subsequent linear RL techniques quickly converge to a near-optimal policy, with only online access to the target task. The sample complexity is close to knowing the ground truth features in the target task, and comparable to prior representation learning results in the source tasks. We complement our positive results with lower bounds without generative access, and validate our findings with empirical evaluation on rich observation MDPs that require deep exploration.

****

Set Discrimination Contrastive Learning

Duong Hoang Le,Binh-Son Hua

In this work, we propose a self-supervised contrastive learning method that integrates the concept of set-based feature learning. The main idea of our method is to randomly construct sets of instances in a mini-batch and then learn to contrast the set representations. Inspired by set-based feature learning, we aggregate set features from individual sample features by a symmetric function. To improve the effectiveness of our set-based contrastive learning, we propose a set construction scheme built upon sample permutation in a mini-batch that allows a sample to appear in multiple sets, which naturally ensures common features among sets by construction. Our set construction scheme also increases both the number of positive and negative sets in a mini-batch, leading to better representation learning. We demonstrate the robustness of our method by seamlessly integrating it into existing contrastive learning methods such as SimCLR and MoCo. Extensive experiments demonstrate that our method consistently improves the performance of these contrastive learning methods in various datasets and downstream tasks.

****

What shapes the loss landscape of self supervised learning?

Liu Ziyin,Ekdeep Singh Lubana,Masahito Ueda,Hidenori Tanaka

Prevention of complete and dimensional collapse of representations has recently become a design principle for self-supervised learning (SSL). However, questions remain in our theoretical understanding: When do those collapses occur? What are the mechanisms and causes? We answer these questions by deriving and thoroughly analyzing an analytically tractable theory of SSL loss landscapes. In this theory, we identify the causes of the dimensional collapse and study the effect of normalization and bias. Finally, we leverage the interpretability afforded by the analytical theory to understand how dimensional collapse can be beneficial and what affects the robustness of SSL against data imbalance.

Learning Lightweight Object Detectors via Progressive Knowledge Distillation

Shengcao Cao,Mengtian Li,James Hays,Deva Ramanan,Yu-Xiong Wang,Liangyan Gui

Resource-constrained perception systems such as edge computing and vision-for-robotics require vision models to be both accurate and lightweight in computation and memory usage. Knowledge distillation is one effective strategy to improve the performance of lightweight classification models, but it is less well-explored for structured outputs such as object detection and instance segmentation, where the variable number of outputs and complex internal network modules complicate the distillation. In this paper, we propose a simple yet surprisingly effective sequential approach to knowledge distillation that progressively transfers the knowledge of a set of teachers to a given lightweight student. Our approach is inspired by curriculum learning: To distill knowledge from a highly accurate but complex teacher model, we construct a sequence of teachers to help the student gradually adapt. Our progressive distillation strategy can be easily combined with existing distillation mechanisms to consistently maximize student performance in various settings. To the best of our knowledge, we are the first to successfully distill knowledge from Transformer-based teacher detectors to convolution-based students, and unprecedentedly boost the performance of ResNet-50 based RetinaNet from 36.5% to 42.0% AP and Mask R-CNN from 38.2% to 42.5% AP on the MS COCO benchmark.

****

Topologically faithful image segmentation via induced matching of persistence barcodes

Nico Stucki,Johannes C. Paetzold,Suprosanna Shit,bjoern menze,Ulrich Bauer

Image segmentation is a largely researched field where neural networks find vast applications in many facets of technology.

Some of the most popular approaches to train segmentation networks employ loss functions optimizing pixel-overlap, an objective that is insufficient for many segmentation tasks. In recent years, their limitations fueled a growing interest in topology-aware methods, which aim to recover the correct topology of the segmented structures. However, so far, none of the existing approaches achieve a spatially correct matching between the topological features (persistence barcodes) of label (ground truth) and prediction (output of the neural network).

In this work, we propose the first topologically and feature-wise accurate metric and loss function for supervised image segmentation, which we term TopoMatch. We show how induced matchings guarantee the spatially correct matching between barcodes in a segmentation setting. Furthermore, we propose an efficient algorithm to compute TopoMatch for images. We show that TopoMatch is an interpretable metric to evaluate the topological correctness of segmentations. Moreover, we demonstrate how induced matchings can be used to train segmentation networks and improve the topological correctness of the segmentations across all 6 baseline datasets while preserving volumetric segmentation performance.

No Reason for No Supervision: Improved Generalization in Supervised Models

Mert Bülent Sar■y■ld■z,Yannis Kalantidis,Karteek Alahari,Diane Larlus

We consider the problem of training a deep neural network on a given classification task, e.g., ImageNet-1K (IN1K), so that it excels at both the training task as well as at other (future) transfer tasks. These two seemingly contradictory properties impose a trade-off between improving the model’s generalization and maintaining its performance on the original task. Models trained with self-supervised learning tend to generalize better than their supervised counterparts for transfer learning; yet, they still lag behind supervised models on IN1K. In this paper, we propose a supervised learning setup that leverages the best of both worlds. We extensively analyze supervised training using multi-scale crops for data augmentation and an expendable projector head, and reveal that the design of the projector allows us to control the trade-off between performance on the training task and transferability. We further replace the last layer of class weights with class prototypes computed on the fly using a memory bank and derive two models: t-ReX that achieves a new state of the art for transfer learning and outperforms top methods such as DINO and PAWS on IN1K, and t-ReX* that matches the highly optimized RSB-A1 model on IN1K while performing better on transfer tasks.
Code and pretrained models: https://europe.naverlabs.com/t-rex

Linear Convergence of Natural Policy Gradient Methods with Log-Linear Policies
Rui Yuan,Simon Shaolei Du,Robert M. Gower,Alessandro Lazaric,Lin Xiao
We consider infinite-horizon discounted Markov decision processes and study the convergence rates of the natural policy gradient (NPG) and the Q-NPG methods with the log-linear policy class. Using the compatible function approximation framework, both methods with log-linear policies can be written as approximate versions of the policy mirror descent (PMD) method. We show that both methods attain linear convergence rates and $\tilde{\mathcal{O}}(1/\epsilon^2)$ sample complexities using a simple, non-adaptive geometrically increasing step size, without resorting to entropy or other strongly convex regularization. Lastly, as a byproduct, we obtain sublinear convergence rates for both methods with arbitrary constant step size.

****

Active Learning with Controllable Augmentation Induced Acquisition
Jianan Yang,Haobo Wang,Sai Wu,Gang Chen,Junbo Zhao
The mission of active learning is to iteratively identify the most informative data samples to annotate, and therefore to attain decent performance with much fewer samples. Despite the promise, the acquisition of informative unlabeled samples can be unreliable --- particularly during early cycles --- owning to limited data samples and sparse supervision. To tackle this, the data augmentation techniques seem straightforward yet promising to easily extend the exploration of the input space. In this work, we thoroughly study the coupling of data augmentation and active learning whereby we propose Controllable Augmentation ManiPulator for Active Learning. In contrast to the few prior work that touched on this line, CAMPAL emphasizes a tighten and better-controlled integration of data augmentation into the active learning framework, as in three folds: (i)-carefully designed data augmentation policies applied separately on labeled and unlabeled data pool in every cycle; (ii)-controlled and quantifiably optimizable augmentation strengths; (iii)-full but flexible coverage for most (if not all) active learning schemes. Through extensive empirical experiments, we bring the performance of active learning methods to a new level: an absolute performance boost of 16.99% on CIFAR-10 and 12.25% on SVHN with 1,000 annotated samples. Complementary to the empirical results, we further provide theoretical analysis and justification of CAMPAL.

****

Learning Axis-Aligned Decision Trees with Gradient Descent
Sascha Marton,Christian Bartelt,Stefan Lüdtke
Decision Trees are commonly used for many machine learning tasks due to their high interpretability. However, learning a decision tree from data is a difficult optimization problem, since it is non-convex and non-differentiable. Therefore, common approaches learn decision trees using a greedy growth algorithm that minimizes the impurity at each internal node. Unfortunately, this greedy procedure c

an lead to suboptimal trees.

In this paper, we present a novel approach for learning univariate, axis-aligned decision trees with gradient descent. This is achieved by applying backpropagation with an adjusted gradient flow on a dense decision tree representation that optimizes all decision tree parameters jointly. We show that our gradient-based optimization outperforms existing baselines on several binary classification benchmarks and achieves competitive results for multi-class tasks. To the best of our knowledge, this is the first approach that attempts to learn univariate, axis-aligned decision trees with gradient descent.

****

DPM-Solver++: Fast Solver for Guided Sampling of Diffusion Probabilistic Models
Cheng Lu,Yuhao Zhou,Fan Bao,Jianfei Chen,Chongxuan Li,Jun Zhu
Diffusion probabilistic models (DPMs) have achieved impressive success in high-resolution image synthesis, especially in recent large-scale text-to-image generation applications. An essential technique for improving the sample quality of DPMs is guided sampling, which usually needs a large guidance scale to obtain the best sample quality. The commonly-used fast sampler for guided sampling is DDIM, a first-order diffusion ODE solver that generally needs 100 to 250 steps for high-quality samples. Although recent works propose dedicated high-order solvers and achieve a further speedup for sampling without guidance, their effectiveness for guided sampling has not been well-tested before. In this work, we demonstrate that previous high-order fast samplers suffer from instability issues, and they even become slower than DDIM when the guidance scale grows large. To further speed up guided sampling, we propose DPM-Solver++, a high-order solver for the guided sampling of DPMs. DPM-Solver++ solves the diffusion ODE with the data prediction model and adopts thresholding methods to keep the solution matches training data distribution. We further propose a multistep variant of DPM-Solver++ to address the instability issue by reducing the effective step size. Experiments show that DPM-Solver++ can generate high-quality samples within only 15 to 20 steps for guided sampling by pixel-space and latent-space DPMs.

EVA3D: Compositional 3D Human Generation from 2D Image Collections
Fangzhou Hong,Zhaoxi Chen,Yushi LAN,Liang Pan,Ziwei Liu
Inverse graphics aims to recover 3D models from 2D observations. Utilizing differentiable rendering, recent 3D-aware generative models have shown impressive results of rigid object generation using 2D images. However, it remains challenging to generate articulated objects, like human bodies, due to their complexity and diversity in poses and appearances. In this work, we propose, EVA3D, an unconditional 3D human generative model learned from 2D image collections only. EVA3D can sample 3D humans with detailed geometry and render high-quality images (up to 512x256) without bells and whistles (e.g. super resolution). At the core of EVA3D is a compositional human NeRF representation, which divides the human body into local parts. Each part is represented by an individual volume. This compositional representation enables 1) inherent human priors, 2) adaptive allocation of network parameters, 3) efficient training and rendering. Moreover, to accommodate for the characteristics of sparse 2D human image collections (e.g. imbalanced pose distribution), we propose a pose-guided sampling strategy for better GAN learning. Extensive experiments validate that EVA3D achieves state-of-the-art 3D human generation performance regarding both geometry and texture quality. Notably, EVA3D demonstrates great potential and scalability to "inverse-graphics" diverse human bodies with a clean framework.

Spurious Local Minima Provably Exist for Deep Convolutional Neural Networks
Bo Liu,Keyi Fu,Tongtong Yuan
In this paper, we prove that a general family of spurious local minima exist in the loss landscape of deep convolutional neural networks with squared loss or cross-entropy loss. For this purpose, we develop some new techniques to solve the challenges introduced by convolutional layers. We solve a combinatorial problem

which considers the limited receptive fields of hidden neurons, and possible distinct activation status for different samples and different locations in feature maps, to show that a differentiation of data samples is always possible somewhere in feature maps. Training loss is then decreased by perturbation of network parameters that can affect different samples in different ways. Despite filters and biases are tied in each feature map, we give a construction in which this perturbation only affects the output of a single ReLU neuron and keeps the outputs at other locations unchanged. Finally, we give an example of nontrivial spurious local minimum in which different activation patterns of samples are explicitly constructed. Experimental results verify our theoretical findings.

Nearly Minimax Optimal Offline Reinforcement Learning with Linear Function Approximation: Single-Agent MDP and Markov Game

Wei Xiong,Han Zhong,Chengshuai Shi,Cong Shen,Liwei Wang,Tong Zhang

Offline reinforcement learning (RL) aims at learning an optimal strategy using a pre-collected dataset without further interactions with the environment. While various algorithms have been proposed for offline RL in the previous literature, the minimax optimality has only been (nearly) established for tabular Markov decision processes (MDPs). In this paper, we focus on offline RL with linear function approximation and propose a new pessimism-based algorithm for offline linear MDP. At the core of our algorithm is the uncertainty decomposition via a reference function, which is new in the literature of offline RL under linear function approximation. Theoretical analysis demonstrates that our algorithm can match the performance lower bound up to logarithmic factors. We also extend our techniques to the two-player zero-sum Markov games (MGs), and establish a new performance lower bound for MGs, which tightens the existing result, and verifies the nearly minimax optimality of the proposed algorithm. To the best of our knowledge, these are the first computationally efficient and nearly minimax optimal algorithms for offline single-agent MDPs and MGs with linear function approximation.

Clustering Structure Identification With Ordering Graph

Zheng Xing,Weibing Zhao

In machine learning, data is often presented in the form of a graph or similarity (or distance) values between samples. Graph-based clustering methods such as spectral clustering are defined for general weighted graphs to identify the clustering structure. Graph construction research has developed significantly for decades, but the graph-based partition study still requires more attention because of its poor performance. For example, spectral clustering needs a post-processing (e.g., K-Means) step to uncover the clustering indicators. Yet, K-Means is sensitive to the initial center setting and easily falls into a local optimum. In this paper, we investigate a new type of graph-based clustering approach. Firstly, we introduce a new algorithm for the purpose of cluster analysis which does not explicitly produce a clustering of a dataset but instead creates an augmented graph representing its density-based ordered clustering structure. This ordered graph contains information equivalent to density-based clustering corresponding to a broad range of parameter settings. Secondly, we found that the graph matrix is shown in a block-diagonal form because of the nature of ordering. We propose a partition method to learn the graph matrix's block-diagonal structure and identify the clustering directly. The global optimality is guaranteed theoretically. We test the proposed method on synthetic datasets and five high-dimensional datasets. Experimental results show that the proposed method outperforms state-of-the-art graph-based clustering methods and improves their performance by roughly 10%-50%.

DaxBench: Benchmarking Deformable Object Manipulation with Differentiable Physics

Siwei Chen,Yiqing Xu,Cunjun Yu,Linfeng Li,Xiao Ma,Zhongwen Xu,David Hsu

Deformable object manipulation (DOM) is a long-standing challenge in robotics and has attracted significant interest recently. This paper presents DaXBench, a differentiable simulation framework for DOM. While existing work often focuses on a specific type of deformable objects, DaXBench supports fluid, rope, cloth ...; it provides a general-purpose benchmark to evaluate widely different DOM methods, including planning, imitation learning, and reinforcement learning. DaXBench combines recent advances in deformable object simulation with JAX, a high-performance computational framework. All DOM tasks in DaXBench are wrapped with the OpenAI Gym API for easy integration with DOM algorithms. We hope that DaXBench provides to the research community a comprehensive, standardized benchmark and a valuable tool to support the development and evaluation of new DOM methods. The code and video are available online.

Voxurf: Voxel-based Efficient and Accurate Neural Surface Reconstruction

Tong Wu,Jiaqi Wang,Xingang Pan,Xudong XU,Christian Theobalt,Ziwei Liu,Dahua Lin

Neural surface reconstruction aims to reconstruct accurate 3D surfaces based on multi-view images. Previous methods based on neural volume rendering mostly train a fully implicit model with MLPs, which typically require hours of training for a single scene. Recent efforts explore the explicit volumetric representation to accelerate the optimization via memorizing significant information with learnable voxel grids. However, existing voxel-based methods often struggle in reconstructing fine-grained geometry, even when combined with an SDF-based volume rendering scheme. We reveal that this is because 1) the voxel grids tend to break the color-geometry dependency that facilitates fine-geometry learning, and 2) the under-constrained voxel grids lack spatial coherence and are vulnerable to local minima. In this work, we present Voxurf, a voxel-based surface reconstruction approach that is both efficient and accurate. Voxurf addresses the aforementioned issues via several key designs, including 1) a two-stage training procedure that attains a coherent coarse shape and recovers fine details successively, 2) a dual color network that maintains color-geometry dependency, and 3) a hierarchical geometry feature to encourage information propagation across voxels. Extensive experiments show that Voxurf achieves high efficiency and high quality at the same time. On the DTU benchmark, Voxurf achieves higher reconstruction quality with a 20x training speedup compared to previous fully implicit methods. Our code is publicly available at https://github.com/wutong16/Voxurf/.

Conditional Positional Encodings for Vision Transformers

Xiangxiang Chu,Zhi Tian,Bo Zhang,Xinlong Wang,Chunhua Shen

We propose a conditional positional encoding (CPE) scheme for vision Transformers. Unlike previous fixed or learnable positional encodings that are predefined and independent of input tokens, CPE is dynamically generated and conditioned on the local neighborhood of the input tokens. As a result, CPE can easily generalize to the input sequences that are longer than what the model has ever seen during the training. Besides, CPE can keep the desired translation equivalence in vision tasks, resulting in improved performance. We implement CPE with a simple Position Encoding Generator (PEG) to get seamlessly incorporated into the current Transformer framework. Built on PEG, we present Conditional Position encoding Vision Transformer (CPVT). We demonstrate that CPVT has visually similar attention maps compared to those with learned positional encodings and delivers outperforming results.

Variational Reparametrized Policy Learning with Differentiable Physics

Zhiao Huang,Litian Liang,Zhan Ling,Xuanlin Li,Chuang Gan,Hao Su

We study the problem of policy parameterization for reinforcement learning (RL) with high-dimensional continuous action space. Our goal is to find a good way to parameterize the policy of continuous RL as a multi-modality distribution. To this end, we propose to treat the continuous RL policy as a generative model over the distribution of optimal trajectories. We use a diffusion process-like strategy to model the policy and derive a novel variational bound which is the optimization objective to learn the policy. To maximize the objective by gradient descent, we introduce the Reparameterized Policy Gradient Theorem. This theorem elegantly connects classical method REINFORCE and trajectory return optimization for computing the gradient of a policy. Moreover, our method enjoys strong explorat ion ability due to the multi-modality policy parameterization; notably, when a strong differentiable world model presents, our method also enjoys the fast convergence speed of trajectory optimization. We evaluate our method on numerical problems and manipulation tasks within a differentiable simulator. Qualitative results show its ability to capture the multi-modality distribution of optimal trajectories, and quantitative results show that it can avoid local optima and outperforms baseline approaches.

GENERALIZED MATRIX LOCAL LOW RANK REPRESENTATION BY RANDOM PROJECTION AND SUBMATRIX PROPAGATION

Pengtao Dang,Wennan Chang,Haiqi Zhu,Changlin Wan,Tong Zhao,Tingo Guo,Paul Salama,Sha Cao,Chi Zhang

Detecting distinct submatrices of low rank property is a highly desirable matrix representation learning technique for the ease of data interpretation, called the matrix local low rank representation (MLLRR). Based on different mathematical assumptions of the local pattern, the MLLRR problem could be categorized into two sub-problems, namely local constant variation (LCV) and local linear low rank (LLR). Existing solutions on MLLRR only focused on the LCV problem, which misses a substantial amount of true and interesting patterns. In this work, we develop a novel matrix computational framework called RPSP (Random Probing based submatrix Propagation) that provides an effective solution for both of the LCV and LLR problems. RPSP detects local low rank patterns that grow from small submatrices of low rank property, which are determined by a random projection approach. RPSP is supported by theories of random projection. Experiments on synthetic data demonstrate that RPSP outperforms all state-of-the-art methods, with the capacity to robustly and correctly identify the low rank matrices under both LCV and LLR settings. On real-world datasets, RPSP also demonstrates its effectiveness in identifying interpretable local low rank matrices.

Stable, Efficient, and Flexible Monotone Operator Implicit Graph Neural Networks

Justin Baker,Qingsong Wang,Bao Wang

Implicit graph neural networks (IGNNs) that solve a fixed-point equilibrium equation for representation learning can learn the long-range dependencies (LRD) in the underlying graphs and show remarkable performance for various graph learning tasks. However, the expressivity of IGNNs is limited by the constraints for their well-posedness guarantee. Moreover, when IGNNs become effective for learning LRD, their eigenvalues converge to the value that slows down the convergence, and their performance is unstable across different tasks. In this paper, we provide a new well-posedness condition of IGNNs leveraging monotone operator theory. The new well-posedness characterization informs us to design effective parameterizations to improve the accuracy, efficiency, and stability of IGNNs. Leveraging accelerated operator splitting schemes and graph diffusion convolution, we design efficient and flexible implementations of monotone operator IGNNs that are significantly faster and more accurate than existing IGNNs.

ManiSkill2: A Unified Benchmark for Generalizable Manipulation Skills

Jiayuan Gu,Fanbo Xiang,Xuanlin Li,Zhan Ling,Xiqiang Liu,Tongzhou Mu,Yihe Tang,Stone Tao,Xinyue Wei,Yunchao Yao,Xiaodi Yuan,Pengwei Xie,Zhiao Huang,Rui Chen,Hao Su

Generalizable manipulation skills, which can be composed to tackle long-horizon and complex daily chores, are one of the cornerstones of Embodied AI. However, existing benchmarks, mostly composed of a suite of simulatable environments, are insufficient to push cutting-edge research works because they lack object-level topological and geometric variations, are not based on fully dynamic simulation, or are short of native support for multiple types of manipulation tasks. To this end, we present ManiSkill2, the next generation of the SAPIEN ManiSkill benchmark, to address critical pain points often encountered by researchers when using benchmarks for generalizable manipulation skills. ManiSkill2 includes 20 manipulation task families with 2000+ object models and 4M+ demonstration frames, whic

h cover stationary/mobile-base, single/dual-arm, and rigid/soft-body manipulation tasks with 2D/3D-input data simulated by fully dynamic engines. It defines a unified interface and evaluation protocol to support a wide range of algorithms (e.g., classic sense-plan-act, RL, IL), visual observations (point cloud, RGBD), and controllers (e.g., action type and parameterization). Moreover, it empowers fast visual input learning algorithms so that a CNN-based policy can collect samples at about 2000 FPS with 1 GPU and 16 processes on a regular workstation. It implements a render server infrastructure to allow sharing rendering resources across all environments, thereby significantly reducing memory usage. We open-source all codes of our benchmark (simulator, environments, and baselines) and host an online challenge open to interdisciplinary researchers.

Deja Vu: Continual Model Generalization for Unseen Domains
Chenxi Liu,Lixu Wang,Lingjuan Lyu,Chen Sun,Xiao Wang,Qi Zhu
In real-world applications, deep learning models often run in non-stationary environments where the target data distribution continually shifts over time. There have been numerous domain adaptation (DA) methods in both online and offline modes to improve cross-domain adaptation ability. However, these DA methods typically only provide good performance after a long period of adaptation, and perform poorly on new domains before and during adaptation – in what we call the “Unfamiliar Period”, especially when domain shifts happen suddenly and significantly. On the other hand, domain generalization (DG) methods have been proposed to improve the model generalization ability on unadapted domains. However, existing DG works are ineffective for continually changing domains due to severe catastrophic forgetting of learned knowledge. To overcome these limitations of DA and DG in handling the Unfamiliar Period during continual domain shift, we propose RaTP, a framework that focuses on improving models’ target domain generalization (TDG) capability, while also achieving effective target domain adaptation (TDA) capability right after training on certain domains and forgetting alleviation (FA) capability on past domains. RaTP includes a training-free data augmentation module to prepare data for TDG, a novel pseudo-labeling mechanism to provide reliable supervision for TDA, and a prototype contrastive alignment algorithm to align different domains for achieving TDG, TDA and FA. Extensive experiments on Digits, PACS, and DomainNet demonstrate that RaTP significantly outperforms state-of-the-art works from Continual DA, Source-Free DA, Test-Time/Online DA, Single DG, Multiple DG and Unified DA&DG in TDG, and achieves comparable TDA and FA capabilities.

A Graph Neural Network Approach to Automated Model Building in Cryo-EM Maps
Kiarash Jamali,Dari Kimanius,Sjors HW Scheres
Electron cryo-microscopy (cryo-EM) produces three-dimensional (3D) maps of the electrostatic potential of biological macromolecules, including proteins. At sufficient resolution, the cryo-EM maps, along with some knowledge about the imaged molecules, allow de novo atomic modelling. Typically, this is done through a laborious manual process. Recent advances in machine learning applications to protein structure prediction show potential for automating this process. Taking inspiration from these techniques, we have built ModelAngelo for automated model building of proteins in cryo-EM maps. ModelAngelo first uses a residual convolutional neural network (CNN) to initialize a graph representation with nodes assigned to individual amino acids of the proteins in the map and edges representing the protein chain. The graph is then refined with a graph neural network (GNN) that combines the cryo-EM data, the amino acid sequence data and prior knowledge about protein geometries. The GNN refines the geometry of the protein chain and classifies the amino acids for each of its nodes. The final graph is post-processed with a hidden Markov model (HMM) search to map each protein chain to entries in a user provided sequence file. Application to 28 test cases shows that ModelAngelo outperforms state-of-the-art and approximates manual building for cryo-EM maps with resolutions better than 3.5 A.

Stealing and Defending Transformer-based Encoders

Adam Dziedzic,Franziska Boenisch,Mingjian Jiang,Haonan Duan,Nicolas Papernot

Self-supervised learning (SSL) has become the predominant approach to training on large amounts of unlabeled data. New real-world APIs offer services to generate high-dimensional representations for given inputs based on SSL encoders with transformer architectures. Recent efforts highlight that it is possible to steal high-quality SSL encoders trained on convolutional neural networks. In this work, we are the first to extend this line of work to stealing and defending transformer-based encoders in both language and vision domains. We show that it is possible to steal transformer-based sentence embedding models solely using their returned representations and with 40x fewer queries than the number of victim's training data points. We also decrease the number of required stealing queries for the vision encoders by leveraging semi-supervised learning. Finally, to defend vision transformers against stealing attacks, we propose a defense technique that combines watermarking with dataset inference. Our method creates a unique encoder signature based on a private data subset that acts as a secret seed during training. By applying dataset inference on the seed, we can then successfully identify stolen transformers.

On the Lower Bound of Minimizing Polyak-■ojasiewicz functions

Pengyun Yue,Cong Fang,Zhouchen Lin

Polyak-■ojasiewicz (PL) [Polyak, 1963] condition is a weaker condition than the strong convexity but suffices to ensure a global convergence for the Gradient Descent algorithm. In this paper, we study the lower bound of algorithms using first-order oracles to find an approximate optimal solution. We show that any first-order algorithm requires at least $\Omega\left((L/\mu)^{1-\alpha} \right)$ gradient costs to find an ϵ-approximate optimal solution for a general L-smooth function that has an μ-PL constant for any $\alpha>0$. This result demonstrates the near optimality of the Gradient Descent algorithm to minimize smooth PL functions in the sense that there exists a ``hard'' PL function such that no first-order algorithm can be faster by a polynomial order. In contrast, it is well-known that the momentum technique, e.g. [Nesterov, 2003, chap. 2] can provably accelerate Gradient Descent to $O\left(\sqrt{L/\hat{\mu}}\log\frac{1}{\epsilon}\right)$ gradient costs for functions that are L-smooth and $\hat{\mu}$-strongly convex. Therefore, our result distinguishes the hardness of minimizing a smooth PL function and a smooth strongly convex function as the complexity of the former cannot be improved by any polynomial order in general.

VectorMapNet: End-to-end Vectorized HD Map Learning

Yicheng Liu,Tianyuan Yuan,Yue Wang,Yilun Wang,Hang Zhao

Autonomous driving systems require a good understanding of surrounding environments, including moving obstacles and static High-Definition (HD) semantic map elements. Existing methods approach the semantic map problem by offline manual annotation, which suffers from serious scalability issues. Recent learning-based methods produce dense rasterized segmentation predictions to construct maps. However, these predictions do not include instance information of individual map elements and require heuristic post-processing to obtain vectorized maps. To tackle these challenges, we introduce an end-to-end vectorized HD map learning pipeline, termed VectorMapNet. VectorMapNet takes onboard sensor observations and predicts a sparse set of polylines in the bird's-eye view. This pipeline can explicitly model the spatial relation between map elements and generate vectorized maps that are friendly to downstream autonomous driving tasks. Extensive experiments show that VectorMapNet achieve strong map learning performance on both nuScenes and Argoverse2 dataset, surpassing previous state-of-the-art methods by 14.2 mAP and 14.6mAP. Qualitatively, we also show that VectorMapNet is capable of generating comprehensive maps and capturing more fine-grained details of road geometry.

To the best of our knowledge, VectorMapNet is the first work designed towards end-to-end vectorized map learning from onboard sensors.

An information-theoretic approach to unsupervised keypoint representation learni

ng
Ali Younes,Simone Schaub-Meyer,Georgia Chalvatzaki

Extracting informative representations from videos is fundamental for the effective learning of various downstream tasks. Inspired by classical works on saliency, we present a novel information-theoretic approach to discover meaningful representations from videos in an unsupervised fashion. We argue that local entropy of pixel neighborhoods and its evolution in a video stream is a valuable intrinsic supervisory signal for learning to attend to salient features. We, thus, abstract visual features into a concise representation of keypoints that serve as dynamic information transporters. We discover in an unsupervised fashion spatio-temporally consistent keypoint representations that carry the prominent information across video frames, thanks to two original information-theoretic losses. First, a loss that maximizes the information covered by the keypoints in a frame. Second, a loss that encourages optimized keypoint transportation over time, thus, imposing consistency of the information flow. We evaluate our keypoint-based representation compared to state-of-the-art baselines in different downstream tasks such as learning object dynamics. To evaluate the expressivity and consistency of the keypoints, we propose a new set of metrics. Our empirical results showcase the superior performance of our information-driven keypoints that resolve challenges like attendance to both static and dynamic objects, and to objects abruptly entering and leaving the scene.

Distilling Cognitive Backdoor Patterns within an Image
Hanxun Huang,Xingjun Ma,Sarah Monazam Erfani,James Bailey

This paper proposes a simple method to distill and detect backdoor patterns within an image: \emph{Cognitive Distillation} (CD). The idea is to extract the ``minimal essence" from an input image responsible for the model's prediction. CD optimizes an input mask to extract a small pattern from the input image that can lead to the same model output (i.e., logits or deep features). The extracted pattern can help understand the cognitive mechanism of a model on clean vs. backdoor images and is thus called a \emph{Cognitive Pattern} (CP). Using CD and the distilled CPs, we uncover an interesting phenomenon of backdoor attacks: despite the various forms and sizes of trigger patterns used by different attacks, the CPs of backdoor samples are all surprisingly and suspiciously small.

One thus can leverage the learned mask to detect and remove backdoor examples from poisoned training datasets.

We conduct extensive experiments to show that CD can robustly detect a wide range of advanced backdoor attacks.

We also show that CD can potentially be applied to help detect potential biases from face datasets.

Code is available at https://github.com/HanxunH/CognitiveDistillation.

Curriculum Reinforcement Learning via Morphology-Environment Co-Evolution
Shuang Ao,Tianyi Zhou,Guodong Long,Jing Jiang

Throughout long history, natural species have learned to survive by evolving their physical structures adaptive to the environment changes. In contrast, current reinforcement learning (RL) studies mainly focus on training an agent with a fixed morphology (e.g., skeletal structure and joint attributes) in a fixed environment, which can hardly generalize to changing environments or new tasks. In this paper, we optimize an RL agent and its morphology through ''morphology-environment co-evolution (MECE)'', in which the morphology keeps being updated to adapt to the changing environment, while the environment is modified progressively to bring new challenges and stimulate the improvement of the morphology. This leads to a curriculum to train generalizable RL, whose morphology and policy are optimized for different environments. Instead of hand-crafting the curriculum, we train two policies to automatically change the morphology and the environment. To this end, (1) we develop two novel and effective rewards for the two policies, which are solely based on the learning dynamics of the RL agent; (2) we design a scheduler to automatically determine when to change the environment and the morphology. We find these two designs are critical to the success of MECE, as veri fied by extensive ablation studies. In experiments on two classes of tasks, the morphology and RL policies trained via MECE exhibit significantly better generalization performance in unseen test environments than SOTA morphology optimization methods. Our ablation studies on the two MECE policies further show that the co-evolution between the morphology and environment is the key to the success.

Domain Generalization with Small Data

Kecheng Chen,Elena Gal,Hong Yan,Haoliang Li

In this work, we propose to tackle the problem of domain generalization in the context of insufficient samples. Instead of extracting latent feature embeddings based on deterministic models, we propose to learn a domain-invariant representation based on the probabilistic framework by mapping each data point into probabilistic embeddings. Specifically, we first extend empirical maximum mean discrepancy (MMD) to a novel probabilistic MMD that can measure the discrepancy between mixture distributions (i.e., source domains) consisted of a serial of latent distributions rather than latent points. Moreover, instead of imposing the contrastive semantic alignment (CSA) loss based on pairs of latent points, a novel probabilistic CSA loss encourages positive probabilistic embedding pairs to be closer while pulling other negative ones apart. Benefiting from the learned representation captured by probabilistic models, our proposed method can marriage the measurement on the distribution over distributions (i.e., the global perspective alignment) and the distribution-based contrastive semantic alignment (i.e., the local perspective alignment). Extensive experimental results on three challenging medical datasets show the effectiveness of our proposed method in the context of insufficient data compared with state-of-the-art baseline methods.

****

3D generation on ImageNet

Ivan Skorokhodov,Aliaksandr Siarohin,Yinghao Xu,Jian Ren,Hsin-Ying Lee,Peter Wonka,Sergey Tulyakov

All existing 3D-from-2D generators are designed for well-curated single-category datasets, where all the objects have (approximately) the same scale, 3D location, and orientation, and the camera always points to the center of the scene. This makes them inapplicable to diverse, in-the-wild datasets of non-alignable scenes rendered from arbitrary camera poses. In this work, we develop a 3D generator with Generic Priors (3DGP): a 3D synthesis framework with more general assumptions about the training data, and show that it scales to very challenging datasets, like ImageNet. Our model is based on three new ideas. First, we incorporate an inaccurate off-the-shelf depth estimator into 3D GAN training via a special depth adaptation module to handle the imprecision. Then, we create a flexible camera model and a regularization strategy for it to learn its distribution parameters during training. Finally, we extend the recent ideas of transferring knowledge from pretrained classifiers into GANs for patch-wise trained models by employing a simple distillation-based technique on top of the discriminator. It achieves more stable training than the existing methods and speeds up the convergence by at least 40%. We explore our model on four datasets: SDIP Dogs 256^2, SDIP Elephants 256^2, LSUN Horses 256^2, and ImageNet 256^2 and demonstrate that 3DGP outperforms the recent state-of-the-art in terms of both texture and geometry quality. Code and visualizations: https://snap-research.github.io/3dgp.

Revocable Deep Reinforcement Learning with Affinity Regularization for Outlier-Robust Graph Matching

Chang Liu,Zetian Jiang,Runzhong Wang,Lingxiao Huang,Pinyan Lu,Junchi Yan

Graph matching (GM) has been a building block in various areas including computer vision and pattern recognition. Despite recent impressive progress, existing deep GM methods often have obvious difficulty in handling outliers, which are ubiquitous in practice. We propose a deep reinforcement learning based approach RGM, whose sequential node matching scheme naturally fits the strategy for selective inlier matching against outliers. A revocable action framework is devised to improve the agent's flexibility against the complex constrained GM. Moreover, we propose a quadratic approximation technique to regularize the affinity score, in the presence of outliers. As such, the agent can finish inlier matching timely when the affinity score stops growing, for which otherwise an additional parameter i.e. the number of inliers is needed to avoid matching outliers. In this paper, we focus on learning the back-end solver under the most general form of GM: the Lawler's QAP, whose input is the affinity matrix. Especially, our approach can also boost existing GM methods that use such input. Experiments on multiple real-world datasets demonstrate its performance regarding both accuracy and robustness.

Hierarchical Prompting Improves Visual Recognition On Accuracy, Data Efficiency and Explainability

Wenhao Wang,Yifan Sun,Wei Li,Yi Yang

When humans try to distinguish some inherently similar visual concepts, e.g., Rosa Peace and China Rose, they may use the underlying hierarchical taxonomy to prompt the recognition. For example, given a prompt that the image belongs to the rose family, a person can narrow down the category range and thus focuses on the comparison between different roses. In this paper, we explore the hierarchical prompting for deep visual recognition (image classification, in particular) based on the prompting mechanism of the transformer. We show that the transformer can take the similar benefit by injecting the coarse-class prompts into the intermediate blocks. The resulting Transformer with Hierarchical Prompting (TransHP) is very simple and consists of three steps: 1) TransHP learns a set of prompt tokens to represent the coarse classes, 2) learns to predict the coarse class of the input image using an intermediate block, and 3) absorbs the prompt token of the predicted coarse class into the feature tokens. Consequently, the injected coarse-class prompt conditions (influences) the subsequent feature extraction and encourages better focus on the relatively subtle differences among the descendant classes. Through extensive experiments on popular image classification datasets, we show that this simple hierarchical prompting improves visual recognition on classification accuracy (e.g., improving ViT-B/16 by $+2.83\%$ ImageNet classification accuracy), training data efficiency (e.g., $+12.69\%$ improvement over the baseline under 10% ImageNet training data), and model explainability.

Convergence of the mini-batch SIHT algorithm

Saeed Damadi,Jinglai Shen

The Iterative Hard Thresholding (IHT) algorithm has been considered extensively as an effective deterministic algorithm for solving sparse optimizations.

The IHT algorithm benefits from the information of the batch (full) gradient at each point and this information is a crucial key for the convergence analysis of the generated sequence. However, this strength becomes a weakness when it comes to machine learning and high dimensional statistical applications because calculating the batch gradient at each iteration is computationally expensive or impractical. Fortunately, in these applications the objective function has a summation structure that can be taken advantage of to approximate the batch gradient by the stochastic mini-batch gradient. In this paper, we study the mini-batch Stochastic IHT (SIHT) algorithm for solving the sparse optimizations. As opposed to previous works where increasing and variable mini-batch size is necessary for derivation, we fix the mini-batch size according to a lower bound that we derive and show our work. To prove stochastic convergence of the objective value function we first establish a critical sparse stochastic gradient descent property. Using this stochastic gradient descent property we show that the sequence generated by the stochastic mini-batch SIHT is a supermartingale sequence and converges with probability one. Unlike previous work we do not assume the function to be a restricted strongly convex. To the best of our knowledge, in the regime of sparse optimization, this is the first time in the literature that it is shown that the sequence of the stochastic function values converges with probability one by fixing the mini-batch size for all steps.

****

Decomposing Texture and Semantics for Out-of-distribution Detection

Jeong-Hyeon Moon,Namhyuk Ahn,Kyung-Ah Sohn

Out-of-distribution (OOD) detection has made significant progress in recent years because the distribution mismatch between the training and testing can severely deteriorate the reliability of a machine learning system.Nevertheless, the lack of precise interpretation of the in-distribution limits the application of OOD detection methods to real-world system pipielines. To tackle this issue, we decompose the definition of the in-distribution into texture and semantics, motivated by real-world scenarios. In addition, we design new benchmarks to measure the robustness that OOD detection methods should have. To achieve a good balance between the OOD detection performance and robustness, our method takes a divide-and-conquer approach. That is, the model first tackles each component of the texture and semantics separately, and then combines them later. Such design philosophy is empirically proven by a series of benchmarks including not only ours but also the conventional counterpart.

Rethinking the Expressive Power of GNNs via Graph Biconnectivity
Bohang Zhang,Shengjie Luo,Liwei Wang,Di He
Designing expressive Graph Neural Networks (GNNs) is a central topic in learning graph-structured data. While numerous approaches have been proposed to improve GNNs with respect to the Weisfeiler-Lehman (WL) test, for most of them, there is still a lack of deep understanding of what additional power they can systematically and provably gain. In this paper, we take a fundamentally different perspective to study the expressive power of GNNs beyond the WL test. Specifically, we introduce a novel class of expressivity metrics via graph biconnectivity and highlight their importance in both theory and practice. As biconnectivity can be easily calculated using simple algorithms that have linear computational costs, it is natural to expect that popular GNNs can learn it easily as well. However, after a thorough review of prior GNN architectures, we surprisingly find that most of them are not expressive for any of these metrics. The only exception is the ESAN framework (Bevilacqua et al., 2022), for which we give a theoretical justification of its power. We proceed to introduce a principled and more efficient approach, called the Generalized Distance Weisfeiler-Lehman (GD-WL), which is provably expressive for all biconnectivity metrics. Practically, we show GD-WL can be implemented by a Transformer-like architecture that preserves expressiveness and enjoys full parallelizability. A set of experiments on both synthetic and real datasets demonstrates that our approach can consistently outperform prior GNN architectures.

One Transformer Can Understand Both 2D & 3D Molecular Data
Shengjie Luo,Tianlang Chen,Yixian Xu,Shuxin Zheng,Tie-Yan Liu,Liwei Wang,Di He
Unlike vision and language data which usually has a unique format, molecules can naturally be characterized using different chemical formulations. One can view a molecule as a 2D graph or define it as a collection of atoms located in a 3D space. For molecular representation learning, most previous works designed neural networks only for a particular data format, making the learned models likely to fail for other data formats. We believe a general-purpose neural network model for chemistry should be able to handle molecular tasks across data modalities. To achieve this goal, in this work, we develop a novel Transformer-based Molecular model called Transformer-M, which can take molecular data of 2D or 3D formats as input and generate meaningful semantic representations. Using the standard Transformer as the backbone architecture, Transformer-M develops two separated channels to encode 2D and 3D structural information and incorporate them with the atom features in the network modules. When the input data is in a particular format, the corresponding channel will be activated, and the other will be disabled. By training on 2D and 3D molecular data with properly designed supervised signals, Transformer-M automatically learns to leverage knowledge from different data modalities and correctly capture the representations. We conducted extensive experiments for Transformer-M. All empirical results show that Transformer-M can simultaneously achieve strong performance on 2D and 3D tasks, suggesting its broad applicability. The code and models will be made publicly available at https://github.com/lsj2408/Transformer-M.

Generating Diverse Cooperative Agents by Learning Incompatible Policies

Rujikorn Charakorn,Poramate Manoonpong,Nat Dilokthanakul

Training a robust cooperative agent requires diverse partner agents. However, obtaining those agents is difficult. Previous works aim to learn diverse behaviors by changing the state-action distribution of agents. But, without information about the task's goal, the diversified agents are not guided to find other important, albeit sub-optimal, solutions: the agents might learn only variations of the same solution. In this work, we propose to learn diverse behaviors via policy compatibility. Conceptually, policy compatibility measures whether policies of interest can coordinate effectively. We theoretically show that incompatible policies are not similar. Thus, policy compatibility—which has been used exclusively as a measure of robustness—can be used as a proxy for learning diverse behaviors. Then, we incorporate the proposed objective into a population-based training scheme to allow concurrent training of multiple agents. Additionally, we use state-action information to induce local variations of each policy. Empirically, the proposed method consistently discovers more solutions than baseline methods across various multi-goal cooperative environments. Finally, in multi-recipe Overcooked, we show that our method produces populations of behaviorally diverse agents, which enables generalist agents trained with such a population to be more robust.

Mind the Gap: Offline Policy Optimization for Imperfect Rewards

Jianxiong Li,Xiao Hu,Haoran Xu,Jingjing Liu,Xianyuan Zhan,Qing-Shan Jia,Ya-Qin Zhang

Reward function is essential in reinforcement learning (RL), serving as the guiding signal to incentivize agents to solve given tasks, however, is also notoriously difficult to design. In many cases, only imperfect rewards are available, which inflicts substantial performance loss for RL agents. In this study, we propose a unified offline policy optimization approach, \textit{RGM (Reward Gap Minimization)}, which can smartly handle diverse types of imperfect rewards. RGM is formulated as a bi-level optimization problem: the upper layer optimizes a reward correction term that performs visitation distribution matching w.r.t. some expert data; the lower layer solves a pessimistic RL problem with the corrected rewards. By exploiting the duality of the lower layer, we derive a tractable algorithm that enables sampled-based learning without any online interactions. Comprehensive experiments demonstrate that RGM achieves superior performance to existing methods under diverse settings of imperfect rewards. Further, RGM can effectively correct wrong or inconsistent rewards against expert preference and retrieve useful information from biased rewards. Code is available at https://github.com/Facebear-ljx/RGM.

Gamma Sampling: Fine-grained Controlling Language Models without Training

Shangda Wu,Maosong Sun

The dominant approaches for controlling language models achieve prominence in controlling high-level attributes (e.g. topic and sentiment). However, these methods often require condition-specific data or are computationally expensive. We propose a new simple guided decoding method, Gamma Sampling, which does not require any training data to achieve fine-grained controllable text generation while maintaining a fast generation speed. Gamma Sampling introduces attribute-related information (provided by humans or language models themselves) into the sampling process to guide language models to generate texts with desired attributes. Since no training is involved, Gamma Sampling can be easily applied to any language model for controllable text generation. Through experiments, we show that Gamma Sampling-steered GPT2-small (117M) outperforms baselines such as PPLM (345M) and CTRL (1.6B) in diversity, attribute relevance, and overall quality of generated samples.

Label Distribution Learning via Implicit Distribution Representation

Zhuoran Zheng,Xiuyi Jia

In contrast to multi-label learning, label distribution learning characterizes the polysemy of examples by a label distribution to represent richer semantics. In the learning process of label distribution, the training data is collected mainly by manual annotation or label enhancement algorithms to generate label distribution. Unfortunately, the complexity of the manual annotation task or the inaccuracy of the label enhancement algorithm leads to noise and uncertainty in the label distribution training set. To alleviate this problem, we introduce the implicit distribution in the label distribution learning framework to characterize the uncertainty of each label value. Specifically, we use deep implicit representation learning to construct a label distribution matrix with Gaussian prior constraints, where each row component corresponds to the distribution estimate of each label value, and this row component is constrained by a prior Gaussian distribution to moderate the noise and uncertainty interference of the label distribution dataset. Finally, each row component of the label distribution matrix is transformed into a standard label distribution form by using the self-attention algorithm. In addition, some approaches with regularization characteristics are conducted in the training phase to improve the performance of the model.

MultiWave: Multiresolution Deep Architectures through Wavelet Decomposition for Multivariate Timeseries Forecasting and Prediction

Iman Deznabi,Madalina Fiterau

One of the challenges in multivariate time series modeling is that changes in signals occur with different frequencies, even when the sampling rate is consistent across signals. In the case of multivariate time series prediction, the outcome is also determined by patterns of different frequencies. These encapsulate both long-term and short-term effects, which have so far not been sufficiently leveraged by deep learning time series models. We fill this gap by introducing a framework, called MultiWave, which augments any deep learning time series model with components operating at the intrinsic frequencies of the signals. MultiWave applies wavelet decomposition on each signal to obtain subsignals of different frequencies and groups all subsignals in the same frequency band together to train a component. The output of the components is combined through a gating mechanism that removes irrelevant frequencies for the given predictive task. We show that MultiWave accurately determines the informative frequency bands and that the augmented models including components trained to operate on those bands outperform the original models. We further show that applying MultiWave on top of different deep learning models improves their performance in several real-world applications.

Learning to Compose Soft Prompts for Compositional Zero-Shot Learning

Nihal V. Nayak,Peilin Yu,Stephen Bach

We introduce compositional soft prompting (CSP), a parameter-efficient learning technique to improve the zero-shot compositionality of large-scale pretrained vision-language models (VLMs) like CLIP. We develop CSP for compositional zero-shot learning, the task of predicting unseen attribute-object compositions (e.g., old cat and young tiger). VLMs have a flexible text encoder that can represent arbitrary classes as natural language prompts but they often underperform task-specific architectures on the compositional zero-shot benchmark datasets. CSP treats the attributes and objects that define classes as learnable tokens of vocabulary. During training, the vocabulary is tuned to recognize classes that compose tokens in multiple ways (e.g., old cat and white cat). At test time, we recompose the learned attribute-object vocabulary in new combinations to recognize novel classes. We show that CSP outperforms the CLIP on benchmark datasets by an average of 10.9 percentage points on AUC. CSP also outperforms CoOp, a soft prompting method that fine-tunes the prefix context tokens, by an average of 5.8 percentage points on AUC. We perform additional experiments to show that CSP improves generalization to higher-order attribute-attribute-object compositions (e.g., old white cat) and combinations of pretrained attributes and fine-tuned objects. The code is available at https://github.com/BatsResearch/csp.

SQA3D: Situated Question Answering in 3D Scenes

Xiaojian Ma,Silong Yong,Zilong Zheng,Qing Li,Yitao Liang,Song-Chun Zhu,Siyuan Huang

We propose a new task to benchmark scene understanding of embodied agents: Situated Question Answering in 3D Scenes (SQA3D). Given a scene context (e.g., 3D scan), SQA3D requires the tested agent to first understand its situation (position, orientation, etc.) in the 3D scene as described by text, then reason about its surrounding environment and answer a question under that situation. Based upon 650 scenes from ScanNet, we provide a dataset centered around 6.8k unique situations, along with 20.4k descriptions and 33.4k diverse reasoning questions for these situations. These questions examine a wide spectrum of reasoning capabilities for an intelligent agent, ranging from spatial relation comprehension to commonsense understanding, navigation, and multi-hop reasoning. SQA3D imposes a significant challenge to current multi-modal especially 3D reasoning models. We evaluate various state-of-the-art approaches and find that the best one only achieves an overall score of 47.20%, while amateur human participants can reach 90.06%. We believe SQA3D could facilitate future embodied AI research with stronger situation understanding and reasoning capability.

The Benefits of Model-Based Generalization in Reinforcement Learning

Kenny John Young,Aditya Ramesh,Louis Kirsch,Jürgen Schmidhuber

Model-Based Reinforcement Learning (RL) is widely believed to have the potential to improve sample efficiency by allowing an agent to synthesize large amounts of imagined experience. Experience Replay (ER) can be considered a simple kind of model, which has proved extremely effective at improving the stability and efficiency of deep RL. In principle, a learned parametric model could improve on ER by generalizing from real experience to augment the dataset with additional plausible experience. However, owing to the many design choices involved in empirically successful algorithms, it can be very hard to establish where the benefits are actually coming from. Here, we provide theoretical and empirical insight into when, and how, we can expect data generated by a learned model to be useful. First, we provide a general theorem motivating how learning a model as an intermediate step can narrow down the set of possible value functions more than learning a value function directly from data using the Bellman equation. Second, we provide an illustrative example showing empirically how a similar effect occurs in a more concrete setting with neural network function approximation. Finally, we provide extensive experiments showing the benefit of model-based learning for online RL in environments with combinatorial complexity, but factored structure that allows a learned model to generalize. In these experiments, we take care to control for other factors in order to isolate, insofar as possible, the benefit of using experience generated by a learned model relative to ER alone.

Revisiting Higher-Order Gradient Methods for Multi-Agent Reinforcement Learning

Ariyan Bighashdel,Daan De Geus,Pavol Jancura,Gijs Dubbelman

This paper revisits Higher-Order Gradient (HOG) methods for Multi-Agent Reinforcement Learning (MARL). HOG methods are algorithms in which agents use higher-order gradient information to account for other agents' anticipated learning, and are shown to improve coordination in games with self-interested agents. So far, however, HOG methods are only applied to games with low-dimensional state spaces due to inefficient computation and preservation of higher-order gradient information. In this work, we solve these limitations and propose a HOG framework that can be applied to games with higher-dimensional state spaces. Moreover, we show that current HOG methods, when applied to games with common-interested agents, i.e., team games, can lead to miscoordination between the agents. To solve this, we propose Hierarchical Reasoning (HR) to improve coordination in team games, and we experimentally show that our proposed HR significantly outperforms state-of-the-art methods in standard multi-agent games. With our contributions, we great

ly improve the applicability of HOG methods for MARL. For reproducibility, the code used for our work will be shared after the reviewing process.

Efficient Covariance Estimation for Sparsified Functional Data
Sijie Zheng,Fandong Meng,Jie Zhou
To avoid prohibitive computation cost of sending entire data, we propose four sparsification schemes Random-knots, Random-knots-Spatial, B-spline, Bspline-Spatial, and present corresponding nonparametric estimation of the covariance function. The covariance estimators are asymptotically equivalent to the sample covariance computed directly from the original data. And the estimated functional principal components effectively approximate the infeasible principal components under regularity conditions. The convergence rate reflects that leveraging spatial correlation and B-spline interpolation helps to reduce information loss. Data-driven selection method is further applied to determine the number of eigenfunctions in the model. Extensive numerical experiments are conducted to illustrate the theoretical results.

Sparse Mixture-of-Experts are Domain Generalizable Learners
Bo Li,Yifei Shen,Jingkang Yang,Yezhen Wang,Jiawei Ren,Tong Che,Jun Zhang,Ziwei Liu
Human visual perception can easily generalize to out-of-distributed visual data, which is far beyond the capability of modern machine learning models. Domain generalization (DG) aims to close this gap, with existing DG methods mainly focusing on the loss function design. In this paper, we propose to explore an orthogonal direction, i.e., the design of the backbone architecture. It is motivated by an empirical finding that transformer-based models trained with empirical risk minimization (ERM) outperform CNN-based models employing state-of-the-art (SOTA) DG algorithms on multiple DG datasets. We develop a formal framework to characterize a network's robustness to distribution shifts by studying its architecture's alignment with the correlations in the dataset. This analysis guides us to propose a novel DG model built upon vision transformers, namely \emph{Generalizable Mixture-of-Experts (GMoE)}. Extensive experiments on DomainBed demonstrate that GMoE trained with ERM outperforms SOTA DG baselines by a large margin. Moreover, GMoE is complementary to existing DG methods and its performance is substantially improved when trained with DG algorithms.

PEER: A Collaborative Language Model
Timo Schick,Jane A. Yu,Zhengbao Jiang,Fabio Petroni,Patrick Lewis,Gautier Izacard,Qingfei You,Christoforos Nalmpantis,Edouard Grave,Sebastian Riedel
Textual content is often the output of a collaborative writing process: We start with an initial draft, ask for suggestions, and repeatedly make changes.
Agnostic of this process, today’s language models are trained to generate only the final result. As a consequence, they lack several abilities crucial for collaborative writing: They are unable to update existing texts, difficult to control and incapable of verbally planning or explaining their actions.
To address these shortcomings, we introduce PEER, a collaborative language model that is trained to imitate the entire writing process itself. PEER can write drafts, add suggestions, propose edits and provide explanations for its actions. Crucially, we train multiple instances of PEER able to infill various parts of the writing process, enabling the use of self-training techniques for increasing the quality, amount and diversity of training data. This unlocks PEER's full potential by making it applicable in domains for which no edit histories are available and improving its ability to follow instructions, to write useful comments, and to explain its actions. We show that PEER achieves strong performance across various domains and editing tasks.

A simple but effective and efficient global modeling paradigm for image restoration
man zhou,Jie Huang,Jie Xiao,Hu Yu,Danfeng Hong,Chongyi Li
Global modelling-based image restoration frameworks (e.g., Transformer-like arch

itecture) has gained popularity. Despite the remarkable advancement, the success may be at the cost of model parameters and FLOPs while the intrinsic characteristics of specific task are ignored. The objective of our work is orthogonal to previous studies and we thus tailor a simple yet effective global modelling paradigm for image restoration. The key insights which motivate our study are two-fold: 1) Fourier transform is capable of disentangling image degradation and content component, acting as the image degradation prior embedded into image restoration framework; 2) Fourier domain innately embraces global property where each pixel of Fourier space is involved with all the spatial pixels. We obey the de facto global modeling rule ``spatial interaction + channel evolution" of previous studies. Differently, we customize the core designs: multi-scale Fourier period spatial modeling and Fourier channel evolution. Equipped with above designs, our image restoration paradigm is verified on mainstream image restoration tasks including image de-raining, image enhancement, image de-hazing, and guided image super-resolution. The extensive experiments suggest that our paradigm achieves the competitive performance with fewer computational resources. Our main focus is not to beat previous frameworks but hopes to provide an alternative global modelling-based customized image restoration framework. Code will be publicly available.

Empowering Networks With Scale and Rotation Equivariance Using A Similarity Convolution
Zikai Sun,Thierry Blu
The translational equivariant nature of Convolutional Neural Networks (CNNs) is a reason for its great success in computer vision. However, networks do not enjoy more general equivariance properties such as rotation or scaling, ultimately limiting their generalization performance. To address this limitation, we devise a method that endows CNNs with simultaneous equivariance with respect to translation, rotation, and scaling. Our approach defines a convolution-like operation and ensures equivariance based on our proposed scalable Fourier-Argand representation. The method maintains similar efficiency as a traditional network and hardly introduces any additional learnable parameters, since it does not face the computational issue that often occurs in group-convolution operators. We validate the efficacy of our approach in the image classification task, demonstrating its robustness and the generalization ability to both scaled and rotated inputs.

ISS: Image as Stepping Stone for Text-Guided 3D Shape Generation
Zhengzhe Liu,Peng Dai,Ruihui Li,XIAOJUAN QI,Chi-Wing Fu
Text-guided 3D shape generation remains challenging due to the absence of large paired text-shape dataset, the substantial semantic gap between these two modalities, and the structural complexity of 3D shapes. This paper presents a new framework called Image as Stepping Stone (ISS) for the task by introducing 2D image as a stepping stone to connect the two modalities and to eliminate the need for paired text-shape data. Our key contribution is a two-stage feature-space-alignment approach that maps CLIP features to shapes by harnessing a pre-trained single-view reconstruction (SVR) model with multi-view supervisions: first map the CLIP image feature to the detail-rich shape space in the SVR model, then map the CLIP text feature to the shape space and optimize the mapping by encouraging CLIP consistency between the input text and the rendered images. Further, we formulate a textguided shape stylization module to dress up the output shapes with novel structures and textures. Beyond existing works on 3D shape generation from text, our new approach is general for creating shapes in a broad range of categories, without requiring paired text-shape data. Experimental results manifest that our approach outperforms the state-of-the-arts and our baselines in terms of fidelity and consistency with text. Further, our approach can stylize the generated shapes with both realistic and fantasy structures and textures. Codes are available at https://github.com/liuzhengzhe/ISS-Image-as-Stepping-Stone-for-Text-Guided-3D-Shape-Generation.

Robust and Controllable Object-Centric Learning through Energy-based Models

Ruixiang ZHANG,Tong Che,Boris Ivanovic,Renhao Wang,Marco Pavone,Yoshua Bengio,Liam Paull

Humans are remarkably good at understanding and reasoning about complex visual scenes. The capability of decomposing low-level observations into discrete objects allows us to build a grounded abstract representation and identify the compositional structure of the world. Thus it is a crucial step for machine learning models to be capable of inferring objects and their properties from visual scene without explicit supervision. However, existing works on object-centric representation learning are either relying on tailor-made neural network modules or assuming sophisticated models of underlying generative and inference processes. In this work, we present EGO, a conceptually simple and general approach to learning object-centric representation through energy-based model. By forming a permutation-invariant energy function using vanilla attention blocks that are readily available in Transformers, we can infer object-centric latent variables via gradient-based MCMC methods where permutation equivariance is automatically guaranteed. We show that EGO can be easily integrated into existing architectures, and can effectively extract high-quality object-centric representations, leading to better segmentation accuracy and competitive downstream task performance. We empirically evaluate the robustness of the learned representation from EGO against distribution shift. Finally, we demonstrate the effectiveness of EGO in systematic compositional generalization, by recomposing learned energy functions for novel scene generation and manipulation.

Learning Antidote Data to Individual Unfairness

Peizhao Li,Ethan Xia,Hongfu Liu

Fairness is an essential factor for machine learning systems deployed in high-stake applications. Among all fairness notions, individual fairness, following a consensus that `similar individuals should be treated similarly,' is a vital notion to guarantee fair treatment for individual cases. Previous methods typically characterize individual fairness as a prediction-invariant problem when perturbing sensitive attributes, and solve it by adopting the Distributionally Robust Optimization (DRO) paradigm. However, adversarial perturbations along a direction covering sensitive information do not consider the inherent feature correlations or innate data constraints, and thus mislead the model to optimize at off-manifold and unrealistic samples. In light of this, we propose a method to learn and generate antidote data that approximately follows the data distribution to remedy individual unfairness. These on-manifold antidote data can be used through a generic optimization procedure with original training data, resulting in a pure pre-processing approach to individual unfairness, or can also fit well with the in-processing DRO paradigm. Through extensive experiments, we demonstrate our antidote data resists individual unfairness at a minimal or zero cost to the model's predictive utility.

Does Continual Learning Equally Forget All Parameters?

Haiyan Zhao,Tianyi Zhou,Guodong Long,Jing Jiang,Chengqi Zhang

Distribution shift (e.g., task or domain shift) in continual learning (CL) usually results in catastrophic forgetting of neural networks. Although it can be alleviated by repeatedly replaying buffered data, the every-step replay is time-consuming and the memory to store historical data is usually too small for retraining all parameters. In this paper, we study which modules in neural networks are more prone to forgetting by investigating their training dynamics during CL. Our proposed metrics show that only a few modules are more task-specific and sensitively alters between tasks, while others can be shared across tasks as common knowledge. Hence, we attribute forgetting mainly to the former and find that finetuning them only on a small buffer at the end of any CL method can bring non-trivial improvement. Due to the small number of finetuned parameters, such ``Forgetting Prioritized Finetuning (FPF)'' is efficient on both the computation and buffer size required. We further propose a more efficient and simpler method that entirely removes the every-step replay and replaces them by only $k$-times of FPF periodically triggered during CL. Surprisingly, this ``k-FPF'' performs compar ably to FPF and outperforms the SOTA CL methods but significantly reduces their computational overhead and cost. In experiments on several benchmarks of class- and domain-incremental CL, FPF consistently improves existing CL methods by a large margin and k-FPF further excels on the efficiency without degrading the accuracy. We also empirically studied the impact of buffer size, epochs per task, and finetuning modules to the cost and accuracy of our methods.

STREET: A MULTI-TASK STRUCTURED REASONING AND EXPLANATION BENCHMARK

Danilo Neves Ribeiro,Shen Wang,Xiaofei Ma,Henghui Zhu,Rui Dong,Deguang Kong,Juliette Burger,Anjelica Ramos,zhiheng huang,William Yang Wang,George Karypis,Bing Xiang,Dan Roth

We introduce STREET, a unified multi-task and multi-domain natural language reasoning and explanation benchmark. Unlike most existing question-answering (QA) datasets, we expect models to not only answer questions, but also produce step-by-step structured explanations describing how premises in the question are used to produce intermediate conclusions that can prove the correctness of a certain answer. We perform extensive evaluation with popular language models such as few-shot prompting GPT-3 and fine-tuned T5. We find that these models still lag behind human performance when producing such structured reasoning steps. We believe this work will provide a way for the community to better train and test systems on multi-step reasoning and explanations in natural language.

****

Topology-aware Robust Optimization for Out-of-Distribution Generalization

Fengchun Qiao,Xi Peng

Out-of-distribution (OOD) generalization is a challenging machine learning problem yet highly desirable in many high-stake applications.

Existing methods suffer from overly pessimistic modeling with low generalization confidence. As generalizing to arbitrary test distributions is impossible, we hypothesize that further structure on the topology of distributions is crucial in developing strong OOD resilience. To this end, we propose topology-aware robust optimization (TRO) that seamlessly integrates distributional topology in a principled optimization framework. More specifically, TRO solves two optimization objectives: (1) Topology Learning which explores data manifold to uncover the distributional topology; (2) Learning on Topology which exploits the topology to constrain robust optimization for tightly-bounded generalization risks. We theoretically demonstrate the effectiveness of our approach, and empirically show that it significantly outperforms the state of the arts in a wide range of tasks including classification, regression, and semantic segmentation. Moreover, we empirically find the data-driven distributional topology is consistent with domain knowledge, enhancing the explainability of our approach.

Exploring Neural Network Representational Similarity using Filter Subspaces

Wei Chen,Zichen Miao,Qiang Qiu

Analyzing representational similarity in neural networks is crucial to numerous tasks, such as interpreting or transferring deep models. One typical approach is to input probing data into convolutional neural networks (CNNs) as stimuli to reveal their deep representation for model similarity analysis. Those methods are often computationally expensive and stimulus-dependent. By representing filter subspace in a CNN as a set of filter atoms, previous work has reported competitive performance in continual learning by learning a different set of filter atoms for each task while sharing common atom coefficients across tasks. Inspired by this observation, in this paper, we propose a new paradigm for reducing representational similarity analysis in CNNs to filter subspace distance assessment. Specifically, when filter atom coefficients are shared across networks, model representational similarity can be significantly simplified as calculating the cosine distance among respective filter atoms, to achieve \textit{millions of times} computation reduction. We provide both theoretical and empirical evidence that this simplified filter subspace-based similarity preserves a strong linear correlation with other popular stimulus-based metrics, while being significantly more efficient and robust to probing data. We further validate the effectiveness of th e proposed method in various applications, such as analyzing training dynamics as well as in federated and continual learning. We hope our findings can help further explorations of real-time large-scale representational similarity analysis in neural networks.

EAGLE: Large-scale Learning of Turbulent Fluid Dynamics with Mesh Transformers

Steeven JANNY,Aurélien Bénéteau,Madiha Nadri,Julie Digne,Nicolas THOME,Christian Wolf

Estimating fluid dynamics is classically done through the simulation and integration of numerical models solving the Navier-Stokes equations, which is computationally complex and time-consuming even on high-end hardware. This is a notoriously hard problem to solve, which has recently been addressed with machine learning, in particular graph neural networks (GNN) and variants trained and evaluated on datasets of static objects in static scenes with fixed geometry. We attempt to go beyond existing work in complexity and introduce a new model, method and benchmark. We propose EAGLE: a large-scale dataset of ~1.1 million 2D meshes resulting from simulations of unsteady fluid dynamics caused by a moving flow source interacting with nonlinear scene structure of varying geometries, with 600 different scenes of three different types in total. To perform future forecasting of pressure and velocity on the challenging EAGLE dataset, we introduce a new mesh transformer. It leverages node clustering, graph pooling and global attention to learn long-range dependencies between spatially distant data points without needing a large number of iterations, as existing GNN methods do. We show that our transformer outperforms state-of-the-art performance on, both, existing synthetic and real datasets and on EAGLE. Finally, we highlight that our approach learns to attend to airflow, integrating complex information in a single iteration.

Limitless Stability for Graph Convolutional Networks

Christian Koke

This work establishes rigorous, novel and widely applicable stability guarantees and transferability bounds for general graph convolutional networks -- without reference to any underlying limit object or statistical distribution. Crucially, utilized graph-shift operators are not necessarily assumed to be normal, allowing for the treatment of networks on both directed- and undirected graphs within the developed framework. In the undirected setting, stability to node-level perturbations is related to an 'adequate spectral covering' property of the filters in each layer. Stability to edge-level perturbations is discussed and related to properties of the utilized filters such as their Lipschitz constants. Results on stability to vertex-set non-preserving perturbations are obtained by utilizing recently developed mathematical-physics based tools. As an exemplifying application of the developed theory, it is showcased that
general graph convolutional networks utilizing the un-normalized graph Laplacian as graph-shift-operator can be rendered stable to collapsing strong edges in the underlying graph if filters are mandated to be constant at infinity. These theoretical results are supported by corresponding numerical investigations showcasing the response of filters and networks to such perturbations.

MiSAL: Active Learning for Every Budget

Guy Hacohen,Daphna Weinshall

In supervised Active Learning (AL), the learner can manipulate the labeled training set by choosing examples to be labeled by an oracle. The size of the labeled set is termed budget. Recent years have seen significant progress in this domain in the context of deep active learning. In particular, it has been shown that in general, different families of AL strategies are suitable for high and low budgets. Here we address for the first time the problem of deciding which family of strategies is most suitable for a given budget in a given task. We start from the theoretical analysis of a mixture model, which motivates a computational approach to decide on the most suitable family of methods for the task and budget at hand. We then propose a practical decision algorithm, which determines what family of strategies should be preferred. Using this algorithm, we introduce MiSAL

- a mixed strategy active learning algorithm. MiSAL combines AL strategies from different families, resulting in a method that fits all budgets. We support the analysis by an empirical study, showing the superiority of our method when dealing with image datasets.

SOM-CPC: Unsupervised Contrastive Learning with Self-Organizing Maps for Structured Representations of High-Rate Time Series
Iris A.M. Huijben,Arthur Andreas Nijdam,Sebastiaan Overeem,Merel M Van Gilst,Ruud Van Sloun
Continuous monitoring with an ever-increasing number of sensors has become ubiquitous across many application domains. Acquired data are typically high-dimensional and difficult to interpret, but they are also hypothesized to lie on a low-dimensional manifold. Dimensionality reduction techniques have, therefore, been sought for. Popular linear methods like Principle Component Analysis (PCA) have been extended to non-linear techniques such as Self-Organizing Maps (SOMs) or deep learning (DL) models. DL models have the ability to act on raw data, preventing heuristic feature selection, but the resulting latent space is often unstructured and still multi-dimensional. PCA and SOMs, on the other hand, need to be preceded with a feature-extraction step, but can then map high-dimensional features to 2D space. In this work we propose SOM-CPC, a model that jointly optimizes Contrastive Predictive Coding and a SOM to find an organized 2D manifold. We address a largely unexplored and challenging set of scenarios comprising high-rate time series, and show on both synthetic and real-life data (medical sleep data and audio recordings) that SOM-CPC outperforms both DL-based feature extraction, followed by PCA, K-means or a SOM, and strong deep-SOM baselines that jointly optimize a DL model and a SOM. SOM-CPC has great potential to expose latent patterns in high-rate data streams and may therefore contribute to a better understanding of many different processes and systems.

DIVISION: Memory Efficient Training via Dual Activation Precision
Guanchu Wang,Zirui Liu,Zhimeng Jiang,Ninghao Liu,na Zou,Xia Hu
Activation compressed training (ACT) has been shown to be a promising way to reduce the memory cost of training deep neural networks (DNNs). However, existing work of ACT relies on searching for optimal bit-width during DNN training to reduce the quantization noise, which makes the procedure complicated and less transparent. To this end, we propose a simple and effective method to compress DNN training. Our method is motivated by an instructive observation: DNN backward propagation mainly utilizes the low-frequency component (LFC) of the activation maps, while the majority of memory is for caching the high-frequency component (HFC) during the training. This indicates the HFC of activation maps is highly redundant and compressible during DNN training, which inspires our proposed Dual Activation Precision (DIVISION). During the training, DIVISION preserves the high-precision copy of LFC and compresses the HFC into a light-weight copy with low numerical precision. This can significantly reduce the memory cost without negatively affecting the precision of backward propagation such that DIVISION maintains competitive model accuracy. Experimental results show DIVISION achieves over 10× compression of activation maps, and significantly higher training throughput than state-of-the-art ACT methods, without loss of model accuracy. The code is available at https://anonymous.4open.science/r/division-5CC0/

CLIP-PAE: Projection-Augmentation Embedding to Extract Relevant Features for a Disentangled, Interpretable and Controllable Text-Guided Image Manipulation
Chenliang Zhou,Fangcheng Zhong,Cengiz Oztireli
Recently introduced Contrastive Language-Image Pre-Training (CLIP) bridges images and text by embedding them into a joint latent space. This opens the door to ample literature that aims to manipulate an input image by providing a textual explanation. However, due to the discrepancy between image and text embeddings in the joint space, using text embeddings as the optimization target often introduces undesired artifacts in the resulting images. Disentanglement, interpretabilit

y, and controllability are also hard to guarantee for manipulation. To alleviate these problems, we propose to define corpus subspaces spanned by prompts to capture specific image characteristics. We introduce CLIP projection-augmentation embedding (PAE) as an optimization target to improve the performance of text-guided image manipulation. Our method is a simple and general paradigm that can be easily computed and adapted, and smoothly incorporated into any CLIP-based latent manipulation algorithm to improve performance. To demonstrate the effectiveness of our method, we conduct several theoretical and empirical system studies. As a case study, we utilize the method for text-guided semantic face editing. We quantitatively and qualitatively demonstrate that PAE facilitates a more disentangled, interpretable, and controllable image manipulation method with state of the art quality and accuracy.

Token Merging: Your ViT But Faster

Daniel Bolya,Cheng-Yang Fu,Xiaoliang Dai,Peizhao Zhang,Christoph Feichtenhofer,Judy Hoffman

We introduce Token Merging (ToMe), a simple method to increase the throughput of existing ViT models without needing to train. ToMe gradually combines similar tokens in a transformer using a general and light-weight matching algorithm that is as fast as pruning while being more accurate. Off-the-shelf, ToMe can 2x the throughput of state-of-the-art ViT-L @ 512 and ViT-H @ 518 models on images and 2.2x the throughput of ViT-L on video with only a 0.2-0.3% accuracy drop in each case. ToMe can also easily be applied during training, improving in practice training speed up to 2x for MAE fine-tuning on video. Training with ToMe further minimizes accuracy drop, leading to 2x the throughput of ViT-B on audio for only a 0.4% mAP drop. Qualitatively, we find that ToMe merges object parts into one token, even over multiple frames of video. Overall, ToMe’s accuracy and speed are competitive with state-of-the-art on images, video, and audio.

Provable Adaptivity in Adam

Bohan Wang,Yushun Zhang,Huishuai Zhang,Qi Meng,Zhi-Ming Ma,Tie-Yan Liu,Wei Chen

Adaptive Moment Estimation (Adam) has been observed to converge faster than stochastic gradient descent (SGD) in practice. However, such an advantage has not been theoretically characterized -- the existing convergence rate of Adam is no better than SGD. We attribute this mismatch between theory and practice to a commonly used assumption: the gradient is globally Lipschitz continuous (called L-smooth condition). Specifically, compared to SGD, Adam adaptively chooses a learning rate better suited to the local gradient Lipschitz constant (called local smoothness). This effect becomes
prominent when the local smoothness varies drastically across the domain.

In this paper, we analyze the convergence of Adam under a condition called (L_0,L_1)-smooth condition, which allows the gradient Lipschitz constant to change with the gradient norm. This condition has been empirically verified to be more realistic for deep neural networks \citep{zhang2019gradient} than the L-smooth condition. Under (L_0,L_1)-smooth condition, we establish the convergence for Adam with practical hyperparameters. As such, we argue that Adam can adapt to this local smoothness condition, justifying Adam's \emph{adaptivity}. In contrast, SGD can be arbitrarily slow under this condition.   Our result can shed light on the benefit of adaptive gradient methods over non-adaptive ones.

De Novo Molecular Generation via Connection-aware Motif Mining

Zijie Geng,Shufang Xie,Yingce Xia,Lijun Wu,Tao Qin,Jie Wang,Yongdong Zhang,Feng Wu,Tie-Yan Liu

De novo molecular generation is an essential task for science discovery. Recently, fragment-based deep generative models have attracted much research attention due to their flexibility in generating novel molecules based on existing molecule fragments. However, the motif vocabulary, i.e., the collection of frequent fragments, is usually built upon heuristic rules, which brings difficulties to capturing common substructures from large amounts of molecules. In this work, we propose MiCaM to generate molecules based on mined connection-aware motifs. Specifi cally, it leverages a data-driven algorithm to automatically discover motifs from a molecule library by iteratively merging subgraphs based on their frequency. The obtained motif vocabulary consists of not only molecular motifs (i.e., the frequent fragments), but also their connection information, indicating how the motifs are connected with each other. Based on the mined connection-aware motifs, MiCaM builds a connection-aware generator, which simultaneously picks up motifs and determines how they are connected. We test our method on distribution-learning benchmarks (i.e., generating novel molecules to resemble the distribution of a given training set) and goal-directed benchmarks (i.e., generating molecules with target properties), and achieve significant improvements over previous fragment-based baselines. Furthermore, we demonstrate that our method can effectively mine domain-specific motifs for different tasks.

GANet: Graph-Aware Network for Point Cloud Completion with Displacement-Aware Point Augmentor

Hongyu Yan,Haoxi Ran,Li Lu

Remarkably, real-world data (e.g., LiDAR-based point clouds) is commonly sparse, uneven, occluded, and truncated. The point cloud completion task draws due attention, which aims to predict a complete and accurate shape from its partial observation. However, existing methods commonly adopt PointNet or PointNet++ to extract features of incomplete point clouds. In this paper, we propose an end-to-end Graph-Aware Network (\textbf{GANet}) to effectively learn from the contour information of the partial point clouds. Moreover, we design Displacements-Aware Augmentor (DPA) to upsample and refine coarse point clouds. With our graph-based feature extractors and Displacements-Aware Transformer, our DPA can precisely capture the geometric and structural features to refine the complete point clouds. Experiments on PCN and MVP datasets demonstrate that our GANet achieves state-of-the-art on the task of shape completion.

Multiple output samples for each input in a single-output Gaussian process

Jeremy Wong,Huayun Zhang,Nancy F. Chen

The standard Gaussian Process (GP) is formulated to only consider a single output sample for each input in the training set. Datasets for subjective tasks, such as spoken language assessment, may be annotated with output labels from multiple human raters for each input. This paper proposes to generalise the GP to allow for multiple output samples per input in the training set. This differs from a multi-output GP, because all output samples are from the same task here. The output density function is formulated to be the joint likelihood of observing all output samples. Through this, the hyper-parameters are optimised using a criterion that is similar to minimising a Kullback-Leibler divergence. The test set predictions are inferred fairly similarly to a standard GP, with a key difference being in the optimised hyper-parameters. This approach is evaluated on spoken language assessment tasks, using the public speechocean762 dataset and an internal Tamil language dataset. The results show that by using the proposed method, the GP is able to compute a test set output distribution that is more similar to the collection of reference outputs annotated by multiple human raters.

Demystifying the Optimization and Generalization of Deep PAC-Bayesian Learning

Wei Huang,Chunrui Liu,Yilan Chen,Richard Yi Da Xu,Miao Zhang,Tsui-Wei Weng

In addition to being a successful generalization bound analysis tool, the PAC-Bayesian bound can also be incorporated into an objective function to train a probabilistic neural network, which we refer to simply as {\it PAC-Bayesian Learning}. PAC-Bayesian learning has been proven to be able to achieve a competitive expected test set error numerically, while providing a tight generalization bound in practice, through gradient descent training. Despite its empirical success, the theoretical analysis of deep PAC-Bayesian learning for neural networks is rarely explored. To this end, this paper proposes a theoretical convergence and generalization analysis for PAC-Bayesian learning. For a deep and wide probabilistic neural network, we show that when PAC-Bayesian learning is applied, the convergence result corresponds to solving a kernel ridge regression when the probabilis tic neural tangent kernel (PNTK) is used as its kernel. Based on this finding, we further obtain an analytic and guaranteed PAC-Bayesian generalization bound for the first time, which is an improvement over the Rademacher complexity-based bound for deterministic neural networks. Finally, drawing insight from our theoretical results, we propose a proxy measure for efficient hyperparameter selection, which is proven to be time-saving on various benchmarks.

Revisiting the Entropy Semiring for Neural Speech Recognition

Oscar Chang,Dongseong Hwang,Olivier Siohan

In streaming settings, speech recognition models have to map sub-sequences of speech to text before the full audio stream becomes available. However, since alignment information between speech and text is rarely available during training, models need to learn it in a completely self-supervised way. In practice, the exponential number of possible alignments makes this extremely challenging, with models often learning peaky or sub-optimal alignments. Prima facie, the exponential nature of the alignment space makes it difficult to even quantify the uncertainty of a model's alignment distribution. Fortunately, it has been known for decades that the entropy of a probabilistic finite state transducer can be computed in time linear to the size of the transducer via a dynamic programming reduction based on semirings. In this work, we revisit the entropy semiring for neural speech recognition models, and show how alignment entropy can be used to supervise models through regularization or distillation. We also contribute an open-source implementation of CTC and RNN-T in the semiring framework that includes numerically stable and highly parallel variants of the entropy semiring. Empirically, we observe that the addition of alignment distillation improves the accuracy and latency of an already well-optimized teacher-student distillation model, achieving state-of-the-art performance on the Librispeech dataset in the streaming scenario.

Rethinking skip connection model as a learnable Markov chain

Chen Dengsheng,Jie Hu,Wenwen Qiang,Xiaoming Wei,Enhua Wu

Over the past few years afterward the birth of ResNet, skip connection has become the defacto standard for the design of modern architectures due to its widespread adoption, easy optimization, and proven performance.

Prior work has explained the effectiveness of the skip connection mechanism from different perspectives.

In this work, we deep dive into the model's behaviors with skip connections which can be formulated as a learnable Markov chain.

An efficient Markov chain is preferred as it always maps the input data to the target domain in a better way.

However, while a model is explained as a Markov chain, it is not guaranteed to be optimized following an efficient Markov chain by existing SGD-based optimizers prone to getting trapped in local optimal points.

In order to move towards a more efficient Markov chain, we propose a simple routine of penal connection to make any residual-like model become a learnable Markov chain.

Aside from that, the penal connection can also be viewed as a particular model regularization and can be easily implemented with one line of code in the most popular deep learning frameworks.

The encouraging experimental results in multi-modal translation and image recognition empirically confirm our conjecture of the learnable Markov chain view and demonstrate the superiority of the proposed penal connection.

Activation Function: Absolute Function,One Function Behaves more Individualized

Jinxin Wei,Zhe Hou

Inspire by nature world mode, a activation function is proposed. It is absolute function.Through test on mnist dataset and fully-connected neural network and convolutional neural network, some conclusions are put forward. The line of accuracy of absolute function is a little shaken that is different from the line of accuracy of relu and leaky relu. The absolute function can keep the negative parts as equal as the positive parts, so the individualization is more active than relu and leaky relu function. The absolute function is less likely to be over-fitting. Through test on mnist and autoencoder, It is that the leaky relu function can do classification task well, while the absolute function can do generation task well. Because the classification task need more universality and generation task need more individualization. The pleasure irritation and painful irritation is not only the magnitude differences, but also the sign differences, so the negative parts should keep as a part. Stimulation which happens frequently is low value, it is showed around zero in figure 1 . Stimulation which happens accidentally is high value, it is showed far away from zero in figure 1. So the high value is the big stimulation, which is individualization.

Measuring axiomatic soundness of counterfactual image models

Miguel Monteiro,Fabio De Sousa Ribeiro,Nick Pawlowski,Daniel C. Castro,Ben Glocker

We present a general framework for evaluating image counterfactuals. The power and flexibility of deep generative models make them valuable tools for learning mechanisms in structural causal models. However, their flexibility makes counterfactual identifiability impossible in the general case.

Motivated by these issues, we revisit Pearl's axiomatic definition of counterfactuals to determine the necessary constraints of any counterfactual inference model: composition, reversibility, and effectiveness. We frame counterfactuals as functions of an input variable, its parents, and counterfactual parents and use the axiomatic constraints to restrict the set of functions that could represent the counterfactual, thus deriving distance metrics between the approximate and ideal functions. We demonstrate how these metrics can be used to compare and choose between different approximate counterfactual inference models and to provide insight into a model's shortcomings and trade-offs.

Alternating Differentiation for Optimization Layers

Haixiang Sun,Ye Shi,Jingya Wang,Hoang Duong Tuan,H. Vincent Poor,Dacheng Tao

The idea of embedding optimization problems into deep neural networks as optimization layers to encode constraints and inductive priors has taken hold in recent years. Most existing methods focus on implicitly differentiating Karush–Kuhn–Tucker (KKT) conditions in a way that requires expensive computations on the Jacobian matrix, which can be slow and memory-intensive. In this paper, we developed a new framework, named Alternating Differentiation (Alt-Diff), that differentiates optimization problems (here, specifically in the form of convex optimization problems with polyhedral constraints) in a fast and recursive way. Alt-Diff decouples the differentiation procedure into a primal update and a dual update in an alternating way. Accordingly, Alt-Diff substantially decreases the dimensions of the Jacobian matrix especially for optimization with large-scale constraints and thus increases the computational speed of implicit differentiation. We show that the gradients obtained by Alt-Diff are consistent with those obtained by differentiating KKT conditions. In addition, we propose to truncate Alt-Diff to further accelerate the computational speed. Under some standard assumptions, we show that the truncation error of gradients is upper bounded by the same order of variables' estimation error. Therefore, Alt-Diff can be truncated to further increase computational speed without sacrificing much accuracy. A series of comprehensive experiments validate the superiority of Alt-Diff.

Out-of-distribution Detection with Implicit Outlier Transformation

Qizhou Wang,Junjie Ye,Feng Liu,Quanyu Dai,Marcus Kalander,Tongliang Liu,Jianye HAO,Bo Han

Outlier exposure (OE) is powerful in out-of-distribution (OOD) detection, enhancing detection capability via model fine-tuning with surrogate OOD data. However, surrogate data typically deviate from test OOD data. Thus, the performance of OE when facing unseen OOD data, can be weaken. To address this issue, we propose a novel OE-based approach that makes the model perform well for unseen OOD situations, even for unseen OOD cases. It leads to a min-max learning scheme---search ing to synthesize OOD data that leads to worst judgments and learning from such OOD data for the uniform performance in OOD detection. In our realization, these worst OOD data are synthesized by transforming original surrogate ones, where the associated transform functions are learned implicitly based on our novel insight that model perturbation leads to data transformation. Our methodology offers an efficient way of synthesizing OOD data, which can further benefit the detection model, besides the surrogate OOD data. We conduct extensive experiments under various OOD detection setups, demonstrating the effectiveness of our method against its advanced counterparts.

****

Parameter Averaging for Feature Ranking

Talip Ucar,Ehsan Hajiramezanali

Neural Networks are known to be sensitive to initialisation. The methods that rely on neural networks for feature ranking are not robust since they can have variations in their ranking when the model is initialized and trained with different random seeds. In this work, we introduce a novel method based on parameter averaging to estimate accurate and robust feature importance in tabular data setting, referred as XTab. We first initialize and train multiple instances of a shallow network (referred as local masks) with "different random seeds" for a downstream task. We then obtain a global mask model by "averaging the parameters" of local masks. We show that although the parameter averaging might result in a global model with higher loss, it still leads to the discovery of the ground-truth feature importance more consistently than an individual model does. We conduct extensive experiments on a variety of synthetic and real-world data, demonstrating that the XTab can be used to obtain the global feature importance that is not sensitive to sub-optimal model initialisation.

Gradient Estimation for Unseen Domain Risk Minimization with Pre-Trained Models

Byounggyu Lew,Donghyun Son,Buru Chang

Domain generalization aims to build generalized models that perform well on unseen domains when only source domains are available for model optimization. Recent studies have demonstrated that large-scale pre-trained models could play an important role in domain generalization by providing their generalization power. However, large-scale pre-trained models are not fully equipped with target task-specific knowledge due to a discrepancy between the pre-training objective and the target task. Although the task-specific knowledge could be learned from source domains by fine-tuning, this hurts the generalization power of the pre-trained models because of gradient bias toward the source domains. To address this issue, we propose a new domain generalization method that estimates unobservable gradients that reduce potential risks in unseen domains, using a large-scale pre-trained model. Our proposed method allows the pre-trained model to learn task-specific knowledge further while preserving its generalization ability with the estimated gradients. Experimental results show that our proposed method outperforms baseline methods on DomainBed, a standard benchmark in domain generalization. We also provide extensive analyses to demonstrate that the estimated unobserved gradients relieve the gradient bias, and the pre-trained model learns the task-specific knowledge without sacrificing its generalization power.

Nearing or Surpassing: Overall Evaluation of Human-Machine Dynamic Vision Ability

Shiyu Hu,Xin Zhao,Yipei Wang,Yanhu Shan,Kaiqi Huang

Dynamic visual ability (DVA), a fundamental function of the human visual system, has been successfully modeled by many computer vision tasks in recent decades. However, the prosperity developments mainly concentrate on using deep neural networks (DNN) to simulate the human DVA system, but evaluation systems still simply compare performance between machines, making it tough to determine how far the gap is between humans and machines in dynamic vision tasks. In fact, neglecting this issue not only makes it hard to determine the correctness of current research routes, but also cannot truly measure the DVA intelligence of machines. To answer the question, this work designs a comprehensive evaluation system based on the 3E paradigm -- we carefully pick 87 videos from various dimensions to construct the environment, confirming it can cover both perceptual and cognitive components of DVA; select 20 representative machines and 15 human subjects to form the task executors, ensuring that different model structures can help us observe the effectiveness of research development; and finally quantify their DVA with a strict evaluation process. Based on detailed experimental analyses, we first determine that the current algorithm research route has effectively shortened the gap. Besides, we further summarize the weaknesses of different executors, and design a human-machine cooperation mechanism with superhuman performance. In summary, the contributions include: (1) Quantifying the DVA of humans and machines, (2) proposing a new view to evaluate DVA intelligence based on the human-machine comparison, and (3) providing a possibility of human-machine cooperation. The datasets, toolkits, codes, and evaluation metrics will be open-sourced to help researchers develop intelligent research on dynamic vision tasks.

Extracting Robust Models with Uncertain Examples

Guanlin Li,Guowen Xu,Shangwei Guo,Han Qiu,Jiwei Li,Tianwei Zhang

Model extraction attacks are proven to be a severe privacy threat to Machine Learning as a Service (MLaaS). A variety of techniques have been designed to steal a remote machine learning model with high accuracy and fidelity. However, how to extract a robust model with similar resilience against adversarial attacks is never investigated. This paper presents the first study toward this goal. We first analyze those existing extraction solutions either fail to maintain the model accuracy or model robustness or lead to the robust overfitting issue. Then we propose Boundary Entropy Searching Thief (BEST), a novel model extraction attack to achieve both accuracy and robustness extraction under restricted attack budgets. BEST generates a new kind of uncertain examples for querying and reconstructing the victim model. These samples have uniform confidence scores across different classes, which can perfectly balance the trade-off between model accuracy and robustness. Extensive experiments demonstrate that BEST outperforms existing attack methods over different datasets and model architectures under limited data. It can also effectively invalidate state-of-the-art extraction defenses.

Neural Groundplans: Persistent Neural Scene Representations from a Single Image

Prafull Sharma,Ayush Tewari,Yilun Du,Sergey Zakharov,Rares Andrei Ambrus,Adrien Gaidon,William T. Freeman,Fredo Durand,Joshua B. Tenenbaum,Vincent Sitzmann

We present a method to map 2D image observations of a scene to a persistent 3D scene representation, enabling novel view synthesis and disentangled representation of the movable and immovable components of the scene. Motivated by the bird’s-eye-view (BEV) representation commonly used in vision and robotics, we propose conditional neural groundplans, ground-aligned 2D feature grids, as persistent and memory-efficient scene representations. Our method is trained self-supervised from unlabeled multi-view observations using differentiable rendering, and learns to complete geometry and appearance of occluded regions. In addition, we show that we can leverage multi-view videos at training time to learn to separately reconstruct static and movable components of the scene from a single image at test time. The ability to separately reconstruct movable objects enables a variety of downstream tasks using simple heuristics, such as extraction of object-centric 3D representations, novel view synthesis, instance-level segmentation, 3D bounding box prediction, and scene editing. This highlights the value of neural groundplans as a backbone for efficient 3D scene understanding models.

****

Semi-supervised Counting via Pixel-by-pixel Density Distribution Modelling

Hui LIN,Zhiheng Ma,Rongrong Ji,Yaowei Wang,su zhou,Xiaopeng Hong

This paper focuses on semi-supervised crowd counting, where only a small portion of the training data are labeled. We formulate the pixel-wise density value to regress as a probability distribution, instead of a single deterministic value, and utilize a dual-branch structure to model the corresponding discrete form of the distribution function. On the basis, we propose a semi-supervised crowd counting model. Firstly, we enhance the transformer decoder by usingdensity tokens t o specialize the forwards of decoders w.r.t. different density intervals; Secondly, we design a pixel-wise distribution matching loss to measure the differences in the pixel-wise density distributions between the prediction and the ground-truth; Thirdly, we propose an interleaving consistency regularization term to align the prediction of two branches and make them consistent. Extensive experiments on four datasets are performed to show that our method clearly outperforms the competitors by a large margin under various labeled ratio settings.

Understanding Self-Supervised Pretraining with Part-Aware Representation Learning

Jiyang Qi,Jie Zhu,Mingyu Ding,Xiaokang Chen,Ping Luo,Leye Wang,Xinggang Wang,Wenyu Liu,Jingdong Wang

In this paper, we are interested in understanding self-supervised pretraining through studying the capability that self-supervised representation pretraining methods learn part-aware representations. The study is mainly motivated by that random views, used in contrastive learning, and random masked (visible) patches, used in masked image modeling, are often about object parts.

We explain that masked image modeling is a part-to-part task: the masked patches of the object are hallucinated from the visible patches, and that contrastive learning is a part-to-whole task: the projection layer hallucinates the whole object representation from the object part representation learned from the encoder. The explanation suggests that the self-supervised pretrained encoder is required to understand the object part. We empirically compare the off-the-shelf encoders pretrained with several representative methods on object-level recognition and part-level recognition. The results show that the fully-supervised model outperforms self-supervised models for object-level recognition, and most self-supervised contrastive learning and masked image modeling methods outperform the fully-supervised method for part-level recognition. It is observed that the combination of contrastive learning and masked image modeling further improves the performance.

****

E-CRF: Embedded Conditional Random Field for Boundary-caused Class Weights Confusion in Semantic Segmentation

Jie Zhu,Huabin Huang,Banghuai Li,Leye Wang

Modern semantic segmentation methods devote much effect to adjusting image feature representations to improve the segmentation performance in various ways, such as architecture design, attention mechnism, etc. However, almost all those methods neglect the particularity of class weights (in the classification layer) in segmentation models. In this paper, we notice that the class weights of categories that tend to share many adjacent boundary pixels lack discrimination, thereby limiting the performance. We call this issue Boundary-caused Class Weights Confusion (BCWC). We try to focus on this problem and propose a novel method named Embedded Conditional Random Field (E-CRF) to alleviate it. E-CRF innovatively fuses the CRF into the CNN network as an organic whole for more effective end-to-end optimization. The reasons are two folds. It utilizes CRF to guide the message passing between pixels in high-level features to purify the feature representation of boundary pixels, with the help of inner pixels belonging to the same object. More importantly, it enables optimizing class weights from both scale and direction during backpropagation. We make detailed theoretical analysis to prove it. Besides, superpixel is integrated into E-CRF and served as an auxiliary to exploit the local object prior for more reliable message passing. Finally, our proposed method yields impressive results on ADE20K, Cityscapes, and Pascal Context datasets.

Sample Complexity of Nonparametric Off-Policy Evaluation on Low-Dimensional Manifolds using Deep Networks

Xiang Ji,Minshuo Chen,Mengdi Wang,Tuo Zhao

We consider the off-policy evaluation problem of reinforcement learning using deep convolutional neural networks. We analyze the deep fitted Q-evaluation method for estimating the expected cumulative reward of a target policy, when the data are generated from an unknown behavior policy. We show that, by choosing network size appropriately, one can leverage any low-dimensional manifold structure in the Markov decision process and obtain a sample-efficient estimator without suffering from the curse of high data ambient dimensionality. Specifically, we establish a sharp error bound for fitted Q-evaluation, which depends on the intrinsic dimension of the state-action space, the smoothness of Bellman operator, and a function class-restricted χ^2-divergence. It is noteworthy that the restricted χ^2-divergence measures the behavior and target policies' {\it mismatch in the function space}, which can be small even if the two policies are not close to each other in their tabular forms. We also develop a novel approximation result for convolutional neural networks in Q-function estimation. Numerical experiments are provided to support our theoretical analysis.

Stochastic Differentially Private and Fair Learning
Andrew Lowy,Devansh Gupta,Meisam Razaviyayn
Machine learning models are increasingly used in high-stakes decision-making systems. In such applications, a major concern is that these models sometimes discriminate against certain demographic groups such as individuals with certain race, gender, or age. Another major concern in these applications is the violation of the privacy of users. While fair learning algorithms have been developed to mitigate discrimination issues, these algorithms can still leak sensitive information, such as individuals’ health or financial records. Utilizing the notion of differential privacy (DP), prior works aimed at developing learning algorithms that are both private and fair. However, existing algorithms for DP fair learning are either not guaranteed to converge or require full batch of data in each iteration of the algorithm to converge. In this paper, we provide the first stochastic differentially private algorithm for fair learning that is guaranteed to converge. Here, the term “stochastic" refers to the fact that our proposed algorithm converges even when minibatches of data are used at each iteration (i.e. stochastic optimization). Our framework is flexible enough to permit different fairness notions, including demographic parity and equalized odds. In addition, our algorithm can be applied to non-binary classification tasks with multiple (non-binary) sensitive attributes. As a byproduct of our convergence analysis, we provide the first utility guarantee for a DP algorithm for solving nonconvex-strongly concave min-max problems. Our numerical experiments show that the proposed algorithm consistently offers significant performance gains over the state-of-the-art baselines, and can be applied to larger scale problems with non-binary target/sensitive attributes.

****

CLIP-FLOW: CONTRASTIVE LEARNING WITH ITERATIVE PSEUDO LABELING FOR OPTICAL FLOW
Zhiqi Zhang,Nitin Bansal,Changjiang Cai,Pan Ji,Qingan Yan,Xiangyu Xu,Yi Xu
Synthetic datasets are often used to pretrain end-to-end optical flow networks, due to the lack of a large amount of labeled, real scene data. But major drops in accuracy occur when moving from synthetic to real scenes. How do we better transfer the knowledge learned from synthetic to real domains? To this end, we propose CLIP-Flow, a semi-supervised iterative pseudo labeling framework to transfer the pretraining knowledge to the target real domain. We leverage large-scale, unlabeled real data to facilitate transfer learning with the supervision of iteratively updated pseudo ground truth labels, bridging the domain gap between the synthetic and the real. In addition, we propose a contrastive flow loss on reference features and the warped features by pseudo ground truth flows, to further boost the accurate matching and dampen the mismatching due to motion, occlusion, or noisy pseudo labels. We adopt RAFT as the backbone and obtain an F1-all error of 4.11%, i.e., a 19% error reduction from RAFT (5.10%) and ranking 2nd place at submission on KITTI 2015 benchmark. Our framework can also be extended to other models, e.g., CRAFT, reducing the F1-all error from 4.79% to 4.66% on KITTI 2015 benchmark.

****

CAN: A simple, efficient and scalable contrastive masked autoencoder framework f or learning visual representations

Shlok Kumar Mishra,Joshua David Robinson,Huiwen Chang,David Jacobs,Weicheng Kuo,Aaron Sarna,Aaron Maschinot,Dilip Krishnan

We introduce CAN, a simple, efficient and scalable method for self-supervised learning of visual representations. Our framework is a minimal and conceptually clean synthesis of (C) contrastive learning, (A) masked autoencoders, and (N) the noise prediction approach used in diffusion models. The learning mechanisms are \emph{complementary} to one another: contrastive learning shapes the embedding space across a batch of image samples; masked autoencoders focus on reconstruction of the low-frequency spatial correlations in a single image sample; and noise prediction encourages the reconstruction of the high-frequency components of an image. The combined approach results in a robust, scalable and simple-to-implement algorithm. The training process is symmetric, with 50% of patches in \emph{both views} being masked at random, yielding a considerable efficiency improvement over prior contrastive learning methods. Extensive empirical studies on linear evaluation, finetuning, transfer learning, and robustness demonstrate that our approach achieves strong downstream performance. For instance, when pre-training ViT-B encoders on the curated ImageNet dataset, CAN achieves 74.8% top-1 linear probing accuracy, an absolute improvement of 6.8% over MAE and 1.3% over SimCLR with the same architecture and data augmentations. CAN is especially useful for pre-training on larger uncurated datasets such as JFT-300M: the finetuned performance on ImageNet of our ViT-L model is 85.9%, compared to 85.0% for SimCLR, and 85.4% for MAE. For linear probe on ImageNet, CAN achieves 75.4% compared to 71.8% for SimCLR and 64.1% for MAE. The overall FLOPs load is 41% \emph{lower} than SimCLR\footnote{Our code will be released at \url{www.xxx.yyy}.}.

On The Inadequacy of Optimizing Alignment and Uniformity in Contrastive Learning of Sentence Representations

Zhijie Nie,Richong Zhang,Yongyi Mao

Contrastive learning is widely used in areas such as visual representation learning (VRL) and sentence representation learning (SRL). Considering the differences between VRL and SRL in terms of negative sample size and evaluation focus, we believe that the solid findings obtained in VRL may not be entirely carried over to SRL. In this work, we consider the suitability of the decoupled form of contrastive loss, i.e., alignment and uniformity, in SRL. We find a performance gap between sentence representations obtained by jointly optimizing alignment and uniformity on the STS task and those obtained using contrastive loss. Further, we find that the joint optimization of alignment and uniformity during training is prone to overfitting, which does not occur on the contrastive loss. Analyzing them based on the variation of the gradient norms, we find that there is a property of ``gradient dissipation'' in contrastive loss and believe that it is the key to preventing overfitting. We simulate similar "gradient dissipation" of contrastive loss on four optimization objectives of two forms, and achieve the same or even better performance than contrastive loss on the STS tasks, confirming our hypothesis.

****

Bidirectional Learning for Offline Model-based Biological Sequence Design

Can Chen,Yingxue Zhang,Xue Liu,Mark Coates

Offline model-based optimization aims to maximize a black-box objective function with a static dataset of designs and their scores. In this paper, we focus on biological sequence design to maximize some sequence score. A recent approach employs bidirectional learning, combining a forward mapping for exploitation and a backward mapping for constraint, and it relies on the neural tangent kernel (NTK) of an infinitely wide network to build a proxy model. Though effective, the NTK cannot learn features because of its parametrization, and its use prevents the incorporation of powerful pre-trained Language Models (LMs) that can capture the rich biophysical information in millions of biological sequences. We adopt an alternative proxy model, adding a linear head to a pre-trained LM, and propose a linearization scheme. This yields a closed-form loss and also takes into accoun t the biophysical information in the pre-trained LM. In addition, the forward mapping and the backward mapping play different roles and thus deserve different weights during sequence optimization. To achieve this, we train an auxiliary model and leverage its weak supervision signal via a bi-level optimization framework to effectively learn how to balance the two mappings. Further, by extending the framework, we develop the first learning rate adaptation module Adaptive-η, which is compatible with all gradient-based algorithms for offline model-based optimization. Experimental results on DNA/protein sequence design tasks verify the effectiveness of our algorithm. Our code is available https://anonymous.4open.science/r/BIB-ICLR2023-Submission/README.md.

Neural Collapse Inspired Feature-Classifier Alignment for Few-Shot Class-Incremental Learning

Yibo Yang,Haobo Yuan,Xiangtai Li,Zhouchen Lin,Philip Torr,Dacheng Tao

Few-shot class-incremental learning (FSCIL) has been a challenging problem as only a few training samples are accessible for each novel class in the new sessions. Finetuning the backbone or adjusting the classifier prototypes trained in the prior sessions would inevitably cause a misalignment between the feature and classifier of old classes, which explains the well-known catastrophic forgetting problem. In this paper, we deal with this misalignment dilemma in FSCIL inspired by the recently discovered phenomenon named neural collapse, which reveals that the last-layer features of the same class will collapse into a vertex, and the vertices of all classes are aligned with the classifier prototypes, which are formed as a simplex equiangular tight frame (ETF). It corresponds to an optimal geometric structure for classification due to the maximized Fisher Discriminant Ratio. We propose a neural collapse inspired framework for FSCIL. A group of classifier prototypes are pre-assigned as a simplex ETF for the whole label space, including the base session and all the incremental sessions. During training, the classifier prototypes are not learnable, and we adopt a novel loss function that drives the features into their corresponding prototypes. Theoretical analysis shows that our method holds the neural collapse optimality and does not break the feature-classifier alignment in an incremental fashion. Experiments on the miniImageNet, CUB-200, and CIFAR-100 datasets demonstrate that our proposed framework outperforms the state-of-the-art performances. Code address: https://github.com/NeuralCollapseApplications/FSCIL

Self-conditioned Embedding Diffusion for Text Generation

Robin Strudel,Corentin Tallec,Florent Altché,Yilun Du,Yaroslav Ganin,Arthur Mensch,Will Sussman Grathwohl,Nikolay Savinov,Sander Dieleman,Laurent Sifre,Rémi Leblond

Can continuous diffusion models bring the same performance breakthrough on natural language they did for image generation? To circumvent the discrete nature of text data, we can simply project tokens in a continuous space of embeddings, as is standard in language modeling. We propose Self-conditioned Embedding Diffusion (SED), a continuous diffusion mechanism that operates on token embeddings and allows to learn flexible and scalable diffusion models for both conditional and unconditional text generation. Through qualitative and quantitative evaluation, we show that our text diffusion models generate samples comparable with those produced by standard autoregressive language models — while being in theory more efficient on accelerator hardware at inference time. Our work paves the way for scaling up diffusion models for text, similarly to autoregressive models, and for improving performance with recent refinements to continuous diffusion.

Decoupling Concept Bottleneck Model

Rui Zhang,Xingbo Du,Junchi Yan,Shihua Zhang

Concept Bottleneck Model (CBM) is a kind of powerful interpretable neural network, which utilizes high-level concepts to explain model decisions and interact with humans. However, CBM cannot always work as expected due to the troublesome collection and commonplace insufficiency of high-level concepts in real-world scenarios. In this paper, we theoretically reveal that insufficient concept informat ion will induce the mixture of explicit and implicit information, which further leads to the inherent dilemma of concept and label distortions in CBM. Motivated by the proposed theorem, we present Decoupling Concept Bottleneck Model (DCBM), a novel concept-based model decoupling heterogeneous information into explicit and implicit concepts, while still retaining high prediction performance and interpretability. Extensive experiments expose the success in the alleviation of concept/label distortions, where DCBM achieves state-of-the-art performances in both concept and label learning tasks. Especially for situations where concepts are insufficient, DCBM significantly outperforms other models based on concept bottleneck and respectively achieves error rates 24.95% and 20.09% lower than other CBMs on concept/label prediction. Moreover, to express effective human-machine interactions for DCBM, we devise two algorithms based on mutual information (MI) estimation, including forward intervention and backward rectification, which can automatically correct labels and trace back to wrong concepts. The construction of the interaction regime can be formulated as a light min-max optimization problem achieved within minutes. Multiple experiments show that such interactions can effectively promote concept/label accuracy.

AQUILA: Communication Efficient Federated Learning with Adaptive Quantization of Lazily-Aggregated Gradients

Zihao Zhao,Yuzhu Mao,Zhenpeng Shi,Muhammad Zeeshan,Yang Liu,Tian Lan,Wenbo Ding

The development and deployment of federated learning (FL) have been bottlenecked by the heavy communication overheads of high-dimensional models between the distributed device nodes and the central server. To achieve better error-communication trade-offs, recent efforts have been made to either adaptively reduce the communication frequency by skipping unimportant updates, a.k.a. lazily-aggregated quantization (LAQ), or adjust the quantization bits for each communication. In this paper, we propose a unifying communication efficient framework for FL based on adaptive quantization of lazily-aggregated gradients (AQUILA), which adaptively adjusts two mutually-dependent factors, the communication frequency, and the quantization level, in a synergistic way. Specifically, we start from a careful investigation of the classical LAQ scheme and formulate AQUILA as an optimization problem where the optimal quantization level per communication is selected by minimizing the model deviation caused by update skipping. Meanwhile, we create a new lazy aggregation strategy to fit the novel quantization criterion better and thus keep the communication frequency at an appropriate level. The effectiveness and convergence of the proposed AQUILA framework are theoretically verified. The experimental results demonstrate that AQUILA can reduce around 60% of overall transmitted bits compared to existing methods while achieving the same level of model accuracy in a number of non-homogeneous FL scenarios, including Non-IID data distribution and heterogeneous model architecture. The proposed AQUILA is highly adaptive and compatible with existing FL settings.

Generaling Multimodal Variational Methods to Sets

Jinzhao Zhou,Yiqun Duan,Zhihong Chen,Yu-Cheng Chang,Chin-teng Lin

Making sense of multiple modalities can yield a more comprehensive description of real-world phenomena. However, learning the co-representation of diverse modalities is still a long-standing endeavor in emerging machine learning applications and research. Previous generative approaches for multimodal input approximate a joint-modality posterior by uni-modality posteriors as product-of-experts (PoE) or mixture-of-experts (MoE). We argue that these approximations lead to a defective bound for the optimization process and loss of semantic connection among modalities. This paper presents a novel variational method on sets called the Set Multimodal VAE (SMVAE) for learning a multimodal latent space while handling the missing modality problem. By modeling the joint-modality posterior distribution directly, the proposed SMVAE learns to exchange information between multiple modalities and compensate for the drawbacks caused by factorization. In public datasets of various domains, the experimental results demonstrate that the proposed method is applicable to order-agnostic cross-modal generation while achieving outstanding performance compared to the state-of-the-art multimodal methods. The source code for our method is available online https://anonymous.4open.science/r/SMVAE-9B3C/.

Towards a Unified View on Visual Parameter-Efficient Transfer Learning

Bruce Yu,Jianlong Chang,Lingbo Liu,Qi Tian,Chang Wen Chen

Since the release of various large-scale natural language processing (NLP) pre-trained models, parameter efficient transfer learning (PETL) has become a popular paradigm capable of achieving impressive performance on various downstream tasks. PETL aims at making good use of the representation knowledge in the pre-trained large models by fine-tuning a small number of parameters. Recently, it has also attracted increasing attention to developing various PETL techniques for vision tasks. Popular PETL techniques such as Prompt Tuning and Adapter have been proposed for high-level visual downstream tasks such as image classification and video recognition. However, Prefix-tuning remains under-explored for vision tasks. In this work, we intend to adapt large video-based models to downstream tasks with a good parameter-accuracy trade-off. Towards this goal, we propose a framework with a unified view of PETL called visual-PETL (V-PETL) to investigate the effects of different PETL techniques, data scales of downstream domains, positions of trainable parameters, and other aspects affecting the trade-off.

Specifically, we analyze the positional importance of trainable parameters and the differences between NLP and vision tasks in terms of data structures and pre-training mechanisms while implementing various PETL techniques, especially for the under-explored prefix-tuning technique. Based on a comprehensive understanding of the differences between NLP and video data, we propose a new variation of prefix-tuning module called parallel attention (PATT) for video-based downstream tasks.

An extensive empirical analysis on two video datasets via different frozen backbones has been carried and the findings show that the proposed PATT can effectively contribute to other PETL techniques. An effective scheme Swin-BAPAT derived from the proposed V-PETL framework achieves significantly better performance than the state-of-the-art AdaptFormer-Swin with slightly more parameters and outperforms full-tuning with far less parameters.

Everyone's Preference Changes Differently: Weighted Multi-Interest Retrieval Model

Hui Shi,Yupeng Gu,Yitong Zhou,Bo Zhao,Sicun Gao,Jishen Zhao

User embeddings (vectorized representations of a user) are essential in recommendation systems. Numerous approaches have been proposed to construct a representation for the user in order to find similar items for retrieval tasks, and they have been proven effective in industrial recommendation systems. Recently people have discovered the power of using multiple embeddings to represent a user, with the hope that each embedding represents the user's interest in a certain topic. With multi-interest representation, it's important to model the user's preference over the different topics and how the preference change with time. However, existing approaches either fail to estimate the user's affinity to each interest or unreasonably assume every interest of every user fades with an equal rate with time, thus hurting the performance of candidate retrieval. In this paper, we propose the Multi-Interest Preference (MIP) model, an approach that not only produces multi-interest for users by using the user's sequential engagement more effectively but also automatically learns a set of weights to represent the preference over each embedding so that the candidates can be retrieved from each interest proportionally. Extensive experiments have been done on various industrial-scale datasets to demonstrate the effectiveness of our approach.

Variational Autoencoders with Decremental Information Bottleneck for Disentanglement

Jiantao Wu,Shentong Mo,Muhammad Awais,Sara Atito,xingshen zhang,Lin Wang,Xiang Yang

One major challenge of disentanglement learning with variational autoencoders is

the trade-off between disentanglement and reconstruction fidelity. Previous methods, spreading the conflict of disentanglement and reconstruction in time, will lose the constraint of disentanglement when expanding the information bottleneck, which causes the information diffusion problem. To tackle this issue, we present a novel decremental variational autoencoder with disentanglement-invariant transformations to spread the conflict on multiple latent spaces, termed DeVAE, for balancing disentanglement and reconstruction fidelity by decreasing the information bottleneck of diverse latent spaces gradually. Benefiting from the multiple latent spaces, DeVAE allows simultaneous optimization of multiple objectives to optimize reconstruction while keeping the constraint of disentanglement, avoiding information diffusion. DeVAE is also compatible with large models with high-dimension latent space. Experimental results on dSprites and Shapes3D that DeVAE achieves the best performance on both disentanglement and reconstruction.

Volumetric Optimal Transportation by Fast Fourier Transform
Na Lei,DONGSHENG An,Min Zhang,Xiaoyin Xu,David Gu
The optimal transportation map finds the most economical way to transport one probability measure to another, and it has been applied in a broad range of applications in machine learning and computer vision. By the Brenier theory, computing the optimal transport map is equivalent to solving a Monge-Amp\`ere equation, which is highly non-linear. Therefore, the computation of optimal transportation maps is intrinsically challenging.

In this work, we propose a novel and powerful method, the FFT-OT (fast Fourier transform-optimal transport), to compute the 3-dimensional OT problems. The method is based on several key ideas: first, the Monge-Amp\`ere equation is linearized to a sequence of linear elliptic PDEs with spacial and temporal variant coefficients; second, the obliqueness property of optimal transportation maps is reformulated as a Neumann boundary condition; and third, the variant coefficient elliptic PDEs are approximated by constant coefficient elliptic PDEs and solved by FFT on GPUs. We also prove that the algorithm converges linearly, namely the approximation error decreases exponentially fast. Experimental results show that the FFT-OT algorithm is more than a hundred times faster than the conventional methods based on the convex geometry. Furthermore, the method can be directly applied for sampling from complex 3D density functions in machine learning and magnifying the volumetric data in medical imaging.

GFlowNets and variational inference
Nikolay Malkin,Salem Lahlou,Tristan Deleu,Xu Ji,Edward J Hu,Katie E Everett,Dinghuai Zhang,Yoshua Bengio
This paper builds bridges between two families of probabilistic algorithms: (hierarchical) variational inference (VI), which is typically used to model distributions over continuous spaces, and generative flow networks (GFlowNets), which have been used for distributions over discrete structures such as graphs. We demonstrate that, in certain cases, VI algorithms are equivalent to special cases of GFlowNets in the sense of equality of expected gradients of their learning objectives. We then point out the differences between the two families and show how these differences emerge experimentally. Notably, GFlowNets, which borrow ideas from reinforcement learning, are more amenable than VI to off-policy training without the cost of high gradient variance induced by importance sampling. We argue that this property of GFlowNets can provide advantages for capturing diversity in multimodal target distributions. Code: https://github.com/GFNOrg/GFN_vs_HVI.

Neural Networks and the Chomsky Hierarchy
Gregoire Deletang,Anian Ruoss,Jordi Grau-Moya,Tim Genewein,Li Kevin Wenliang,Elliot Catt,Chris Cundy,Marcus Hutter,Shane Legg,Joel Veness,Pedro A Ortega
Reliable generalization lies at the heart of safe ML and AI. However, understanding when and how neural networks generalize remains one of the most important unsolved problems in the field. In this work, we conduct an extensive empirical study (20'910 models, 15 tasks) to investigate whether insights from the theory of

computation can predict the limits of neural network generalization in practice. We demonstrate that grouping tasks according to the Chomsky hierarchy allows us to forecast whether certain architectures will be able to generalize to out-of-distribution inputs. This includes negative results where even extensive amounts of data and training time never lead to any non-trivial generalization, despite models having sufficient capacity to fit the training data perfectly. Our results show that, for our subset of tasks, RNNs and Transformers fail to generalize on non-regular tasks, LSTMs can solve regular and counter-language tasks, and only networks augmented with structured memory (such as a stack or memory tape) can successfully generalize on context-free and context-sensitive tasks.

Neural ePDOs: Spatially Adaptive Equivariant Partial Differential Operator Based Networks

Lingshen He,Yuxuan Chen,Zhengyang Shen,Yibo Yang,Zhouchen Lin

Endowing deep learning models with symmetry priors can lead to a considerable performance improvement. As an interesting bridge between physics and deep learning, the equivariant partial differential operators (PDOs) have drawn much researchers' attention recently. However, to ensure the PDOs translation equivariance, previous works have to require coefficient matrices to be constant and spatially shared for their linearity, which could lead to the sub-optimal feature learning at each position. In this work, we propose a novel nonlinear PDOs scheme that is both spatially adaptive and translation equivariant. The coefficient matrices are obtained by local features through a generator rather than spatially shared. Besides, we establish a new theory on incorporating more equivariance like rotations for such PDOs. Based on our theoretical results, we efficiently implement the generator with an equivariant multilayer perceptron (EMLP). As such equivariant PDOs are generated by neural networks, we call them Neural ePDOs. In experiments, we show that our method can significantly improve previous works with smaller model size in various datasets. Especially, we achieve the state-of-the-art performance on the MNIST-rot dataset with only half parameters of the previous best model.

An Image is Worth One Word: Personalizing Text-to-Image Generation using Textual Inversion

Rinon Gal,Yuval Alaluf,Yuval Atzmon,Or Patashnik,Amit Haim Bermano,Gal Chechik,Daniel Cohen-or

Text-to-image models offer unprecedented freedom to guide creation through natural language. Yet, it is unclear how such freedom can be exercised to generate images of specific unique concepts, modify their appearance, or compose them in new roles and novel scenes.

In other words, we ask: how can we use language-guided models to turn *our* cat into a painting, or imagine a new product based on *our* favorite toy?

Here we present a simple approach that allows such creative freedom. Using only 3-5 images of a user-provided concept, like an object or a style, we learn to represent it through new ``words" in the embedding space of a frozen text-to-image model.

These ``words" can be composed into natural language sentences, guiding *personalized* creation in an intuitive way.

Notably, we find evidence that a *single* word embedding is sufficient for capturing unique and varied concepts.

We compare our approach to a wide range of baselines, and demonstrate that it can more faithfully portray the concepts across a range of applications and tasks. Our code, data and new words will be available.

Cutting Long Gradient Flows: Decoupling End-to-End Backpropagation Based on Supervised Contrastive Learning

Cheng-Kai Wang,Hung-Hsuan Chen

End-to-end backpropagation (BP) is the foundation of current deep learning technology. Unfortunately, as a network becomes deeper, BP becomes inefficient for various reasons. This paper proposes a new methodology for decoupling BP to transf orm a long gradient flow into multiple short ones in order to address the optimization issues caused by long gradient flows. We report thorough experiments conducted to illustrate the effectiveness of our model compared with BP and associated learning (AL), a state-of-the-art methodology for backpropagation decoupling. We will release the source code for the experiments after acceptance.

Hierarchical Relational Learning for Few-Shot Knowledge Graph Completion
Han Wu,Jie Yin,Bala Rajaratnam,Jianyuan Guo

Knowledge graphs (KGs) are powerful in terms of their inference abilities, but are also notorious for their incompleteness and long-tail distribution of relations. To address these challenges and expand the coverage of KGs, few-shot KG completion aims to make predictions for triplets involving novel relations when only a few training triplets are provided as reference. Previous methods have focused on designing local neighbor aggregators to learn entity-level information and/or imposing sequential dependency assumption at the triplet level to learn meta relation information. However, pairwise triplet-level interactions and context-level relational information have been largely overlooked for learning meta representations of few-shot relations. In this paper, we propose a hierarchical relational learning method (HiRe) for few-shot KG completion. By jointly capturing three levels of relational information (entity-level, triplet-level and context-level), HiRe can effectively learn and refine the meta representation of few-shot relations, and consequently generalize well to new unseen relations. Extensive experiments on two benchmark datasets validate the superiority of HiRe over state-of-the-art methods. The code of HiRe can be found in supplementary material and will be released after acceptance.

Learn to Know Unknowns: A Bionic Memory Network for Unsupervised Anomaly Detection
Jiahao Li,Yiqiang Chen,Yunbing Xing

Is generalization always beneficial? Over-strong generalization induces the model insensitive to anomalies. Unsupervised anomaly detection requires only unlabeled non-anomalous data to learn and generalize normal patterns, which results in a modest reconstruction error when reconstructing normal instances and a significant reconstruction error when reconstructing anomalies. However, over-strong generalization leads to the indistinguishable reconstruction error of normal instances and anomalies, which means that the model well reconstructs the unknown anomalies, resulting in unnoticeable reconstruction error. Inspired by the cascade structure of the hippocampus and cortex in human brain memory, we proposed a re-representation memory network called Random Forgetting Twin Memory (RFTM) to decompose the latent space and introduce a configurable reintegration mechanism to suppress overgeneralization. RFTM shows striking brain-like memory characteristics, which enables the model to know what it does not know. RFTM has the convenience of a single line of code boosting at the model level without adding any additional extra loss terms at the loss function level. RFTM-based models have achieved state-of-the-art experimental results on different public benchmarks.

Function-Consistent Feature Distillation
Dongyang Liu,Meina Kan,Shiguang Shan,Xilin CHEN

Feature distillation makes the student mimic the intermediate features of the teacher. Nearly all existing feature-distillation methods use L2 distance or its slight variants as the distance metric between teacher and student features. However, while L2 distance is isotropic w.r.t. all dimensions, the neural network’s operation on different dimensions is usually anisotropic, i.e., perturbations with the same 2-norm but in different dimensions of intermediate features lead to changes in the final output with largely different magnitude. Considering this, we argue that the similarity between teacher and student features should \textit{not} be measured merely based on their appearance (i.e., L2 distance), but should, more importantly, be measured by their difference in function, namely how later layers of the network will read, decode, and process them. Therefore, we pro pose Function-Consistent Feature Distillation (FCFD), which explicitly optimizes the functional similarity between teacher and student features. The core idea of FCFD is to make teacher and student features not only numerically similar, but more importantly produce similar outputs when fed to the later part of the same network. With FCFD, the student mimics the teacher more faithfully and learns more from the teacher. Extensive experiments on image classification and object detection demonstrate the superiority of FCFD to existing methods. Furthermore, we can combine FCFD with many existing methods to obtain even higher accuracy. Our codes are available at https://github.com/LiuDongyang6/FCFD.

Multi-User Reinforcement Learning with Low Rank Rewards

Dheeraj Mysore Nagaraj,Suhas S Kowshik,Praneeth Netrapalli,Naman Agarwal,Prateek Jain

In this work, we consider the problem of collaborative multi-user reinforcement learning. In this setting there are multiple users with the same state-action space and transition probabilities but with different rewards. Under the assumption that the reward matrix of the N users has a low-rank structure -- a standard and practically successful assumption in the offline collaborative filtering setting-- the question is can we design algorithms with significantly lower sample complexity compared to the ones that learn the MDP individually for each user. Our main contribution is an algorithm which explores rewards collaboratively with N user-specific MDPs and can learn rewards efficiently in two key settings: tabular MDPs and linear MDPs. When N is large and the rank is constant, the sample complexity per MDP depends logarithmically over the size of the state-space, which represents an exponential reduction (in the state-space size) when compared to the standard ``non-collaborative'' algorithms.

The Devil is in the Wrongly-classified Samples: Towards Unified Open-set Recognition

Jun CEN,Di Luan,Shiwei Zhang,Yixuan Pei,Yingya Zhang,Deli Zhao,Shaojie Shen,Qifeng Chen

Open-set Recognition (OSR) aims to identify test samples whose classes are not seen during the training process. Recently, Unified Open-set Recognition (UOSR) has been proposed to reject not only unknown samples but also known but wrongly classified samples, which tends to be more practical in real-world applications. In this paper, we deeply analyze the UOSR task under different training and evaluation settings to shed light on this promising research direction. For this purpose, we first evaluate the UOSR performance of several OSR methods and show a significant finding that the uncertainty distribution of almost all these methods is actually closer to the expectation of UOSR than OSR. We show that the reason lies in the known but wrongly classified samples, as their uncertainty distribution is extremely close to unknown samples rather than known and correctly classified samples. Second, we analyze how the two training settings of OSR (i.e., pre-training and outlier exposure) influence the UOSR. We find although they are both beneficial for distinguishing known and correctly classified samples from unknown samples, pre-training is also helpful for identifying known but wrongly classified samples while outlier exposure is not. In addition to different training settings, we also formulate a new evaluation setting for UOSR which is called few-shot UOSR, where only one or five samples per unknown class are available during evaluation to help identify unknown samples. We propose FS-KNNS for the few-shot UOSR to achieve state-of-the-art performance under all settings.

Approximated Anomalous Diffusion: Gaussian Mixture Score-based Generative Models

Hengyuan Ma,Li Zhang,Xiatian Zhu,Jianfeng Feng

Score-based generative models (SGMs) can generate high-quality samples via Langevin dynamics with a drift term and a diffusion term (Gaussian noise) iteratively calculated and added to a sample until convergence. In biological systems, it is observed that the neural population can conduct heavy-tailed L\'{e}vy dynamics for sampling-based probabilistic representation through neural fluctuations. Critically, unlike the existing sampling process of SGMs, L\'{e}vy dynamics can pr oduce both large jumps and small roaming to explore the sampling space, resulting in better sampling results than Langevin dynamics with a lacking of large jumps. Motivated by this contrast, we explore a new class of SGMs with the sampling based on the L\'{e}vy dynamics. However, exact numerical simulation of the L\'{e}vy dynamics is significantly more challenging and intractable. We hence propose an approximation solution by leveraging Gaussian mixture noises during training to achieve the desired large jumps and small roaming properties. Theoretically, GM-SGMs conduct a probabilistic graphical model used by empirical Bayes for sampling, expanding the maximum a posteriori (MAP) estimation applied by conventional SGMs. Expensive experiments on the challenging image generation tasks show that our GM-SGMs exhibit superior sampling quality over prior art SGMs across various sampling iterations.

MCAL: Minimum Cost Human-Machine Active Labeling

Hang Qiu,Krishna Chintalapudi,Ramesh Govindan

Today, ground-truth generation uses data sets annotated by cloud-based annotation services. These services rely on human annotation, which can be prohibitively expensive. In this paper, we consider the problem of hybrid human-machine labeling, which trains a classifier to accurately auto-label part of the data set. However, training the classifier can be expensive too. We propose an iterative approach that minimizes total overall cost by, at each step, jointly determining which samples to label using humans and which to label using the trained classifier. We validate our approach on well known public data sets such as Fashion-MNIST, CIFAR-10, CIFAR-100, and ImageNet. In some cases, our approach has 6× lower overall cost relative to human labeling the entire data set, and is always cheaper than the cheapest competing strategy.

****

SegNeRF: 3D Part Segmentation with Neural Radiance Fields

Jesus Zarzar,Sara Rojas Martinez,Silvio Giancola,Bernard Ghanem

Recent advances in Neural Radiance Fields (NeRF) boast impressive performances for generative tasks such as novel view synthesis and 3D reconstruction. Methods based on neural radiance fields are able to represent the 3D world implicitly by relying exclusively on posed images. Yet, they have seldom been explored in the realm of discriminative tasks such as 3D part segmentation. In this work, we attempt to bridge that gap by proposing SegNeRF: a neural field representation that integrates a semantic field along with the usual radiance field. SegNeRF inherits from previous works the ability to perform novel view synthesis and 3D reconstruction, and enables 3D part segmentation from a few images. Our extensive experiments on PartNet show that SegNeRF is capable of simultaneously predicting geometry, appearance, and semantic information from posed images, even for unseen objects. The predicted semantic fields allow SegNeRF to achieve an average mIoU of 30.30% for 2D novel view segmentation, and 37.46% for 3D part segmentation, boasting competitive performance against point-based methods by using only a few posed images. Additionally, SegNeRF is able to generate an explicit 3D model from a single image of an object taken in the wild, with its corresponding part segmentation.

EyeDAS: Securing Perception of Autonomous Cars Against the Stereoblindness Syndrome

Efrat Levy,Ben Nassi,Raz Swissa,Yuval Elovici

The ability to detect whether an object is a 2D or 3D object is extremely important in autonomous driving, since a detection error can have life-threatening consequences, endangering the safety of the driver, passengers, pedestrians, and others on the road.

Methods proposed to distinguish between 2 and 3D objects (e.g., liveness detection methods) are not suitable for autonomous driving, because they are object dependent or do not consider the constraints associated with autonomous driving (e.g., the need for real-time decision-making while the vehicle is moving).

In this paper, we present EyeDAS, a novel few-shot learning-based method aimed at securing an object detector (OD) against the threat posed by the stereoblindne ss syndrome (i.e., the inability to distinguish between 2D and 3D objects).

We evaluate EyeDAS's real-time performance using 2,000 objects extracted from seven YouTube video recordings of street views taken by a dash cam from the driver's seat perspective.

When applying EyeDAS to seven state-of-the-art ODs as a countermeasure, EyeDAS was able to reduce the 2D misclassification rate from 71.42-100% to 2.4% with a 3D misclassification rate of 0% (TPR of 1.0).

We also show that EyeDAS outperforms the baseline method and achieves an AUC of over 0.999.

Learnable Topological Features For Phylogenetic Inference via Graph Neural Networks

Cheng Zhang

Structural information of phylogenetic tree topologies plays an important role in phylogenetic inference. However, finding appropriate topological structures for specific phylogenetic inference tasks often requires significant design effort and domain expertise. In this paper, we propose a novel structural representation method for phylogenetic inference based on learnable topological features. By combining the raw node features that minimize the Dirichlet energy with modern graph representation learning techniques, our learnable topological features can provide efficient structural information of phylogenetic trees that automatically adapts to different downstream tasks without requiring domain expertise. We demonstrate the effectiveness and efficiency of our method on a simulated data tree probability estimation task and a benchmark of challenging real data variational Bayesian phylogenetic inference problems.

Double dynamic sparse training for GANs

Yite Wang,Jing Wu,Naira Hovakimyan,Ruoyu Sun

The past decade has witnessed a drastic increase in modern deep neural networks (DNNs) size, especially for generative adversarial networks (GANs). Since GANs usually suffer from high computational complexity, researchers have shown an increased interest in applying pruning methods to reduce the training and inference costs of GANs. Among different pruning methods invented for supervised learning, dynamic sparse training (DST) has gained increasing attention recently as it enjoys excellent training efficiency with comparable performance to post-hoc pruning. Hence, applying DST on GANs, where we train a sparse GAN with a fixed parameter count throughout training, seems to be a good candidate for reducing GAN training costs. However, a few challenges, including the degrading training instability, emerge due to the adversarial nature of GANs. Hence, we introduce a quantity called balance ratio (BR) to quantify the balance of the generator and the discriminator. We conduct a series of experiments to show the importance of BR in understanding sparse GAN training. Building upon single dynamic sparse training (SDST), where only the generator is adjusted during training, we propose double dynamic sparse training (DDST) to control the BR during GAN training. Empirically, DDST automatically determines the density of the discriminator and greatly boosts the performance of sparse GANs on multiple datasets.

Hardware-restriction-aware training (HRAT) for memristor neural networks

Zhimin Tang,Rujie Zhao,Linkai Luo,Haibo Wang,Chao Lu

Memristor neural network (MNN), which utilizes memristor crossbars for vector-matrix multiplication, has huge advantages in terms of scalability and energy efficiency for neuromorphic computing. MNN weights are usually trained offline and then deployed as memristor conductances through a sequence of programming voltage pulses. Although weight uncertainties caused by process variation have been addressed in variation-aware training algorithms, efficient design and training of MNNs have not been systematically explored to date. In this work, we propose Hardware-Restriction-Aware Training (HRAT), which takes into account various non-negligible limitations and non-idealities of memristor devices, circuits, and systems. HRAT considers MNN's realistic behavior and circuit restrictions during offline training, thereby bridging the gap between offline training and hardware de

ployment. HRAT uses a new batch normalization (BN) fusing strategy to align the distortion caused by hardware restrictions between offline training and hardware inference. This not only improves inference accuracy but also eliminates the need for dedicated circuitry for BN operations. Furthermore, most normal scale signals are limited in amplitude due to the restriction of non-destructive threshold voltage of memristors. To avoid input signal distortion of memristor crossbars, HRAT dynamically adjusts the input signal magnitude during training using a learned scale factor. These scale factors can be incorporated into the parameters of linear operation together with fused BN, so no additional signal scaling circuits are required. To evaluate the proposed HRAT methodology, FC-4 and LeNet-5 on MNIST are firstly trained by HRAT and then deployed in hardware. Hardware simulations match well with the offline HRAT results. We also carried out various experiments using VGG-16 on the CIFAR datasets. The study shows that HRAT leads to high-performance MNNs without device calibration or on-chip training, thus greatly facilitating commercial MNN deployment.
****

DifFace: Blind Face Restoration with Diffused Error Contraction

Zongsheng Yue,Chen Change Loy

While deep learning-based methods for blind face restoration have achieved unprecedented success, they still suffer from two major limitations. First, most of them deteriorate when facing complex degradations out of their training data. Second, these methods require multiple constraints, e.g., fidelity, perceptual, and adversarial losses, which requires laborious hyper-parameters tuning to stabilize and balance their influences. In this work, we propose a novel method named DifFace, being able to cope with unseen and complex degradations more gracefully without complicated loss designs. The key of our method is to establish a posterior distribution from the observed low-quality (LQ) image to its high-quality (HQ) counterpart. In particular, we design a transition distribution from the LQ image to the intermediate state of a pre-trained diffusion model and then gradually transmit from this intermediate state to the HQ target by recursively applying a pre-trained diffusion model. The transition distribution only relies on a restoration backbone that is trained with L2 loss on some synthetic data, which favorably avoids the cumbersome training process in existing methods. Moreover, the transition distribution is capable of contracting the error of the restoration backbone and thus makes our method more robust to unknown degradations. Comprehensive experiments show that DifFace is superior to current state-of-the-art methods, especially in cases with severe degradations. Code and model will be released.

Fairness-aware Contrastive Learning with Partially Annotated Sensitive Attributes

Fengda Zhang,Kun Kuang,Long Chen,Yuxuan Liu,Chao Wu,Jun Xiao

Learning high-quality representation is important and essential for visual recognition. Unfortunately, traditional representation learning suffers from fairness issues since the model may learn information of sensitive attributes. Recently, a series of studies have been proposed to improve fairness by explicitly decorrelating target labels and sensitive attributes. Most of these methods, however, rely on the assumption that fully annotated labels on target variable and sensitive attributes are available, which is unrealistic due to the expensive annotation cost. In this paper, we investigate a novel and practical problem of Fair Unsupervised Representation Learning with Partially annotated Sensitive labels (FURL-PS). FURL-PS has two key challenges: 1) how to make full use of the samples that are not annotated with sensitive attributes; 2) how to eliminate bias in the dataset without target labels. To address these challenges, we propose a general Fairness-aware Contrastive Learning (FairCL) framework consisting of two stages. Firstly, we generate contrastive sample pairs, which share the same visual information apart from sensitive attributes, for each instance in the original dataset. In this way, we construct a balanced and unbiased dataset. Then, we execute fair contrastive learning by closing the distance between representations of contrastive sample pairs. Besides, we also propose an unsupervised way to balance

the utility and fairness of learned representations by feature reweighting. Extensive experimental results illustrate the effectiveness of our method in terms of fairness and utility, even with very limited sensitive attributes and serious data bias.

Training Instability and Disharmony Between ReLU and Batch Normalization
Inyoung Paik,Jaesik Choi
Deep neural networks based on batch normalization and ReLU-like activation functions experience instability during early stages of training owing to the high gradient induced by temporal gradient explosion. ReLU reduces the variance by more than the expected amount and batch normalization amplifies the gradient during its recovery. In this paper, we explain the explosion of a gradient mathematically while the forward propagation remains stable, and also the alleviation of the problem during training. Based on this, we propose a Layer-wise Asymmetric Learning rate Clipping (LALC) algorithm, which outperforms existing learning rate scaling methods in large batch training and can also be used to replace WarmUp in small batch training.
****
Rotamer Density Estimator is an Unsupervised Learner of the Effect of Mutations on Protein-Protein Interaction
Shitong Luo,Yufeng Su,Zuofan Wu,Chenpeng Su,Jian Peng,Jianzhu Ma
Protein-protein interactions are crucial to many biological processes, and predicting the effect of amino acid mutations on binding is important for protein engineering. While data-driven approaches using deep learning have shown promise, the scarcity of annotated experimental data remains a major challenge. In this work, we propose a new approach that predicts mutational effects on binding using the change in conformational flexibility of the protein-protein interface. Our approach, named Rotamer Density Estimator (RDE), employs a flow-based generative model to estimate the probability distribution of protein side-chain conformations and uses entropy to measure flexibility. RDE is trained solely on protein structures and does not require the supervision of experimental values of changes in binding affinities. Furthermore, the unsupervised representations extracted by RDE can be used for downstream neural network predictions with even greater accuracy. Our method outperforms empirical energy functions and other machine learning-based approaches.
****
Dilated convolution with learnable spacings
Ismail Khalfaoui Hassani,Thomas Pellegrini,Timothée Masquelier
Recent works indicate that convolutional neural networks (CNN) need large receptive fields (RF) to compete with visual transformers and their attention mechanism. In CNNs, RFs can simply be enlarged by increasing the convolution kernel sizes. Yet the number of trainable parameters, which scales quadratically with the kernel's size in the 2D case, rapidly becomes prohibitive, and the training is notoriously difficult. This paper presents a new method to increase the RF size without increasing the number of parameters. The dilated convolution (DC) has already been proposed for the same purpose. DC can be seen as a convolution with a kernel that contains only a few non-zero elements placed on a regular grid. Here we present a new version of the DC in which the spacings between the non-zero elements, or equivalently their positions, are no longer fixed but learnable via backpropagation thanks to an interpolation technique. We call this method “Dilated Convolution with Learnable Spacings” (DCLS) and generalize it to the n-dimensional convolution case. However, our main focus here will be on the 2D case. We first tried our approach on ResNet50: we drop-in replaced the standard convolutions with DCLS ones, which increased the accuracy of ImageNet1k classification at iso-parameters, but at the expense of the throughput. Next, we used the recent ConvNeXt state-of-the-art convolutional architecture and drop-in replaced the depthwise convolutions with DCLS ones. This not only increased the accuracy of ImageNet1k classification but also of typical downstream and robustness tasks, again at iso-parameters but this time with negligible cost on throughput, as ConvNeXt uses separable convolutions. Conversely, classic DC led to poor performance wit

h both ResNet50 and ConvNeXt. The code of the method is based on PyTorch and available at: https://github.com/K-H-Ismail/Dilated-Convolution-with-Learnable-Spacings-PyTorch.

PatchDCT: Patch Refinement for High Quality Instance Segmentation

Qinrou Wen,Jirui Yang,Xue Yang,Kewei Liang

High-quality instance segmentation has shown emerging importance in computer vision. Without any refinement, DCT-Mask directly generates high-resolution masks by compressed vectors. To further refine masks obtained by compressed vectors, we propose for the first time a compressed vector based multi-stage refinement framework. However, the vanilla combination does not bring significant gains, because changes in some elements of the DCT vector will affect the prediction of the entire mask. Thus, we propose a simple and novel method named PatchDCT, which separates the mask decoded from a DCT vector into several patches and refines each patch by the designed classifier and regressor. Specifically, the classifier is used to distinguish mixed patches from all patches, and to correct previously mispredicted foreground and background patches. In contrast, the regressor is used for DCT vector prediction of mixed patches, further refining the segmentation quality at boundary locations. Experiments on COCO show that our method achieves 2.0\%, 3.2\%, 4.5\% AP and 3.4\%, 5.3\%, 7.0\% Boundary AP improvements over Mask-RCNN on COCO, LVIS, and Cityscapes, respectively. It also surpasses DCT-Mask by 0.7\%, 1.1\%, 1.3\% AP and 0.9\%, 1.7\%, 4.2\% Boundary AP on COCO, LVIS and Cityscapes. Besides, the performance of PatchDCT is also competitive with other state-of-the-art methods.

Global Prototype Encoding for Incremental Video Highlights Detection

Sen Pei,Shixiong Xu,Ye Yuan,Jiashi Feng,Xiaohui Shen,Xiaojie Jin

Video highlights detection (VHD) is an active research field in computer vision, aiming to locate the most user-appealing clips given raw video inputs. However, most VHD methods are based on the closed world assumption, \emph{i.e.}, a fixed number of highlight categories is defined in advance and all training data are available beforehand. Consequently, existing methods have poor scalability with respect to increasing highlight domains and training data. To address above issues, we propose a novel video highlight detection method named \textbf{G}lobal \textbf{P}rototype \textbf{E}ncoding (GPE) to learn incrementally for adapting to new domains via parameterized prototypes. To facilitate this new research direction, we collect a finely annotated dataset termed \emph{LiveFood}, including over 5,100 live gourmet videos that consist of four domains: \emph{cooking}, \emph{eating}, \emph{ingredients} and \emph{presentation}. To the best of our knowledge, this is the first work to explore video highlight detection in the incremental learning setting, opening up new land to apply VHD for practical scenarios where both the concerned highlight domains and training data increase over time. We demonstrate the effectiveness of GPE through extensive experiments. Notably, GPE surpasses popular domain-incremental learning methods on \emph{LiveFood}, achieving significant mAP improvements on all domains. The code and dataset will be made publicly available.

WaGI: Wavelet-based GAN Inversion for Preserving High-Frequency Image Details

SeungJun Moon,Chaewon Kim,Gyeong-Moon Park

Recent GAN inversion models focus on preserving image-specific details through various methods, e.g., generator tuning or feature mixing.

While those are helpful for preserving details compared to naive low-rate latent inversion, they still fail to maintain high-frequency features precisely. In this paper, we point out that existing GAN inversion models have inherent limitations in both structural and training aspects, which preclude the delicate reconstruction of high-frequency features. Especially, we prove that the widely-used loss term in GAN inversion, i.e., is biased to mainly reconstructing low-frequency features. To overcome this problem, we propose a novel GAN inversion model, coined WaGI, which enables handling high-frequency features explicitly, by using a novel wavelet-based loss term and a newly proposed wavelet fusion scheme. To the best of our knowledge, WaGI is the first approach to interpret GAN inversion in the frequency domain. We demonstrate that WaGI shows outstanding results on both inversion and editing, compared to existing state-of-the-art GAN inversion models. Especially, WaGI robustly preserves high-frequency features of images even in the editing scenario. We will release our code with the pre-trained model after the review.

Neural-Symbolic Recursive Machine for Systematic Generalization

Qing Li,Yixin Zhu,Yitao Liang,Ying Nian Wu,Song-Chun Zhu,Siyuan Huang

Despite the tremendous success, existing machine learning models still fall short of human-like systematic generalization—learning compositional rules from limited data and applying them to unseen combinations in various domains. We propose Neural-Symbolic Recursive Machine (NSR) to tackle this deficiency. The core representation of NSR is a Grounded Symbol System (GSS) with combina- torial syntax and semantics, which entirely emerges from training data. Akin to the neuroscience studies suggesting separate brain systems for perceptual, syntactic, and semantic processing, NSR implements analogous separate modules of neural perception, syntactic parsing, and semantic reasoning, which are jointly learned by a deduction-abduction algorithm. We prove that NSR is expressive enough to model various sequence-to-sequence tasks. Superior systematic generalization is achieved via the inductive biases of equivariance and recursiveness embedded in NSR. In experiments, NSR achieves state-of-the-art performance in three benchmarks from different domains: SCAN for semantic parsing, PCFG for string manipulation, and HINT for arithmetic reasoning. Specifically, NSR achieves 100% generalization accuracy on SCAN and PCFG and outperforms state-of-the-art models on HINT by about 23%. Our NSR demonstrates stronger generalization than pure neural networks due to its symbolic representation and inductive biases. NSR also demonstrates better transferability than existing neural-symbolic approaches due to less domain-specific knowledge required.

ChiroDiff: Modelling chirographic data with Diffusion Models

Ayan Das,Yongxin Yang,Timothy Hospedales,Tao Xiang,Yi-Zhe Song

Generative modelling over continuous-time geometric constructs, a.k.a $chirographic\ data$ such as handwriting, sketches, drawings etc., have been accomplished through autoregressive distributions. Such strictly-ordered discrete factorization however falls short of capturing key properties of chirographic data -- it fails to build holistic understanding of the temporal concept due to one-way visibility (causality). Consequently, temporal data has been modelled as discrete token sequences of fixed sampling rate instead of capturing the true underlying concept. In this paper, we introduce a powerful model-class namely Denoising\ Diffusion\ Probabilistic\ Models or DDPMs for chirographic data that specifically addresses these flaws. Our model named "ChiroDiff", being non-autoregressive, learns to capture holistic concepts and therefore remains resilient to higher temporal sampling rate up to a good extent. Moreover, we show that many important downstream utilities (e.g. conditional sampling, creative mixing) can be flexibly implemented using ChiroDiff. We further show some unique use-cases like stochastic vectorization, de-noising/healing, abstraction are also possible with this model-class. We perform quantitative and qualitative evaluation of our framework on relevant datasets and found it to be better or on par with competing approaches.

Active Topological Mapping by Metric-Free Exploration via Task and Motion Imitation

Yuhang He,Irving Fang,Yiming Li,Chen Feng

Topological map is an effective environment representation for visual navigation. It is a graph of image nodes and spatial neighborhood edges without metric information such as global or relative agent poses. However, currently such a map construction relies on either less-efficient random exploration or more demanding training involving metric information. To overcome these issues, we propose active topological mapping (ATM), consisting of an active visual exploration and a topological mapping by visual place recognition. Our main novelty is the simple

and lightweight active exploration policy that works entirely in the image feature space involving no metric information. More specifically, ATM's metric-free exploration is based on task and motion planning (TAMP). The task planner is a recurrent neural network using the latest local image observation sequence to hallucinate a feature as the next-step best exploration goal. The motion planner then fuses the current and the hallucinated feature to generate an action taking the agent towards the hallucinated feature goal. The two planners are jointly trained via deeply-supervised imitation learning from expert exploration demonstrations. Extensive experiments in both exploration and navigation tasks on the photo-realistic Gibson and MP3D datasets validate ATM's effectiveness and generalizability.

SoundCount: Sound Counting from Raw Audio with Dyadic Decomposition Neural Network

Yuhang He,Zhuangzhuang Dai,Niki Trigoni,Andrew Markham

In this paper, we study an underexplored, yet important and challenging problem: counting the number of distinct sound events in data characterized by a high degree of polyphonicity and spectral overlap. A key example is counting individual bird calls in bioacoustic data, from which biodiversity can be estimated. We do so by systematically proposing a novel end-to-end trainable neural network, designing new evaluation protocols, quantifying the difficulty of counting depending on sound polyphonicity, and creating a new dataset tailored for concurrent sound event counting. Unlike existing methods that all apply frequency-selective filters on the raw waveform in a one-stage manner, our neural network progressively decomposes the raw waveform dyadically in frequency domain. Taking inspiration from wavelet decomposition, intermediate waveforms convolved by a parent filter are successively processed by a pair of children filters that evenly split the parent filter's carried frequency response. An energy gain normalization module is introduced to normalize received sound events' loudness variance and spectrum overlap. The network is fully convolutional and parameter-frugal so it is light-weight and computationally efficient. We further design a set of polyphony-aware metrics to quantify sound counting difficulty level from different perspectives. To show the efficiency and generalization of our method (we call DyDecNet), we do experiments on both bioacoustic bird sound (both synthetic and real-world sound), telephone-ring sound and music sound data. Comprehensive experiment results show our method outperforms existing sound event detection (SED) methods significantly. The dyadic decomposition front-end network can be used by existing methods to improve their performance accordingly.

SoundNeRirF: Receiver-to-Receiver Sound Neural Room Impulse Response Field

Yuhang He,Jia-Xing Zhong,Zhuangzhuang Dai,Niki Trigoni,Andrew Markham

We present SoundNeRirF, a framework that learns a continuous receiver-to-receiver neural room impulse response field~(r2r-RIR) to help robot efficiently predict the sound to be heard at novel locations. It represents a room acoustic scene as a continuous 6D function, whose input is a reference receiver's 3D position and a target receiver's 3D position, and whose outputs are an inverse room impulse response~(inverse-RIR) and a forward room impulse response~(forward-RIR) that jointly project the sound from the reference position to the target position. SoundNeRirF requires knowledge of neither sound source (e.g. location and number of sound sources) nor room acoustic properties~(e.g. room size, geometry, materials). Instead, it merely depends on a sparse set of sound receivers' positions, as well as the recorded sound at each position. We instantiate the continuous 6D function as multi-layer perceptrons~(MLP), so it is fully differentiable and continuous at any spatial position. SoundNeRirF is encouraged, during the training stage, to implicitly encode the interaction between sound sources, receivers and room acoustic properties by minimizing the discrepancy between the predicted sound and the truly heard sound at the target position. During inference, the sound at a novel position is predicted by giving a reference position and the corresponding reference sound. Extensive experiments on both synthetic and real-world datasets show SoundNeRirF is capable of predicting high-fidelity and audio-realis tic sound that fully captures room reverberation characteristics, significantly outperforming existing methods in terms of accuracy and efficiency.

Towards Sustainable Self-supervised Learning

Shang-Hua Gao,Pan Zhou,Ming-Ming Cheng,Shuicheng YAN

Though increasingly training-expensive, most self-supervised learning (SSL) models have repeatedly been trained from scratch but not fully utilized since only a few SOTAs are adopted for downstream tasks. In this work, we explore a sustainable SSL framework with two major challenges: i) learning a stronger new SSL model based on the existing pretrained SSL model in a cost-friendly manner, ii) allowing the training of the new model to be compatible with various base models. We propose a Target-Enhanced Conditional (TEC) scheme, which introduces two components to existing mask-reconstruction based SSL. Firstly, we introduce patch-relation enhanced targets to encourage the new model to learn semantic-relation knowledge from the base model using incomplete inputs. This hardening and target-enhancing could help the new model surpass the base model, since they enforce additional patch relation modeling to handle incomplete input. Secondly, we introduce a conditional adapter that adaptively adjusts new model prediction to align with the target of each base model. Experimental results show that our TEC scheme can accelerate the learning speed and also improve SOTA SSL models, e.g., MAE and iBOT, taking an explorative step towards sustainable SSL.

Real-Time Image Demoir$\acute{e}$ing on Mobile Devices

Yuxin Zhang,Mingbao Lin,Xunchao Li,Han Liu,Guozhi Wang,Fei Chao,Ren Shuai,Yafei Wen,Xiaoxin Chen,Rongrong Ji

Moir$\acute{e}$ patterns appear frequently when taking photos of digital screens, drastically degrading the image quality. Despite the advance of CNNs in image demoir$\acute{e}$ing, existing networks are with heavy design, causing massive computation burden for mobile devices. In this paper, we launch the first study on accelerating demoir$\acute{e}$ing networks and propose a dynamic demoir$\acute{e}$ing acceleration method (DDA) towards a real-time deployment on mobile devices. Our stimulus stems from a simple-yet-universal fact that moir${\'e}$ patterns often unbalancedly distribute across an image. Consequently, excessive computation is wasted upon non-moir$\acute{e}$ areas. Therefore, we reallocate computation costs in proportion to the complexity of image patches. In order to achieve this aim, we measure the complexity of an image patch by a novel moir$\acute{e}$ prior that considers both colorfulness and frequency information of moir$\acute{e}$ patterns. Then, we restore higher-complex image patches using larger networks and the lower-complex ones are assigned with smaller networks to relieve the computation burden. At last, we train all networks in a parameter-shared supernet paradigm to avoid additional parameter burden. Extensive experiments on several benchmarks demonstrate the efficacy of our DDA. In addition, the acceleration evaluated on the VIVO X80 Pro smartphone equipped with the chip of Snapdragon 8 Gen 1 also shows that our method can drastically reduce the inference time, leading to a real-time image demoir$\acute{e}$ing on mobile devices. Source codes and models are released at https://github.com/zyxxmu/DDA.

Domain Generalization via Independent Regularization from Early-branching Networks

Liang Chen,Yong Zhang,Yibing Song,Jue Wang,Lingqiao Liu

Learning domain-invariant feature representations is critical for achieving domain generalization, where a model is required to perform well on unseen domains. The critical challenge is that standard training often results in entangled domain-invariant and domain-specific features. To address this issue, we use a dual-branching network to learn two features, one for the domain classification problem and the other for the original target classification problem, and the feature of the latter is required to be independent of the former. While this idea seems straightforward, we show that several factors need to be carefully considered for it to work effectively. In particular, we investigate different branching st ructures and discover that the common practice of using a shared base feature extractor with two lightweight prediction heads is detrimental to the performance. Instead, a simple early-branching architecture, where the domain classification and target classification branches share the first few blocks while diverging thereafter, leads to better results. Moreover, we also incorporate a random style augmentation scheme as an extension to further unleash the power of the proposed method, which can be seamlessly integrated into the dual-branching network by our loss terms. Such an extension gives rise to an effective domain generalization method. Experimental results show that the proposed method outperforms state-of-the-art domain generalization methods on various benchmark datasets.

****

AutoSKDBERT: Learn to Stochastically Distill BERT

Zixiang Ding,GUO-QING JIANG,Shuai Zhang,Lin Guo,Wei Lin

In this paper, we propose AutoSKDBERT, a new knowledge distillation paradigm for BERT compression, that stochastically samples a teacher from a predefined teacher team following a categorical distribution in each step, to transfer knowledge into student. AutoSKDBERT aims to discover the optimal categorical distribution which plays an important role to achieve high performance. The optimization procedure of AutoSKDBERT can be divided into two phases: 1) phase-1 optimization distinguishes effective teachers from ineffective teachers, and 2) phase-2 optimization further optimizes the sampling weights of the effective teachers to obtain satisfactory categorical distribution. Moreover, after phase-1 optimization completion, AutoSKDBERT adopts teacher selection strategy to discard the ineffective teachers whose sampling weights are assigned to the effective teachers. Particularly, to alleviate the gap between categorical distribution optimization and evaluation, we also propose a stochastic single-weight optimization strategy which only updates the weight of the sampled teacher in each step. Extensive experiments on GLUE benchmark show that the proposed AutoSKDBERT achieves state-of-the-art score compared to previous compression approaches on several downstream tasks, including pushing MRPC F1 and accuracy to 93.2 (0.6 point absolute improvement) and 90.7 (1.2 point absolute improvement), RTE accuracy to 76.9 (2.9 point absolute improvement).

Training A Multi-stage Deep Classifier with Feedback Signals

Chao Xu,Yu Yang,Rongzhao Wang,Guan Wang,Bojia Lin

Multi-Stage Classifier (MSC) - several classifiers working sequentially in an arranged order and classification decision is partially made at each step - is widely used in industrial applications for various resource limitation reasons. The classifiers of a multi-stage process are usually Neural Network (NN) models trained independently or in their inference order without considering the signals from the latter stages. Aimed at two-stage binary classification process, the most common type of MSC, we propose a novel training framework, named Feedback Training. The classifiers are trained in an order reverse to their actual working order, and the classifier at the later stage is used to guide the training of initial-stage classifier via a sample weighting method. We experimentally show the efficacy of our proposed approach, and its great superiority under the scenario of few-shot training.

Is Self-Supervised Contrastive Learning More Robust Than Supervised Learning?

Yuanyi Zhong,Haoran Tang,Junkun Chen,Jian Peng,Yu-Xiong Wang

Prior work on self-supervised contrastive learning has primarily focused on evaluating the recognition accuracy, but has overlooked other behavioral aspects. In addition to accuracy, distributional robustness plays a critical role in the reliability of machine learning models. We design and conduct a series of robustness tests to quantify the behavioral differences between contrastive learning and supervised learning to downstream and pre-training data distribution changes. These tests leverage data corruptions at multiple levels, ranging from pixel-level distortion to patch-level shuffling and to dataset-level distribution shift, including both natural and unnatural corruptions. Our tests unveil intriguing robustness behaviors of contrastive and supervised learning: while we generally obs erve that contrastive learning is more robust than supervised learning under downstream corruptions, we surprisingly discover the robustness vulnerability of contrastive learning under pixel and patch level corruptions during pre-training. Furthermore, we observe the higher dependence of contrastive learning on spatial image coherence information during pre-training, e.g., it is particularly sensitive to global patch shuffling. We explain these results by connecting to feature space uniformity and data augmentation. Our analysis has implications in improving the downstream robustness of supervised learning, and calls for more studies on understanding contrastive learning.

An Empirical Study of Metrics to Measure Representational Harms in Pre-Trained Language Models

Saghar Hosseini,Ahmed Hassan Awadallah,Hamid Palangi

Large-scale Pre-Trained Language Models (PTLMs) capture knowledge from massive human-written data which contains latent societal biases and toxic contents. In this paper, we leverage the primary task of PTLMs, i.e. language modeling, and propose a new metric to quantify manifested implicit representational harms in PTLMs towards 13 marginalized demographics. Using this metric, we conducted an empirical analysis of 24 widely used PTLMs. Our analysis provides insights into the correlation between the proposed metric in this work and other related fairness metrics. We observe that our metric correlates with the majority of gender-specific fairness metrics in the literature. Through extensive experiments, we explore the connections between PTLMs architectures and representational harms across two dimensions: depth and width of the networks. We found that prioritizing depth over width, mitigates representational harms in some PTLMs.

****

Unsupervised Learning of Causal Relationships from Unstructured Data

Marian Longa,Joao F. Henriques

Endowing deep neural networks with the ability to reason about cause and effect would be an important step to make them more robust and interpretable. In this work we propose a variational framework that allows deep networks to learn latent variables and their causal relationships from unstructured data, with no supervision, or labeled interventions. Starting from an abstract Structural Equation Model (SEM), we show that maximizing its posterior probability yields a similar construction to a Variational Auto-Encoder (VAE), but with a structured prior coupled by non-linear equations. This prior represents an interpretable SEM with learnable parameters (such as a physical model or dependence structure), which can be fitted to data while simultaneously learning the latent variables. Unfortunately, computing KL-divergences with this non-linear prior is intractable. We show how linearizing arbitrary SEMs via back-propagation produces local non-isotropic Gaussian priors, for which the KL-divergences can be computed efficiently and differentiably. We propose two versions, one for IID data (such as images) which detects related causal variables within a sample, and one for non-IID data (such as video) which detects variables that are also related over time. Our proposal is complementary to causal discovery techniques, which assume given variables, and instead discovers both variables and their causal relationships. We experiment with recovering causal models from images, and learning temporal relations based on the Super Mario Bros videogame.

The Biased Artist: Exploiting Cultural Biases via Homoglyphs in Text-Guided Image Generation Models

Lukas Struppek,Dominik Hintersdorf,Kristian Kersting

Text-guided image generation models, such as DALL-E2 and Stable Diffusion, have recently received much attention from academia and the general public. Provided with textual descriptions, these models are capable of generating high-quality images depicting various concepts and styles. However, such models are trained on large amounts of public data and implicitly learn relationships from their training data that are not immediately apparent. We demonstrate that common multimodal models implicitly learned cultural biases that can be triggered and injected into the generated images by simply replacing single characters in the textual d escription with visually similar non-Latin characters. These so-called homoglyph replacements enable malicious users or service providers to induce biases into the generated images and even render the whole generation process useless. We practically illustrate such attacks on DALL-E2 and Stable Diffusion as text-guided image generation models and further show that CLIP also behaves similarly. Our results further indicate that text encoders trained on multilingual data provide a way to mitigate the effects of homoglyph replacements.

Parameterized projected Bellman operator

Théo Vincent,Alberto Maria Metelli,Jan Peters,Marcello Restelli,Carlo D'Eramo

The Bellman operator is a cornerstone of reinforcement learning, widely used in a plethora of works, from value-based methods to modern actor-critic approaches. In problems with unknown models, the Bellman operator requires transition samples that strongly determine its behavior, as uninformative samples can result in negligible updates or long detours before reaching the fixed point. In this work, we introduce the novel idea of obtaining an approximation of the Bellman operator, which we call projected Bellman operator (PBO). Our PBO is a parametric operator on the parameter space of a given value function. Given the parameters of a value function, PBO outputs the parameters of a new value function and converges to a fixed point in the limit, as a standard Bellman operator. Notably, our PBO can approximate repeated applications of the true Bellman operator at once, as opposed to the sequential nature of the standard Bellman operator. We prove the important consequences of this finding for different classes of problems by analyzing PBO in terms of stability, convergence, and approximation error. Eventually, we propose an approximate value-iteration algorithm to show how PBO can overcome the limitations of classical methods, opening up multiple research directions as a novel paradigm in reinforcement learning.

Cross-Level Distillation and Feature Denoising for Cross-Domain Few-Shot Classification

Hao ZHENG,Runqi Wang,Jianzhuang Liu,Asako Kanezaki

The conventional few-shot classification aims at learning a model on a large labeled base dataset and rapidly adapting to a target dataset that is from the same distribution as the base dataset. However, in practice, the base and the target datasets of few-shot classification are usually from different domains, which is the problem of cross-domain few-shot classification. We tackle this problem by making a small proportion of unlabeled images in the target domain accessible in the training stage. In this setup, even though the base data are sufficient and labeled, the large domain shift still makes transferring the knowledge from the base dataset difficult. We meticulously design a cross-level knowledge distillation method, which can strengthen the ability of the model to extract more discriminative features in the target dataset by guiding the network's shallow layers to learn higher-level information. Furthermore, in order to alleviate the overfitting in the evaluation stage, we propose a feature denoising operation which can reduce the feature redundancy and mitigate overfitting. Our approach can surpass the previous state-of-the-art method, Dynamic-Distillation, by 5.44% on 1-shot and 1.37% on 5-shot classification tasks on average in the BSCD-FSL benchmark. The implementation code will be available at https://gitee.com/mindspore/models/tree/master/research/cv/CLDFD.

kaBEDONN: posthoc eXplainable Artificial Intelligence with Data Ordered Neural Network

Erico Tjoa,Cuntai Guan

Different approaches to eXplainable Artificial Intelligence (XAI) have been explored including (1) the systematic study of the effect of individual training data sample on the final model (2) posthoc attribution methods that assign importance values to the components of each data sample. Combining concepts from both approaches, we introduce kaBEDONN, a system of ordered dataset coupled with a posthoc and model-agnostic method for querying \textit{relevant} training data samples. These \textit{relevant} data are intended as the explanations for model pred

ictions that are both user-friendly and easily adjustable by developers. Explanations can thus be finetuned and damage control can be performed with ease.
****

DELTA: DEGRADATION-FREE FULLY TEST-TIME ADAPTATION
Bowen Zhao,Chen Chen,Shu-Tao Xia
Fully test-time adaptation aims at adapting a pre-trained model to the test stream during real-time inference, which is urgently required when the test distribution differs from the training distribution. Several efforts have been devoted to improving adaptation performance. However, we find that two unfavorable defects are concealed in the prevalent adaptation methodologies like test-time batch normalization (BN) and self-learning. First, we reveal that the normalization statistics in test-time BN are completely affected by the currently received test samples, resulting in inaccurate estimates. Second, we show that during test-time adaptation, the parameter update is biased towards some dominant classes. In addition to the extensively studied test stream with independent and class-balanced samples, we further observe that the defects can be exacerbated in more complicated test environments, such as (time) dependent or class-imbalanced data. We observe that previous approaches work well in certain scenarios while show performance degradation in others due to their faults. In this paper, we provide a plug-in solution called DELTA for Degradation-freE fuLly Test-time Adaptation, which consists of two components: (i) Test-time Batch Renormalization (TBR), introduced to improve the estimated normalization statistics. (ii) Dynamic Online re-weighTing (DOT), designed to address the class bias within optimization. We investigate various test-time adaptation methods on three commonly used datasets with four scenarios, and a newly introduced real-world dataset. DELTA can help them deal with all scenarios simultaneously, leading to SOTA performance.

Bit-Pruning: A Sparse Multiplication-Less Dot-Product
Yusuke Sekikawa,Shingo Yashima
Dot-product is a central building block in neural networks.
However, multiplication ($\texttt{mult}$) in dot-product consumes intensive energy and space costs that challenge deployment on resource-constrained edge devices.
In this study, we realize energy-efficient neural networks by exploiting a $\texttt{mult}$-less, sparse dot-product. We first reformulate a dot-product between an integer weight and activation into an equivalent operation comprised of additions followed by bit-shifts ($\texttt{add-shift-add}$).
In this formulation, the number of $\texttt{add}$ operations equals the number of bits of the integer weight in binary format.
Leveraging this observation, we propose Bit-Pruning, which removes unnecessary bits in each weight value during training to reduce the energy consumption of $\texttt{add-shift-add}$. Bit-Pruning can be seen as soft Weight-Pruning as it prunes bits, not the whole weight element.
In extensive experiments, we demonstrate that sparse $\texttt{mult}$-less networks trained with Bit-Pruning show a better accuracy-energy trade-off than sparse $\texttt{mult}$ networks trained with Weight-Pruning.

Abstract-to-Executable Trajectory Translation for One-Shot Task Generalization
Stone Tao,Xiaochen Li,Tongzhou Mu,Zhiao Huang,Yuzhe Qin,Hao Su
Training long-horizon robotic policies in complex physical environments is essential for many applications, such as robotic manipulation. However, learning a policy that can generalize to unseen tasks is challenging. In this work, we propose to achieve one-shot task generalization by decoupling plan generation and plan execution. Specifically, our method solves complex long-horizon tasks in three steps: build a paired abstract environment by simplifying geometry and physics, generate abstract trajectories, and solve the original task by an abstract-to-executable trajectory translator. In the abstract environment, complex dynamics such as physical manipulation are removed, making abstract trajectories easier to generate. However, this introduces a large domain gap between abstract trajectories and the actual executed trajectories as abstract trajectories lack low-level

details and aren’t aligned frame-to-frame with the executed trajectory. In a manner reminiscent of language translation, our approach leverages a seq-to-seq model to overcome the large domain gap between the abstract and executable trajectories, enabling the low-level policy to follow the abstract trajectory. Experimental results on various unseen long-horizon tasks with different robot embodiments demonstrate the practicability of our methods to achieve one-shot task generalization. Videos and more details can be found in the supplementary materials and project page: https://sites.google.com/view/abstract-to-executable-iclr23/

Unveiling The Mask of Position-Information Pattern Through the Mist of Image Features

Chieh Hubert Lin,Hung-Yu Tseng,Hsin-Ying Lee,Maneesh Kumar Singh,Ming-Hsuan Yang

Recent studies have shown that paddings in convolutional neural networks encode absolute position information which can negatively affect the model performance for certain tasks. However, existing metrics for quantifying the strength of positional information remain unreliable and frequently lead to erroneous results. To address this issue, we propose novel metrics for measuring and visualizing the encoded positional information. We formally define the encoded information as Position-information Pattern from Padding (PPP) and conduct a series of experiments to study its properties as well as its formation. The proposed metrics measure the presence of positional information more reliably than the existing metrics based on PosENet and tests in F-Conv. We also demonstrate that for any extant (and proposed) padding schemes, PPP is primarily a learning artifact and is less dependent on the characteristics of the underlying padding schemes.

kNN-Diffusion: Image Generation via Large-Scale Retrieval

Shelly Sheynin,Oron Ashual,Adam Polyak,Uriel Singer,Oran Gafni,Eliya Nachmani,Yaniv Taigman

Recent text-to-image models have achieved impressive results. However, since they require large-scale datasets of text-image pairs, it is impractical to train them on new domains where data is scarce or not labeled.

In this work, we propose using large-scale retrieval methods, in particular, efficient k-Nearest-Neighbors (kNN), which offers novel capabilities: (1) training a substantially small and efficient text-to-image diffusion model using only pre-trained multi-modal embeddings, but without an explicit text-image dataset, (2) generating out-of-distribution images by simply swapping the retrieval database at inference time, and (3) performing text-driven local semantic manipulations while preserving object identity. To demonstrate the robustness of our method, we apply our kNN approach on two state-of-the-art diffusion backbones, and show results on several different datasets. As evaluated by human studies and automatic metrics, our method achieves state-of-the-art results compared to existing approaches that train text-to-image generation models using images-only dataset.

IS SYNTHETIC DATA FROM GENERATIVE MODELS READY FOR IMAGE RECOGNITION?

Ruifei He,Shuyang Sun,Xin Yu,Chuhui Xue,Wenqing Zhang,Philip Torr,Song Bai,XIAOJUAN QI

Recent text-to-image generation models have shown promising results in generating high-fidelity photo-realistic images. Though the results are astonishing to human eyes, how applicable these generated images are for recognition tasks remains under-explored. In this work, we extensively study whether and how synthetic images generated from state-of-the-art text-to-image generation models can be used for image recognition tasks, and focus on two perspectives: synthetic data for improving classification models in the data-scare settings (i.e. zero-shot and few-shot), and synthetic data for large-scale model pre-training for transfer learning. We showcase the powerfulness and shortcomings of synthetic data from existing generative models, and propose strategies for better applying synthetic data for recognition tasks. Code: https://github.com/CVMI-Lab/SyntheticData.

Learnable Behavior Control: Breaking Atari Human World Records via Sample-Efficient Behavior Selection

Jiajun Fan,Yuzheng Zhuang,Yuecheng Liu,Jianye HAO,Bin Wang,Jiangcheng Zhu,Hao Wang,Shu-Tao Xia

The exploration problem is one of the main challenges in deep reinforcement learning (RL). Recent promising works tried to handle the problem with population-based methods, which collect samples with diverse behaviors derived from a population of different exploratory policies. Adaptive policy selection has been adopted for behavior control. However, the behavior selection space is largely limited by the predefined policy population, which further limits behavior diversity.

In this paper, we propose a general framework called Learnable Behavioral Control (LBC) to address the limitation, which a) enables a significantly enlarged behavior selection space via formulating a hybrid behavior mapping from all policies; b) constructs a unified learnable process for behavior selection. We introduce LBC into distributed off-policy actor-critic methods and achieve behavior control via optimizing the selection of the behavior mappings with bandit-based meta-controllers. Our agents have achieved 10077.52% mean human normalized score and surpassed 24 human world records within 1B training frames in the Arcade Learning Environment, which demonstrates our significant state-of-the-art (SOTA) performance without degrading the sample efficiency.

Decompose to Generalize: Species-Generalized Animal Pose Estimation

Guangrui Li,Yifan Sun,Zongxin Yang,Yi Yang

This paper challenges the cross-species generalization problem for animal pose estimation, aiming to learn a pose estimator that can be well generalized to novel species. We find the relation between different joints is important with two-fold impact: 1) on the one hand, some relation is consistent across all the species and may help two joints mutually confirm each other, e.g., the eyes help confirm the nose and vice versa because they are close in all species. 2) on the other hand, some relation is inconsistent for different species due to the species variation and may bring severe distraction rather than benefit. With these two insights, we propose a Decompose-to-Generalize (D-Gen) pose estimation method to break the inconsistent relations while preserving the consistent ones. Specifically, D-Gen first decomposes the body joints into several joint concepts so that each concept contains multiple closely-related joints. Given these joint concepts, D-Gen 1) promotes the interaction between intra-concept joints to enhance their reliable mutual confirmation, and 2) suppresses the interaction between inter-concept joints to prohibit their mutual distraction. Importantly, we explore various decomposition approaches, i.e., heuristic, geometric and attention-based approaches. Experimental results show that all these decomposition manners yield reasonable joint concepts and substantially improve cross-species generalization (and the attention-based approach is the best).

IDEAL: Query-Efficient Data-Free Learning from Black-Box Models

Jie Zhang,Chen Chen,Lingjuan Lyu

Knowledge Distillation (KD) is a typical method for training a lightweight student model with the help of a well-trained teacher model.

However, most KD methods require access to either the teacher's training data or model parameter, which is unrealistic. To tackle this problem, recent works study KD under data-free and black-box settings. Nevertheless, these works require a large number of queries to the teacher model, which incurs significant monetary and computational costs. To address these problems, we propose a novel method called \emph{query-effIcient Data-free lEarning from blAck-box modeLs} (IDEAL), which aims to query-efficiently learn from black-box model APIs to train a good student without any real data.   In detail, IDEAL trains the student model in two stages: data generation and model distillation. Note that IDEAL does not require any query in the data generation stage and queries the teacher only once for each sample in the distillation stage. Extensive experiments on various real-world datasets show the effectiveness of the proposed IDEAL. For instance, IDEAL can improve the performance of the best baseline method DFME by 5.83\% on CIFAR10 dataset with only $0.02\times$ the query budget of DFME.

MapTR: Structured Modeling and Learning for Online Vectorized HD Map Construction

Bencheng Liao,Shaoyu Chen,Xinggang Wang,Tianheng Cheng,Qian Zhang,Wenyu Liu,Chang Huang

High-definition (HD) map provides abundant and precise environmental information of the driving scene, serving as a fundamental and indispensable component for planning in autonomous driving system. We present MapTR, a structured end-to-end Transformer for efficient online vectorized HD map construction. We propose a unified permutation-equivalent modeling approach, i.e., modeling map element as a point set with a group of equivalent permutations, which accurately describes the shape of map element and stabilizes the learning process. We design a hierarchical query embedding scheme to flexibly encode structured map information and perform hierarchical bipartite matching for map element learning. MapTR achieves the best performance and efficiency with only camera input among existing vectorized map construction approaches on nuScenes dataset. In particular, MapTR-nano runs at real-time inference speed (25.1 FPS) on RTX 3090, $8\times$ faster than the existing state-of-the-art camera-based method while achieving 5.0 higher mAP. Even compared with the existing state-of-the-art multi-modality method, MapTR-nano achieves 0.7 higher mAP and $8\times$ faster inference speed, and MapTR-tiny achieves 13.5 higher mAP and $3\times$ faster inference speed. Abundant qualitative results show that MapTR maintains stable and robust map construction quality in complex and various driving scenes. MapTR is of great application value in autonomous driving. Code and more demos are available at https://github.com/hustvl/MapTR.

(LA)YER-NEIGH(BOR) SAMPLING: DEFUSING NEIGHBORHOOD EXPLOSION

Muhammed Fatih Balin,Umit Catalyurek

Graph Neural Networks have recently received a significant attention, however, training them at a large scale still remains as a challenge.
Minibatch training coupled with sampling is used to alleviate this challenge.
However existing approaches either suffer from the neighborhood explosion phenomenon or does not have good performance.
To deal with these issues, we propose a new sampling algorithm called LAyer-neighBOR sampling (LABOR).
It is designed to be a direct replacement for Neighborhood Sampling with the same fanout hyperparameter while sampling much fewer vertices, without sacrificing quality.
By design, the variance of the estimator of each vertex matches Neighbor Sampling from the point of view from a single vertex.
In our experiments, we demonstrate the superiority of our approach when it comes to model convergence behaviour against Neighbor Sampling and also the other Layer Sampling approaches under the same limited vertex sampling budget constraints.

****

Probing into Overfitting for Video Recognition

Yitian Zhang,Yue Bai,Huan Wang,Yizhou Wang,Yun Fu

Video recognition methods based on 2D networks have thrived in recent years, leveraging advanced image classification techniques. However, overfitting is an even severe problem in 2D video recognition models as 1) the scale of video datasets is relatively small compared to image recognition datasets like ImageNet; 2) current pipeline treats background and semantic frames equally during optimization which aggravates overfitting. Based on these challenges, we design a video-specific data augmentation approach, named as Ghost Motion (GM), to alleviate overfitting. Specifically, GM shifts channels along temporal dimension to enable semantic motion information diffused into other frames which may be irrelevant originally, leading to improvement in frame-wise accuracy. In addition, for challenging video samples with significant temporal dependency (e.g., Something-Something), we further scale the logits during training to prevent overconfident predictions on background frames. Comprehensive empirical validation on various popular datasets shows that the proposed method can improve the generalization of existi ng methods and is compatible to other competing data augmentation approaches.

****

Image as Set of Points

Xu Ma,Yuqian Zhou,Huan Wang,Can Qin,Bin Sun,Chang Liu,Yun Fu

What is an image, and how to extract latent features?

Convolutional Networks (ConvNets) consider an image as organized pixels in a rectangular shape and extract features via convolutional operation in a local region; Vision Transformers (ViTs) treat an image as a sequence of patches and extract features via attention mechanism in a global range. In this work, we introduce a straightforward and promising paradigm for visual representation, which is called Context Clusters. Context clusters (CoCs) view an image as a set of unorganized points and extract features via a simplified clustering algorithm. In detail, each point includes the raw feature (e.g., color) and positional information (e.g., coordinates), and a simplified clustering algorithm is employed to group and extract deep features hierarchically. Our CoCs are convolution- and attention-free, only relying on clustering algorithm for spatial interaction. Owing to the simple design, we show CoCs endow gratifying interpretability via the visualization of the clustering process.

Our CoCs aim at providing a new perspective on image and visual representation, which may enjoy broad applications in different domains and exhibit profound insights. Even though we are not targeting SOTA performance, COCs still achieve comparable or even better performance than ConvNets or ViTs on several benchmarks.

Hybrid Neuro-Symbolic Reasoning based on Multimodal Fusion

Subrata Das,Bodong Zhou

Deep neural models and symbolic Artificial Intelligence (AI) systems have contrasting advantages and disadvantages. Neural models can be trained from raw, incomplete and noisy data to obtain abstraction of features at various levels, but their uninterpretability is well-known. On the other hand, the traditional rule-based symbolic reasoning encodes domain knowledge, but its failure is often attributed to the acquisition bottleneck. We propose to build a hybrid learning and reasoning system which is based on multimodal fusion approach that brings together advantageous features from both the paradigms. Specifically, we enhance convolutional neural networks (CNNs) with the structured information of ‘if-then’ symbolic logic rules obtained via word embeddings corresponding to propositional symbols and terms. With many dozens of intuitive rules relating the type of a scene with its typical constituent objects, we are able to achieve significant improvement over the base CNN-based classification. Our approach is extendible to handle first-order logical syntax for rules and other deep learning models.

Distilling Text-Image Foundation Models

Qifeng Wu,Huan Wang,Xu Ma,Yun Fu

Large pretrained foundation models (such as CLIP, DALL-E) are among the most recent significant advances in the AI community. Their implication is profound. This paper examines the value of these foundation models as a model knowledge base -- we aim to distill the knowledge in these foundation models for training lightweight models designed for specific tasks in practical application scenarios with improved performance. Despite abundant progress in knowledge distillation (KD) in traditional models trained under the supervision of class labels in datasets encoded as integers, distilling such text-image contrastive learning model has not been explored extensively. Meanwhile, KD is well-known for being bothered by the capacity gap problem (i.e., distilling knowledge from a teacher significantly larger than a student often degrades the performance of the student). The teacher-student capacity gap in distilling foundation models is even larger. Therefore, how to overcome this potential issue is also elusive now. This paper presents detailed analyses of these questions aiming to successfully tap into a pretrained foundation model (CLIP) to boost the student's performance. Besides the practical performance benefits, several interesting discoveries are unveiled: (1) CLIP is not bothered by the capacity gap, which may let us re-evaluate if the "ca

pacity-gap" issue is really due to the capacity gap (2) We find the reason is largely due to that CLIP is not over-confident on the wrong labels when misclassifies input image samples.
****
Trainability Preserving Neural Pruning
Huan Wang,Yun Fu
Many recent works have shown trainability plays a central role in neural network pruning -- unattended broken trainability can lead to severe under-performance and unintentionally amplify the effect of retraining learning rate, resulting in biased (or even misinterpreted) benchmark results. This paper introduces trainability preserving pruning (TPP), a scalable method to preserve network trainability against pruning, aiming for improved pruning performance and being more robust to retraining hyper-parameters (e.g., learning rate). Specifically, we propose to penalize the gram matrix of convolutional filters to decorrelate the pruned filters from the retained filters. In addition to the convolutional layers, per the spirit of preserving the trainability of the whole network, we also propose to regularize the batch normalization parameters (scale and bias). Empirical studies on linear MLP networks show that TPP can perform on par with the oracle trainability recovery scheme. On nonlinear ConvNets (ResNet56/VGG19) on CIFAR10/100, TPP outperforms the other counterpart approaches by an obvious margin. Moreover, results on ImageNet-1K with ResNets suggest that TPP consistently performs more favorably against other top-performing structured pruning approaches. Code: https://github.com/MingSun-Tse/TPP.

Robustness Exploration of Semantic Information in Adversarial Training
Huafeng Kuang,Hong Liu,Mingliang Xu,YONGJIAN WU,Rongrong Ji
In this paper, we look into the problem of adversarial robustness from the semantic information perspective. We demonstrate a novel insight that adversarial attacks destroy the correlation between visual representations and semantic word vectors, and adversarial training fixed it. We further find that the correlation between robust features of different categories is consistent with the correlation between corresponding semantic word vectors. Based on that, we introduce the semantic information to assist model training and propose Semantic Constraint Adversarial Robust Learning (SCARL). First, we follow an information-theoretical lens to formulate the mutual information between the visual representation and the corresponding semantic word vector in the embedding space to bridge the information gap. We further provide a differentiable lower bound to optimize such mutual information efficiently. Second, we propose a novel semantic structural constraint, encouraging the trained model to keep the structure of visual representations consistent with that of semantic word vectors. Finally, we combine these two techniques with adversarial training to learn robust visual representation. Experimentally, we conduct extensive experiments on several benchmarks, demonstrating that semantic information is indeed beneficial to model robustness.

Learning Implicit Scale Conditioned Memory Compensation for Talking Head Generation
Fa-Ting Hong,Dan Xu
Talking head video generation aims to animate the pose and expression of a person in a target driving video using motion information contained in the video, while maintaining a person's identity in a given still source image. Highly dynamic and complex motions in the driving video cause ambiguous generation from the source image, because the still source image cannot provide sufficient appearance information for occluded regions or delicate expressions, which severely produces artifacts and significantly degrades the generation quality. However, existing works mainly focus on learning more accurate motion estimation and representation in 2D and 3D, and they ignore the facial structural prior in addressing the facial ambiguities. Therefore, effective handling of the ambiguities in the dramatic appearance changes of the source to largely improve facial details and completeness in generation still remains barely explored. To this end, we propose a novel implicit scale conditioned memory compensation network (MCNet) for high-fid

elity talking head generation. Specifically, considering human faces are symmetric and structured, we aim to automatically learn a representative global facial memory bank from all training data as a prior to compensate for the facial generation features. Each face in the source image contains a scale that can be reflected in detected facial keypoints. To better query the learned global memory, we further propose to learn implicit scale representations from the discrete keypoints, which can be used to condition on the query of the global memory, to obtain scale-aware memory for the feature compensation. Extensive experiments from quantitative and qualitative perspectives demonstrate that MCNet can learn representative and complementary facial memory, and can clearly outperform previous state-of-the-art methods on VoxCeleb1 and CelebV datasets.

Diagnosing and Rectifying Vision Models using Language

Yuhui Zhang,Jeff Z. HaoChen,Shih-Cheng Huang,Kuan-Chieh Wang,James Zou,Serena Yeung

Recent multi-modal contrastive learning models have demonstrated the ability to learn an embedding space suitable for building strong vision classifiers, by leveraging the rich information in large-scale image-caption datasets. Our work highlights a distinct advantage of this multi-modal embedding space: the ability to diagnose vision classifiers through natural language. The traditional process of diagnosing model behaviors in deployment settings involves labor-intensive data acquisition and annotation. Our proposed method can discover high-error data slices, identify influential attributes and further rectify undesirable model behaviors, without requiring any visual data. Through a combination of theoretical explanation and empirical verification, we present conditions under which classifiers trained on embeddings from one modality can be equivalently applied to embeddings from another modality. On a range of image datasets with known error slices, we demonstrate that our method can effectively identify the error slices and influential attributes, and can further use language to rectify failure modes of the classifier.

Harnessing Out-Of-Distribution Examples via Augmenting Content and Style

Zhuo Huang,Xiaobo Xia,Li Shen,Bo Han,Mingming Gong,Chen Gong,Tongliang Liu

Machine learning models are vulnerable to Out-Of-Distribution (OOD) examples, such a problem has drawn much attention. However, current methods lack a full understanding of different types of OOD data: there are benign OOD data that can be properly adapted to enhance the learning performance, while other malign OOD data would severely degenerate the classification result. To Harness OOD data, this paper proposes HOOD method that can leverage the content and style from each image instance to identify benign and malign OOD data. Particularly, we design a variational inference framework to causally disentangle content and style features by constructing a structural causal model. Subsequently, we augment the content and style through an intervention process to produce malign and benign OOD data, respectively. The benign OOD data contain novel styles but hold our interested contents, and they can be leveraged to help train a style-invariant model. In contrast, the malign OOD data inherit unknown contents but carry familiar styles, by detecting them can improve model robustness against deceiving anomalies. Thanks to the proposed novel disentanglement and data augmentation techniques, HOOD can effectively deal with OOD examples in unknown and open environments, whose effectiveness is empirically validated in three typical OOD applications including OOD detection, open-set semi-supervised learning, and open-set domain adaptation.

On Stability and Generalization of Bilevel Optimization Problems

Meng Ding,Mingxi Lei,Yunwen Lei,Di Wang,Jinhui Xu

(Stochastic) bilevel optimization is a frequently encountered problem in machine learning with a wide range of applications such as meta-learning, hyper-parameter optimization, and reinforcement learning. Most of the existing studies on this problem only focused on analyzing the convergence or improving the convergence rate, while little effort has been devoted to understanding its generalization behaviors. In this paper, we conduct a thorough analysis on the generalization of first-order (gradient-based) methods for the bilevel optimization problem. We first establish a fundamental connection between algorithmic stability and generalization error in different forms and give a high probability generalization bound which improves the previous best one from $O(\sqrt{n})$ to $O(\log n)$, where n is the sample size. We then provide the first stability bounds for the general case where both inner and outer level parameters are subject to continuous update, while existing work allows only the outer level parameter to be updated. Our analysis can be applied in various standard settings such as strongly-convex-strongly-convex (SC-SC), convex-convex (C-C), and nonconvex-nonconvex (NC-NC). Our analysis for the NC-NC setting can also be extended to a particular nonconvex-strongly-convex (NC-SC) setting that is commonly encountered in practice. Finally, we corroborate our theoretical analysis and demonstrate how iterations can affect the generalization error by experiments on meta-learning and hyper-parameter optimization.

Learning GFlowNets from partial episodes for improved convergence and stability

Kanika Madan,Jarrid Rector-Brooks,Maksym Korablyov,Emmanuel Bengio,Moksh Jain,Andrei Cristian Nica,Tom Bosc,Yoshua Bengio,Nikolay Malkin

Generative flow networks (GFlowNets) are a family of algorithms for training a sequential sampler of discrete objects under an unnormalized target density and have been successfully used for various probabilistic modeling tasks. Existing training objectives for GFlowNets are either local to states or transitions, or propagate a reward signal over an entire sampling trajectory. We argue that these alternatives represent opposite ends of a gradient bias-variance tradeoff and propose a way to exploit this tradeoff to mitigate its harmful effects. Inspired by the TD(λ) algorithm in reinforcement learning, we introduce subtrajectory balance or SubTB(λ), a GFlowNet training objective that can learn from partial action subsequences of varying lengths. We show that SubTB(λ) accelerates sampler convergence in previously studied and new environments and enables training GFlowNets in environments with longer action sequences and sparser reward landscapes than what was possible before. We also perform a comparative analysis of stochastic gradient dynamics, shedding light on the bias-variance tradeoff in GFlowNet training and the advantages of subtrajectory balance.

****

DropIT: Dropping Intermediate Tensors for Memory-Efficient DNN Training

Joya Chen,Kai Xu,Yuhui Wang,Yifei Cheng,Angela Yao

A standard hardware bottleneck when training deep neural networks is GPU memory. The bulk of memory is occupied by caching intermediate tensors for gradient computation in the backward pass. We propose a novel method to reduce this footprint - Dropping Intermediate Tensors (DropIT). DropIT drops min-k elements of the intermediate tensors and approximates gradients from the sparsified tensors in the backward pass. Theoretically, DropIT reduces noise on estimated gradients and therefore has a higher rate of convergence than vanilla-SGD. Experiments show that we can drop up to 90\% of the intermediate tensor elements in fully-connected and convolutional layers while achieving higher testing accuracy for Visual Transformers and Convolutional Neural Networks on various tasks (e.g., classification, object detection, instance segmentation). Our code and models are available at https://github.com/chenjoya/dropit.

Self-attentive Rationalization for Graph Contrastive Learning

Sihang Li,Yanchen Luo,An Zhang,Xiang Wang,Xiangnan He,Tat-Seng Chua

Graph augmentation is the key component to reveal instance-discriminative features of a graph as its rationale in graph contrastive learning (GCL).

And existing rationale-aware augmentation mechanisms in GCL frameworks roughly fall into two categories and suffer from inherent limitations: (1) non-heuristic methods with the guidance of domain knowledge to preserve salient features, which require expensive expertise and lacks generality, or (2) heuristic augmentations with a co-trained auxiliary model to identify crucial substructures, which face not only the dilemma between system complexity and transformation diversity, but also the instability stemming from the co-training of two separated sub-models.

Inspired by recent studies on transformers, we propose $\underline{S}$elf-attentive $\underline{R}$ationale guided $\underline{G}$raph $\underline{C}$ontrastive $\underline{L}$earning (SR-GCL), which integrates rationale finder and encoder together, leverages the self-attention values in transformer module as a natural guidance to delineate semantically informative substructures from both node- and edge-wise views, and contrasts on rationale-aware augmented pairs.

On real world biochemistry datasets, visualization results verify the effectiveness of self-attentive rationalization and the performance on downstream tasks demonstrates the state-of-the-art performance of SR-GCL for graph model pre-training.

****

A Unified Framework for Soft Threshold Pruning

Yanqi Chen,Zhengyu Ma,Wei Fang,Xiawu Zheng,Zhaofei Yu,Yonghong Tian

Soft threshold pruning is among the cutting-edge pruning methods with state-of-the-art performance. However, previous methods either perform aimless searching on the threshold scheduler or simply set the threshold trainable, lacking theoretical explanation from a unified perspective. In this work, we reformulate soft threshold pruning as an implicit optimization problem solved using the Iterative Shrinkage-Thresholding Algorithm (ISTA), a classic method from the fields of sparse recovery and compressed sensing. Under this theoretical framework, all threshold tuning strategies proposed in previous studies of soft threshold pruning are concluded as different styles of tuning L_1-regularization term. We further derive an optimal threshold scheduler through an in-depth study of threshold scheduling based on our framework. This scheduler keeps L_1-regularization coefficient stable, implying a time-invariant objective function from the perspective of optimization. In principle, the derived pruning algorithm could sparsify any mathematical model trained via SGD. We conduct extensive experiments and verify its state-of-the-art performance on both Artificial Neural Networks (ResNet-50 and MobileNet-V1) and Spiking Neural Networks (SEW ResNet-18) on ImageNet datasets. On the basis of this framework, we derive a family of pruning methods, including sparsify-during-training, early pruning, and pruning at initialization. The code is available at https://github.com/Yanqi-Chen/LATS.

Efficient Automatic Machine Learning via Design Graphs

Ying-Xin Wu,Jiaxuan You,Jure Leskovec,Zhitao Ying

Despite the success of automated machine learning (AutoML), which aims to find the best design, including the architecture of deep networks and hyper-parameters, conventional AutoML methods are computationally expensive and hardly provide insights into the relations of different model design choices. To tackle the challenges, we propose FALCON, an efficient sample-based method to search for the optimal model design. Our key insight is to model the design space of possible model designs as a design graph, where the nodes represent design choices, and the edges denote design similarities. FALCON features 1) a task-agnostic module, which performs message passing on the design graph via a Graph Neural Network (GNN), and 2) a task-specific module, which conducts label propagation of the known model performance information on the design graph. Both modules are combined to predict the design performances in the design space, navigating the search direction. We conduct extensive experiments on 27 node and graph classification tasks from various application domains, and an image classification task on the CIFAR-10 dataset. We empirically show that FALCON can efficiently obtain the well-performing designs for each task using only 30 explored nodes. Specifically, FALCON has a comparable time cost with the one-shot approaches while achieving an average improvement of 3.3% compared with the best baselines.

TaskPrompter: Spatial-Channel Multi-Task Prompting for Dense Scene Understanding

Hanrong Ye,Dan Xu

Learning effective representations simultaneously from multiple tasks in a unified network framework is a fundamental paradigm for multi-task dense visual scene understanding. This requires joint modeling (i) task-generic and (ii) task-specific representations, and (iii) cross-task representation interactions. Existing works typically model these three perspectives with separately designed structures, using shared network modules for task-generic learning, different modules for task-specific learning, and establishing connections among these components for cross-task interactions. It is barely explored in the literature to model these three perspectives in each network layer in an end-to-end manner, which can not only minimize the effort of carefully designing empirical structures for the three multi-task representation learning objectives, but also greatly improve the representation learning capability of the multi-task network since all the model capacity will be used to optimize the three objectives together. In this paper, we propose TaskPrompter, a novel spatial-channel multi-task prompting transformer framework to achieve this target. Specifically, we design a set of spatial-channel task prompts and learn their spatial- and channel interactions with the shared image tokens in each transformer layer with attention mechanism, as aggregating spatial and channel information is critical for dense prediction tasks. Each task prompt learns task-specific representation for one task, while all the prompts can jointly contribute to the learning of the shared image token representations, and the interactions between different task prompts model the cross-task relationship. To decode dense predictions for multiple tasks with the learned spatial-channel task prompts from transformer, we accordingly design a dense task prompt decoding mechanism, which queries the shared image tokens using task prompts to obtain spatial- and channel-wise task-specific representations. Extensive experiments on two challenging multi-task dense scene understanding benchmarks (i.e. NYUD-V2 and PASCAL-Context) show the superiority of the proposed framework and TaskPrompter establishes significant state-of-the-art performances on multi-task dense predictions. Codes and models are made publicly available at https://github.com/prismformore/Multi-Task-Transformer.

Individual Privacy Accounting for Differentially Private Stochastic Gradient Descent

Da Yu,Gautam Kamath,Janardhan Kulkarni,Tie-Yan Liu,Jian Yin,Huishuai Zhang

Differentially private stochastic gradient descent (DP-SGD) is the workhorse algorithm for recent advances in private deep learning. It provides a single privacy guarantee to all datapoints in the dataset. We propose an efficient algorithm to compute privacy guarantees for individual examples when releasing models trained by DP-SGD. We use our algorithm to investigate individual privacy parameters across a number of datasets. We find that most examples enjoy stronger privacy guarantees than the worst-case bound. We further discover that the training loss and the privacy parameter of an example are well-correlated. This implies groups that are underserved in terms of model utility are simultaneously underserved in terms of privacy guarantee. For example, on CIFAR-10, the average ε of the class with the lowest test accuracy is 43.6% higher than that of the class with the highest accuracy. We also run membership inference attacks to show this reflects disparate empirical privacy risks.

****

CI-VAE: a Class-Informed Deep Variational Autoencoder for Enhanced Class-Specific Data Interpolation

Mohsen Nabian,Zahra Eftekhari,Alec Wong

We proposed Class-Informed Variational Autoencoder (CI-VAE) to enable interpolation between arbitrary pairs of observations of the same class. CI-VAE combines the general VAE architecture with a linear discriminator layer on the latent space to enforce the construction of a latent space such that observations from different classes are linearly separable. In conventional VAEs, class overlapping on the latent space usually occurs. However, in CI-VAE, the enforced linear separability of classes on the latent space allows for robust latent-space linear traversal and data generation between two arbitrary observations of the same class. Class-specific data interpolation has extensive potential applications in science, particularly in biology, such as uncovering the biological trajectory of dise ases or cancer. We used the MNIST dataset of handwritten digits as a case study to compare the performance of CI-VAE and VAE in class-specific data augmentation. We showed that CI-VAE significantly improved class-specific linear traversal and data augmentation compared with VAE while maintaining comparable reconstruction error. In a study of Colon cancer genomics data, we showed that the interpolation between normal cells and tumor cells using CI-VAE may enhance our understanding of cancer development.

Attention De-sparsification Matters: Inducing Diversity in Digital Pathology Representation Learning

Saarthak Kapse,Srijan Das,Jingwei Zhang,Rajarsi R. Gupta,Joel Saltz,Dimitris Samaras,Prateek Prasanna

In this work, we develop Di-SSL, a Diversity-inducing Self-Supervised Learning technique for histopathology image analysis. SSL techniques, such as contrastive and non-contrastive approaches, have been shown to learn rich and effective representations without any human supervision. Lately, computational pathology has also benefited from the resounding success of SSL. In this work, we develop a novel domain-aware pretext task to enhance representation learning in digital pathology. Our analysis of vanilla SSL-pretrained models’ attention distribution reveals an insightful observation: sparsity in attention, i.e, models tends to localize most of their attention to some prominent patterns in the image. Although atten- tion sparsity can be beneficial in natural images due to these prominent patterns being the object of interest itself, this can be sub-optimal in digital pathology; this is because, unlike natural images, digital pathology scans are not object-centric, but rather a complex phenotype of various spatially intermixed biological com- ponents. Inadequate diversification of attention in these complex images could result in crucial information loss. To address this, we first leverage cell segmenta- tion to densely extract multiple histopathology-specific representations. We then propose a dense pretext task for SSL, designed to match the multiple correspond- ing representations between the views. Through this, the model learns to attend to various components more closely and evenly, thus inducing adequate diversi- fication in attention for capturing context rich representations. Through quantita- tive and qualitative analysis on multiple slide-level tasks across cancer types, and patch-level classification tasks, we demonstrate the efficacy of our method and observe that the attention is more globally distributed. Specifically, we obtain a relative improvement in accuracy of up to 6.9% in slide-level and 2% in patch level classification tasks (corresponding AUC improvement up to 7.9% and 0.7%, respectively) over a baseline SSL model.

Learning Domain-Agnostic Representation for Disease Diagnosis

Churan Wang,Jing Li,Xinwei Sun,Fandong Zhang,Yizhou Yu,Yizhou Wang

In clinical environments, image-based diagnosis is desired to achieve robustness on multi-center samples. Toward this goal, a natural way is to capture only clinically disease-related features. However, such disease-related features are often entangled with center-effect, disabling robust transferring to unseen centers/domains. To disentangle disease-related features, we first leverage structural causal modeling to explicitly model disease-related and center-effects that are provable to be disentangled from each other. Guided by this, we propose a novel Domain Agnostic Representation Model (DarMo) based on variational Auto-Encoder. To facilitate disentanglement, we design domain-agnostic and domain-aware encoders to respectively capture disease-related features and varied center-effects by incorporating a domain-aware batch normalization layer. Besides, we constrain the disease-related features to well predict the disease label as well as clinical attributes, by leveraging Graph Convolutional Network (GCN) into our decoder. The effectiveness and utility of our method are demonstrated by the superior performance over others on both public datasets and inhouse datasets.

Boosting Out-of-Distribution Detection with Multiple Pre-trained Models

Feng Xue,Zi He,Chuanlong Xie,Falong Tan,Zhenguo Li

Out-of-Distribution (OOD) detection, i.e., identifying whether an input is sampl ed from a novel distribution other than the training distribution, is a critical task for safely deploying machine learning systems in the open world. Recently, post hoc detection utilizing pre-trained models has shown promising performance and can be scaled to large-scale problems. This advance raises a natural question: Can we leverage the diversity of multiple pre-trained models to improve the performance of post hoc detection methods? In this work, we propose a detection enhancement method by ensembling multiple detection decisions derived from a zoo of pre-trained models. Our approach uses the p-value instead of the commonly used hard threshold and leverages a fundamental framework of multiple hypothesis testing to control the true positive rate for In-Distribution (ID) data. We focus on the usage of model zoos and provide systematic empirical comparisons with current state-of-the-art methods on various OOD detection benchmarks. The proposed ensemble scheme shows consistent improvement compared to single-model detectors and significantly outperforms the current competitive methods. Our method substantially improves the relative performance by 65.40% and 26.96% on the CIFAR10 and ImageNet benchmarks.

Minimax Optimal Kernel Operator Learning via Multilevel Training

Jikai Jin,Yiping Lu,Jose Blanchet,Lexing Ying

Learning mappings between infinite-dimensional function spaces have achieved empirical success in many disciplines of machine learning, including generative modeling, functional data analysis, causal inference, and multi-agent reinforcement learning. In this paper, we study the statistical limit of learning a Hilbert-Schmidt operator between two infinite-dimensional Sobolev reproducing kernel Hilbert spaces. We establish the information-theoretic lower bound in terms of the Sobolev Hilbert-Schmidt norm and show that a regularization that learns the spectral components below the bias contour and ignores the ones above the variance contour can achieve the optimal learning rate. At the same time, the spectral components between the bias and variance contours give us flexibility in designing computationally feasible machine learning algorithms. Based on this observation, we develop a multilevel kernel operator learning algorithm that is optimal when learning linear operators between infinite-dimensional function spaces.

MixQuant: A Quantization Bit-width Search that Can Optimize the Performance of your Quantization Method

Eliska Kloberdanz,Wei Le

Quantization is a technique for creating efficient Deep Neural Networks (DNNs), which involves performing computations and storing tensors at lower bit-widths than f32 floating point precision. Quantization reduces model size and inference latency, and therefore allows for DNNs to be deployed on platforms with constrained computational resources and real-time systems. However, quantization can lead to numerical instability caused by roundoff error which leads to inaccurate computations and therefore, a decrease in quantized model accuracy. In this paper we focus on simulated quantized inference, where the quantized model parameters are stored in low-precision, but the mathematical operations on them (e.g. matrix multiplications and additions) are performed with floating point arithmetic. This means that the DNN parameters are first quantized from f32 to, for example, int4, and then dequantized back to f32 to perform computations. We show that the roundtrip process of quantizing and dequantizing the model parameters leads to roundoff error, which may lead to numerical instability. Similarly to prior works, which have shown that both biases and activations are more sensitive to quantization and are best kept in full precision or quantized with higher bit-widths, we show that some weights are more sensitive than others which should be reflected on their quantization bit-width. To that end we propose MixQuant, a search algorithm that finds the optimal custom quantization bit-width for each layer weight based on roundoff error and can be combined with any quantization method as a form of pre-processing optimization. We show that combining MixQuant with BRECQ, a state-of-the-art quantization method, yields better quantized model accuracy than BRECQ alone. Additionally, we combine MixQuant with vanilla asymmetric quantization to show that MixQuant has the potential to optimize the performance o f any quantization technique.

Logical Entity Representation in Knowledge-Graphs for Differentiable Rule Learning

Chi Han,Qizheng He,Charles Yu,Xinya Du,Hanghang Tong,Heng Ji

Probabilistic logical rule learning has shown great strength in logical rule mining and knowledge graph completion. It learns logical rules to predict missing edges by reasoning on existing edges in the knowledge graph. However, previous efforts have largely been limited to only modeling chain-like Horn clauses such as R1(x; z) ^ R2(z; y)) H(x; y). This formulation overlooks additional contextual information from neighboring sub-graphs of entity variables x, y and z. Intuitively, there is a large gap here, as local sub-graphs have been found to provide important information for knowledge graph completion. Inspired by these observations, we propose Logical Entity RePresentation (LERP) to encode contextual information of entities in the knowledge graph. A LERP is designed as a vector of probabilistic logical functions on the entity’s neighboring sub-graph. It is an interpretable representation while allowing for differentiable optimization. We can then incorporate LERP into probabilistic logical rule learning to learn more expressive rules. Empirical results demonstrate that with LERP, our model outperforms other rule learning methods in knowledge graph completion and is comparable or even superior to state-of-the-art black-box methods. Moreover, we find that our model can discover a more expressive family of logical rules. LERP can also be further combined with embedding learning methods like TransE to make it more interpretable.

S-SOLVER: Numerically Stable Adaptive Step Size Solver for Neural ODEs

Eliska Kloberdanz,Wei Le

A neural ordinary differential equation (ODE) is a relation between an unknown function and its derivatives, where the ODE is parameterized by a neural network. Therefore, to obtain a solution to a neural ODE requires a solver that performs numerical integration. Dopri5 is one of the most popular neural ODE solvers and also the default solver in torchdiffeq, a PyTorch library of ODE solvers. It is an adaptive step size solver based on the Runge-Kutta (RK) numerical methods. These methods rely on estimation of the local truncation error to select and adjust integration step size, which determines the numerical stability of the solution. A step size that is too large leads to numerical instability, while a step size that is too small may cause the solver to take unnecessarily many steps, which is computationally expensive and may even cause rounding error build up. Therefore, accurate local truncation error estimation is paramount for choosing an appropriate step size to obtain an accurate, numerically stable, and fast solution to the ODE. In this paper we propose a novel local truncation error approximation that is the first to consider solutions of four different RK orders to obtain a more reliable error estimate. This leads to a novel solver S-SOLVER (Stable Solver), which is more numerically stable; and therefore accurate. We demonstrate S-SOLVER's competitive performance in experiments on image recognition with ODE-Net, learning hamiltonian dynamics with Symplectic ODE-Net, and continuous normalizing flows (CNF).

TT-NF: Tensor Train Neural Fields

Anton Obukhov,Mikhail Usvyatsov,Christos Sakaridis,Konrad Schindler,Luc Van Gool

Learning neural fields has been an active topic in deep learning research, focusing, among other issues, on finding more compact and easy-to-fit representations. In this paper, we introduce a novel low-rank representation termed Tensor Train Neural Fields (TT-NF) for learning neural fields on dense regular grids and efficient methods for sampling from them. Our representation is a TT parameterization of the neural field, trained with backpropagation to minimize a non-convex objective. We analyze the effect of low-rank compression on the downstream task quality metrics in two settings. First, we demonstrate the efficiency of our method in a sandbox task of tensor denoising, which admits comparison with SVD-based schemes designed to minimize reconstruction error. Furthermore, we apply the pr oposed approach to Neural Radiance Fields, where the low-rank structure of the field corresponding to the best quality can be discovered only through learning.

****

Partial transportability for domain generalization

Alexis Bellot,Elias Bareinboim

Learning prediction models that generalize to related domains is one of the most fundamental challenges in artificial intelligence. There exists a growing literature that argues for learning invariant associations using data from multiple source domains. However, whether invariant predictors generalize to a given target domain depends crucially on the assumed structural changes between domains. Using the perspective of transportability theory, we show that invariance learning, and the settings in which invariant predictors are optimal in terms of worst-case losses, is a special case of a more general partial transportability task. Specifically, the partial transportability task seeks to identify / bound a conditional expectation $\mathbb E_{P_{\pi^*}}[y\mid\mathbf x]$ in an unseen domain π^* using knowledge of qualitative changes across domains in the form of causal graphs and data from source domains $\pi^1,\dots,\pi^k$. We show that solutions to this problem have a much wider generalization guarantee that subsumes those of invariance learning and other robust optimization methods that are inspired by causality. For computations in practice, we develop an algorithm that provably provides tight bounds asymptotically in the number of data samples from source domains for any partial transportability problem with discrete observables and illustrate its use on synthetic datasets.

Feint in Multi-Player Games

Junyu Liu,Wangkai Jin,Xiangjun Peng

This paper introduces the first formalization, implementation and quantitative evaluation of \feint in Multi-Player Games. Our work first formalizes \feint from the perspective of Multi-Player Games, in terms of the temporal, spatial and their collective impacts. The formalization is built upon \textit{Non-transitive Active Markov Game Model}, where \feint can have a considerable amount of impacts. Then, our work considers practical implementation details of \feint in Multi-Player Games, under the state-of-the-art progress of multi-agent modeling to date (namely Multi-Agent Reinforcement Learning). Finally, our work quantitatively examines the effectiveness of our design, and the results show that our design of Feint can (1) greatly improve the reward gains from the game; (2) significantly improve the diversity of Multi-Player Games; and (3) only incur negligible overheads in terms of time consumption. We conclude that our design of Feint is effective and practical, to make Multi-Player Games more interesting.

Succinct Compression: Lossless Compression for Fast and Memory-Efficient Deep Neural Network Inference

Yicun Duan,Xiangjun Peng

This paper introduces ``Succinct Compression”, a method to provide lossless compression of Deep Neural Network (DNN) models for fast and memory-efficient inference. The key insight of our method leverages the concept of \textit{Succinct Data Structures}, which supports fast queries without decompressing the compressed representations. Our method consists of three new insights. First, we introduce two basic building blocks to formulate DNN models, and how they can be extended to be synergistic with compressed models (e.g. pruned or quantized models). Then, we propose a scheme to enable mixed-formulation inference for different layers, to better extract its benefits. Finally, our method exploits a specialized execution pipeline to incorporate different model formulations for fast inference. We quantitatively demonstrate that: our method can (1) enable faster and more memory-efficient inference on uncompressed models; (2) be synergistic with a variety of structure-altered/unaltered compression schemes with better speedup and compression ratio, while preserving the accuracy; and (3) can outperform all other state-of-the-art Model Coding approaches.

BEVDistill: Cross-Modal BEV Distillation for Multi-View 3D Object Detection
Zehui Chen,Zhenyu Li,Shiquan Zhang,Liangji Fang,Qinhong Jiang,Feng Zhao

3D object detection from multiple image views is a fundamental and challenging task for visual scene understanding. Owing to its low cost and high efficiency, multi-view 3D object detection has demonstrated promising application prospects. However, accurately detecting objects through perspective views is extremely difficult due to the lack of depth information. Current approaches tend to adopt heavy backbones for image encoders, making them inapplicable for real-world deployment. Different from the images, LiDAR points are superior in providing spatial cues, resulting in highly precise localization. In this paper, we explore the incorporation of LiDAR-based detectors for multi-view 3D object detection. Instead of directly training a depth prediction network, we unify the image and LiDAR features in the Bird-Eye-View (BEV) space and adaptively transfer knowledge across non-homogenous representations in a teacher-student paradigm. To this end, we propose BEVDistill, a cross-modal BEV knowledge distillation (KD) framework for multi-view 3D object detection.

Extensive experiments demonstrate that the proposed method outperforms current KD approaches on a highly-competitive baseline, BEVFormer, without introducing any extra cost in the inference phase. Notably, our best model achieves 59.4 NDS on the nuScenes test leaderboard, achieving new state-of-the-arts in comparison with various image-based detectors. Code will be available at https://github.com/zehuichen123/BEVDistill.

Expanding Datasets With Guided Imagination
Yifan Zhang,Zhou Daquan,Bryan Hooi,Kai Wang,Jiashi Feng

The power of Deep Neural Networks (DNNs) depends heavily on the training data quantity, quality and diversity. However, in many real scenarios, it is costly and time-consuming to collect and annotate large-scale data. This has severely hindered the application of DNNs. To address this challenge, we explore a new task of dataset expansion, which seeks to automatically create new labeled samples to expand a small dataset. To this end, we present a Guided Imagination Framework (GIF) that leverages the recently developed big generative models (e.g., DALL-E2) to ``imagine'' and create informative new data from seed data to expand small datasets. Specifically, GIF conducts imagination by optimizing the latent features of seed data in a semantically meaningful space, which are fed into the generative models to generate photo-realistic images with new contents. For guiding the imagination towards creating samples useful for model training, we exploit the zero-shot recognition ability of CLIP and introduce three criteria to encourage informative sample generation, i.e., prediction consistency, entropy maximization and diversity promotion. With these essential criteria as guidance, GIF works well for expanding datasets in different domains, leading to 29.9\% accuracy gain on average over six natural image datasets, and 10.4\% accuracy gain on average over three medical image datasets. The source code will be made public.

ThinkSum: Probabilistic reasoning over sets using large language models
Batu Ozturkler,Nikolay Malkin,Zhen Wang,Nebojsa Jojic

Large language models (LLMs) have a substantial capacity for high-level analogical reasoning: reproducing patterns in linear text that occur in their training data (zero-shot evaluation) or in the provided context (few-shot in-context learning). However, recent studies show that even the largest LLMs fail in scenarios that require reasoning over multiple objects or facts or making sequences of logical deductions. We propose a two-stage probabilistic inference paradigm, ThinkSum, that reasons over sets of objects or facts in a structured manner. In the first stage (Think -- 'fast' retrieval of associations), a LLM is queried in parallel over a set of phrases extracted from the prompt or an auxiliary model call. In the second stage (Sum -- 'slow' probabilistic inference or reasoning), the results of these queries are aggregated to make the final prediction. We demonstrate the advantages of ThinkSum on the BIG-bench suite of evaluation tasks, achieving improvements over the state of the art using GPT-family models on ten difficult tasks, often with far smaller model variants. We compare and contrast ThinkS um with other proposed modifications to direct prompting of LLMs, such as variants of chain-of-thought prompting. We argue that because the probabilistic inference in ThinkSum is performed outside of calls to the LLM, ThinkSum is less sensitive to prompt design, yields more interpretable predictions, and can be flexibly combined with latent variable models to extract structured knowledge from LLMs.

****

Confidence and Dispersity Speak: Characterising Prediction Matrix for Unsupervised Accuracy Estimation

Weijian Deng,Yumin Suh,Stephen Gould,Liang Zheng

This work focuses on estimating how well a model performs on out-of-distribution (OOD) datasets without using labels. Our intuition is that a well-performing model should give predictions with high confidence and high dispersity. While recent methods study the prediction confidence, this work newly finds dispersity is another informative cue. Confidence reflects whether the individual prediction is certain; dispersity indicates how the overall predictions are distributed across all categories. To achieve a more accurate estimation, we propose to jointly consider these two properties by using the nuclear norm of the prediction matrix. In our experiments, we extensively validate the effectiveness of nuclear norm for various models (e.g., ViT and ConvNeXt), different datasets (e.g., ImageNet and CUB-200), and diverse types of distribution shifts (e.g., style shift and reproduction shift). We show that the nuclear norm is more accurate and robust in predicting OOD accuracy than existing methods. Lastly, we study the limitation of the nuclear norm and discuss potential directions.

Design of the topology for contrastive visual-textual alignment

Zhun Sun

Pre-training weakly related image-text pairs in the contrastive style shows great power in learning semantic aligning cross-modal models. The common choice to measure the distance between the feature representations of the image-text pairs is the cosine similarity, which can be considered as the negative inner product distance of features embedded on a sphere, mathematically. However, empirically, aligning image-text pairs on the spherical topology is vulnerable to the semantic ambiguity phenomenon resulting from the noise in the pre-training datasets. Specifically, under the noisy training data, instead of the optimal alignment-uniformity solution, the system would achieve an equilibrium (a gap between distances of positive and negative pairs), when the gradients for attraction and repulsion are neutralized. Although intuitively, the model should always find this equilibrium given a sufficiently long training scheme, its numerical values might be out of the distance range (e.g. [-1, 1] for the cosine similarity). In the practice of former studies, this problem is partly tackled by introducing a learnable softmax temperature parameter, in other words, by explicitly scaling the range of the distance function. In this work, we alternatively design the topology of embedding space and its endowed distance function. Motivated by studies that make use of Riemannian geometry for visual tasks, we propose a rather simple solution to address the aforementioned equilibrium problem. That is, we map the feature representations onto the oblique manifold endowed with the negative inner product as the distance function. In the experimental analysis, we show that we can improve the baseline performance by a large margin (e.g. 4\% in the zero-shot image to text retrieval task) by changing only two lines of the training codes.

****

Slimmable Networks for Contrastive Self-supervised Learning

Shuai Zhao,Xiaohan Wang,Linchao Zhu,Yi Yang

Self-supervised learning makes great progress in large model pre-training but suffers in training small models. Previous solutions to this problem mainly rely on knowledge distillation and indeed have a two-stage learning procedure: first train a large teacher model, then distill it to improve the generalization ability of small ones. In this work, we present a new one-stage solution to obtain pre-trained small models without extra teachers: slimmable networks for contrastive self-supervised learning (SlimCLR). A slimmable network contains a full network and several weight-sharing sub-networks. We can pre-train for only one time and obtain various networks including small ones with low computation costs. However, in self-supervised cases, the interference between weight-sharing networks leads to severe performance degradation. One evidence of the interference is gradient imbalance: a small proportion of parameters produces dominant gradients during backpropagation, and the main parameters may not be fully optimized. The divergence in gradient directions of various networks may also cause interference between networks. To overcome these problems, we make the main parameters produce dominant gradients and provide consistent guidance for sub-networks via three techniques: slow start training of sub-networks, online distillation, and loss re-weighting according to model sizes. Besides, a switchable linear probe layer is applied during linear evaluation to avoid the interference of weight-sharing linear layers. We instantiate SlimCLR with typical contrastive learning frameworks and achieve better performance than previous arts with fewer parameters and FLOPs.

****

A Multi-Grained Self-Interpretable Symbolic-Neural Model For Single/Multi-Labeled Text Classification

Xiang Hu,XinYu KONG,Kewei Tu

Deep neural networks based on layer-stacking architectures have historically suffered from poor inherent interpretability. Meanwhile, symbolic probabilistic models function with clear interpretability, but how to combine them with neural networks to enhance their performance remains to be explored. In this paper, we try to marry these two systems for text classification via a structured language model. We propose a Symbolic-Neural model that can learn to explicitly predict class labels of text spans from a constituency tree without requiring any access to span-level gold labels. As the structured language model learns to predict constituency trees in a self-supervised manner, only raw texts and sentence-level labels are required as training data, which makes it essentially a general constituent-level self-interpretable classification model. Our experiments demonstrate that our approach could achieve good prediction accuracy in downstream tasks. Meanwhile, the predicted span labels are consistent with human rationales to a certain degree.

****

Suppressing the Heterogeneity: A Strong Feature Extractor for Few-shot Segmentation

Zhengdong Hu,Yifan Sun,Yi Yang

This paper tackles the Few-shot Semantic Segmentation (FSS) task with focus on learning the feature extractor. Somehow the feature extractor has been overlooked by recent state-of-the-art methods, which directly use a deep model pretrained on ImageNet for feature extraction (without further fine-tuning). Under this background, we think the FSS feature extractor deserves exploration and observe the heterogeneity (i.e., the intra-class diversity in the raw images) as a critical challenge hindering the intra-class feature compactness. The heterogeneity has three levels from coarse to fine: 1) Sample-level: the inevitable distribution gap between the support and query images makes them heterogeneous from each other. 2) Region-level: the background in FSS actually contains multiple regions with different semantics. 3) Patch-level: some neighboring patches belonging to a same class may appear quite different from each other. Motivated by these observations, we propose a feature extractor with Multi-level Heterogeneity Suppressing (MuHS). MuHS leverages the attention mechanism in transformer backbone to effectively suppress all these three-level heterogeneity. Concretely, MuHS reinforces the attention / interaction between different samples (query and support), different regions and neighboring patches by constructing cross-sample attention, cross-region interaction and a novel masked image segmentation (inspired by the recent masked image modeling), respectively. We empirically show that 1) MuHS brings consistent improvement for various FSS heads and 2) using a simple linear classification head, MuHS sets new states of the art on multiple FSS datasets, validating the importance of FSS feature learning.

Communication Efficient Fair Federated Recommender System

KIRANDEEP KAUR,Sujit Gujar,Shweta Jain

Federated Recommender Systems (FRSs) aim to provide recommendations to clients in a distributed manner with privacy preservation. FRSs suffer from high communication costs due to the communication between the server and many clients. Some past literature on federated supervised learning shows that sampling clients randomly improve communication efficiency without jeopardizing accuracy. However, each user is considered a separate client in FRS and clients communicate only item gradients. Thus, incorporating random sampling and determining the number of clients to be sampled in each communication round to retain the model's accuracy in FRS becomes challenging. This paper provides sample complexity bounds on the number of clients that must be sampled in an FRS to preserve accuracy. Next, we consider the issue of demographic bias in FRS, quantified as the difference in the average error rates across different groups. Supervised learning algorithms mitigate the group bias by adding the fairness constraint in the training loss, which requires sharing protected attributes with the server. This is prohibited in a federated setting to ensure clients' privacy. We design \ouralgo, a Random Sampling based Fair Federated Recommender System, which trains to achieve a fair global model. In addition, it also trains local clients towards a fair global model to reduce demographic bias at the client level without the need to share their protected attributes. We empirically demonstrate all our results across the two most popular real-world datasets (ML1M, ML100k) and different sensitive features (age and gender) to prove that RS-FairFRS helps reduce communication cost and demographic bias with improved model accuracy.

****

Grassmannian Class Representation in Deep Learning

Haoqi Wang,Zhizhong Li,Wayne Zhang

We generalize the class representative vector found in deep classification networks to linear subspaces and show that the new formulation enables the simultaneous enhancement of the inter-class discrimination and intra-class feature variation. Traditionally, the logit is computed by the inner product between a feature and the class vector. In our modeling, classes are subspaces and the logit is defined as the norm of the projection from a feature onto the subspace. Since the set of subspaces forms Grassmann manifolds, finding the optimal subspace representation for classes is to optimize the loss on a Grassmannian. We integrate the Riemannian SGD into existing deep learning frameworks such that the class subspaces in a Grassmannian are jointly optimized with other model parameters in Euclidean. Compared to the vector form, subspaces have two appealing properties: they can be multi-dimensional and they are scaleless. Empirically, we reveal that these distinct characteristics improve various tasks. (1) Image classification. The new formulation brings the top-1 accuracy of ResNet50-D on ImageNet-1K from 78.04% to 79.37% using the standard augmentation in 100 training epochs. This confirms that the representative capability of subspaces is more powerful than vectors. (2) Feature transfer. Subspaces provide freedom for features to vary and we observed that the intra-class variability of features increases when the subspace dimensions are larger. Consequently, the quality of features is better for downstream tasks. The average transfer accuracy across 6 datasets improves from 77.98% to 80.12% compared to the strong baseline of vanilla softmax. (3) Long-tail classification. The scaleless property of subspaces benefits classification in the long-tail scenario and improves the accuracy of ImageNet-LT from 46.83% to 48.94% compared to the standard formulation. With these encouraging results, we believe that more applications could benefit from the Grassmannian class representation. Codes will be released.

****

Refining Visual Representation for Generalized Zero-Shot Recognition through Implicit-Semantics-Guided Metric Learning

YanHe Chen,Mei-Chen Yeh

Deep metric learning (DML) is effective to address the large intra- and the smal l inter-class variation problem in visual recognition; however, when applied for generalized zero-shot learning (GZSL) in which the label of a target image may belong to an unseen category, this technique can be easily biased towards seen classes. Alternatively in GZSL some form of semantic space is available, which plays an important role in relating seen and unseen classes and is widely used to guide the learning of visual representation. To take advantage of DML while avoiding overfitting to seen classes, we propose a novel representation learning framework$\textemdash$Metric Learning with Implicit Semantics (MLIS)$\textemdash$to refine discriminative and generalizable visual features for GZSL. Specifically, we disentangle the effects of semantics on feature extractor and image classification of the model, so that semantics only participate in feature learning, and classification only uses the refined visual features. We further relax the visual-semantic alignment requirement, avoiding performing pair-wise comparisons between the image and the class embeddings. Experimental results demonstrate that the proposed MLIS framework bridges DML and GZSL. It achieves state-of-the-art performance, and is robust and flexible to the integration with several metric learning based loss functions.

****

Reward Learning with Trees: Methods and Evaluation

Tom Bewley,Jonathan Lawry,Arthur Richards,Rachel Craddock,Ian Henderson

Recent efforts to learn reward functions from human feedback have tended to use deep neural networks, whose lack of transparency hampers our ability to explain agent behaviour or verify alignment. We explore the merits of learning intrinsically interpretable tree models instead. We develop a recently proposed method for learning reward trees from preference labels, and show it to be broadly competitive with neural networks on challenging high-dimensional tasks, with good robustness to limited or corrupted data. Having found that reward tree learning can be done effectively in complex settings, we then consider why it should be used, demonstrating that the interpretable reward structure gives significant scope for traceability, verification and explanation.

Achieve the Minimum Width of Neural Networks for Universal Approximation

Yongqiang Cai

The universal approximation property (UAP) of neural networks is fundamental for deep learning, and it is well known that wide neural networks are universal approximators of continuous functions within both the L^p norm and the continuous/uniform norm. However, the exact minimum width, $w_{\min}$, for the UAP has not been studied thoroughly. Recently, using a decoder-memorizer-encoder scheme, \citet{Park2021Minimum} found that $w_{\min} = \max(d_x+1,d_y)$ for both the L^p-UAP of ReLU networks and the C-UAP of ReLU+STEP networks, where d_x,d_y are the input and output dimensions, respectively. In this paper, we consider neural networks with an arbitrary set of activation functions. We prove that both C-UAP and L^p-UAP for functions on compact domains share a universal lower bound of the minimal width; that is, $w^*_{\min} = \max(d_x,d_y)$. In particular, the critical width, $w^*_{\min}$, for L^p-UAP can be achieved by leaky-ReLU networks, provided that the input or output dimension is larger than one. Our construction is based on the approximation power of neural ordinary differential equations and the ability to approximate flow maps by neural networks. The nonmonotone or discontinuous activation functions case and the one-dimensional case are also discussed.

H2RBox: Horizontal Box Annotation is All You Need for Oriented Object Detection

Xue Yang,Gefan Zhang,Wentong Li,Yue Zhou,Xuehui Wang,Junchi Yan

Oriented object detection emerges in many applications from aerial images to autonomous driving, while many existing detection benchmarks are annotated with horizontal bounding box only which is also less costive than fine-grained rotated box, leading to a gap between the readily available training corpus and the rising demand for oriented object detection. This paper proposes a simple yet effective oriented object detection approach called H2RBox merely using horizontal box annotation for weakly-supervised training, which closes the above gap and shows competitive performance even against those trained with rotated boxes. The cores of our method are weakly- and self-supervised learning, which predicts the angle of the object by learning the consistency of two different views. To our best knowledge, H2RBox is the first horizontal box annotation-based oriented object detector. Compared to an alternative i.e. horizontal box-supervised instance segmentation with our post adaption to oriented object detection, our approach is not susceptible to the prediction quality of mask and can perform more robustly in complex scenes containing a large number of dense objects and outliers. Experimental results show that H2RBox has significant performance and speed advantages over horizontal box-supervised instance segmentation methods, as well as lower memory requirements. While compared to rotated box-supervised oriented object detectors, our method shows very close performance and speed. The source code is available at PyTorch-based \href{https://github.com/yangxue0827/h2rbox-mmrotate}{MMRotate} and Jittor-based \href{https://github.com/yangxue0827/h2rbox-jittor}{JDet}.

Designing BERT for Convolutional Networks: Sparse and Hierarchical Masked Modeling

Keyu Tian,Yi Jiang,qishuai diao,Chen Lin,Liwei Wang,Zehuan Yuan

We identify and overcome two key obstacles in extending the success of BERT-style pre-training, or masked image modeling, to convolutional networks (convnets): (i) convolution operation cannot handle irregular, randomly masked input images; (ii) the single-scale nature of BERT pre-training is inconsistent with convnet’s hierarchical structure. For (i), we treat unmasked pixels as sparse voxels of 3D point clouds and use sparse convolution to encode. This is the first use of sparse convolution for 2D masked modeling. For (ii), we develop a hierarchical decoder to reconstruct images from multi-scale encoded features. Our method, called Sparse masKed modeling (SparK), is general: it can be used directly on any convolutional model without backbone modifications. We validate it on both classical (ResNet) and modern (ConvNeXt) models: on three downstream tasks, it surpasses both state-of-the-art contrastive learning and transformer-based masked modeling by similarly large margins (around +1.0%). The improvements on object detection and instance segmentation are more significant (up to +3.5%), validating the strong transferability of features learned. We also find SparK’s favorable scaling behavior by observing more gains on larger networks. All of these findings support the promising future of generative pre-training on convnets. Both codes and pre-trained models have been released at https://github.com/keyu-tian/SparK.

Functional Relation Field: A Model-Agnostic Framework for Multivariate Time Series Forecasting

Bing Yu,Ting Li,Jianguo Li,Bin Dong,Zhanxing Zhu

In multivariate time series forecasting, the most popular strategy for modeling the relationship between multiple time series is the construction of graph, where each time series is represented as a node and related nodes are connected by edges, i.e. spatial-temporal graph neural networks. The graph structure is either given apriori or learned based the similarity between nodes. However, the relationship between multiple time series is typically complicated, for instance, the sum of outflows from upstream nodes may be equal to the inflows of downstream nodes. Such relations widely exist in many real-world multivariate time series forecasting scenarios, yet are far from well studied. In these cases, graph might only be a crude description on the dependency between nodes. To this end, we explore a new framework to model the inter-node relationship in a more precise way based our proposed inductive bias for graphs, Functional Relation Field, where a group of functions parameterized by neural networks are learned to characterize the dependency between multiple time series. These learned functions are versatile: they can then be used to discover the underlying graph structure by identifying the most relevant neighbors of the target node; and on the other hand, the learned functions will form a “field” where the nodes in the backbone prediction networks are enforced to satisfy the constraints defined by these functions. Th e experiment is conducted on one toy dataset to show our approach can well recover the true constraint relationship between nodes. And two real-world MiniApp calling traffic and road network datasets are also considered with various different backbone networks. Results show that the prediction error can be reduced remarkably with the aid of the proposed functional relation field framework.

Motion-inductive Self-supervised Object Discovery in Videos

Shuangrui Ding,Weidi Xie,Yabo Chen,Rui Qian,XIAOPENG ZHANG,Hongkai Xiong,Qi Tian

In this paper, we consider the task of unsupervised object discovery in videos. Previous works have shown promising results via processing optical flows to segment objects. However, taking flow as input brings about two drawbacks. First, flow cannot capture sufficient cues when objects remain static or partially occluded. Second, it is challenging to establish temporal coherency from flow-only input, due to the missing texture information. To tackle these limitations, we propose a model for directly processing consecutive RGB frames, and infer the optical flow between any pair of frames using a layered representation, with the opacity channels being treated as the segmentation. Additionally, to enforce object permanence, we apply temporal consistency loss on the inferred masks from randomly-paired frames, which refer to the motions at different paces, and encourage the model to segment the objects even if they may not move at the current time point. Experimentally, we demonstrate superior performance over previous state-of-the-art methods on three public video segmentation datasets (DAVIS2016, SegTrackv2, and FBMS-59), while being computationally efficient by avoiding the overhead of computing optical flow as input.

Group DETR: Fast DETR Training with Group-Wise One-to-Many Assignment

Qiang Chen,Xiaokang Chen,Jian Wang,Shan Zhang,Haocheng Feng,Junyu Han,Errui Ding,Gang Zeng,Jingdong Wang

Detection Transformer (DETR) relies on one-to-one assignment for end-to-end object detection and lacks the capability of exploiting multiple positive object queries. We present a novel DETR training approach, named {\em Group DETR}, to support one-to-many assignment in a group-wise manner. To achieve it, we make simple modifications during training: (i) adopt K groups of object queries; (ii) conduct decoder self-attention on each group of object queries with the same parameters; (iii) perform one-to-one assignment for each group, leading to K positive object queries for each ground-truth object. In inference, we only use one group of object queries, making no modifications to model architectures and inference processes. Group DETR is a versatile training method and is applicable to various DETR variants. Our experiments show that Group DETR significantly speeds up the training convergences and improves the performances of various DETR-based methods.

Transcendental Idealism of Planner: Evaluating Perception from Planning Perspective for Autonomous Driving

Weixin Li,Xiaodong Yang

Evaluating the performance of perception module in autonomous driving is one of the most critical tasks in developing these complex intelligent systems. While module-level unit test methodologies adopted from traditional computer vision tasks are viable to a certain extent, it still remains far less explored to evaluate how changes in a perception module can impact the planning of an autonomous vehicle in a consistent and holistic manner. In this work, we propose a principled framework that provides a coherent and systematic understanding of how perception modules affect the planning of an autonomous vehicle that actually controls the vehicle. Specifically, planning of an autonomous vehicle is formulated as an expected utility maximisation problem, where all input signals from upstream modules jointly provide a world state description, and the planner aims to find the optimal action to execute by finding the solution to maximise the expected utility determined by both the world state and the action. We show that, under some mild conditions, the objective function can be represented as an inner product between the world state description and the utility function in a Hilbert space.

This geometric interpretation enables a novel way to formulate, analyse and evaluate the impact of noise in world state estimation on the solution to the problem, and leads to a universal quantitative metric for such purpose. The whole framework resembles the idea of transcendental idealism in the classical philosophy literature, which gives the name to our approach.
****
Pushing the Limits of Fewshot Anomaly Detection in Industry Vision: Graphcore
Guoyang Xie,Jinbao Wang,Jiaqi Liu,Yaochu Jin,Feng Zheng
In the area of few-shot anomaly detection (FSAD), efficient visual feature plays an essential role in the memory bank $\mathcal{M}$-based methods. However, these methods do not account for the relationship between the visual feature and its rotated visual feature, drastically limiting the anomaly detection performance. To push the limits, we reveal that rotation-invariant feature property has a significant impact on industrial-based FSAD. Specifically, we utilize graph representation in FSAD and provide a novel visual isometric invariant feature (VIIF) as an anomaly measurement feature. As a result, VIIF can robustly improve the anomaly discriminating ability and can further reduce the size of redundant features stored in $\mathcal{M}$ by a large amount. Besides, we provide a novel model GraphCore via VIIFs that can fast implement unsupervised FSAD training and improve the performance of anomaly detection. A comprehensive evaluation is provided for comparing GraphCore and other SOTA anomaly detection models under our proposed few-shot anomaly detection setting, which shows GraphCore can increase average AUC by 5.8%, 4.1%, 3.4%, and 1.6% on MVTec AD and by 25.5%, 22.0%, 16.9%, and 14.1% on MPDD for 1, 2, 4, and 8-shot cases, respectively.

Evaluating Weakly Supervised Object Localization Methods Right? A Study on Heatmap-based XAI and Neural Backed Decision Tree
Erico Tjoa,Cuntai Guan
Choe et al have investigated several aspects of Weakly Supervised Object Localization (WSOL) with only image label. They addressed the ill-posed nature of the problem and showed that WSOL has not significantly improved beyond the baseline method class activation mapping (CAM). We report the results of similar experiments on ResNet50 with some crucial differences: (1) we perform WSOL using heatmap-based eXplanaible AI (XAI) methods (2) our model is not class agnostic since we are interested in the XAI aspect as well. Under similar protocol, we find that XAI methods perform WSOL with very sub-standard MaxBoxAcc scores. The experiment is then repeated for the same model trained with Neural Backed Decision Tree (NBDT) and we found that vanilla CAM yields significantly better WSOL performance after NBDT training.
****
Representation Learning for Low-rank General-sum Markov Games
Chengzhuo Ni,Yuda Song,Xuezhou Zhang,Zihan Ding,Chi Jin,Mengdi Wang
We study multi-agent general-sum Markov games with nonlinear function approximation. We focus on low-rank Markov games whose transition matrix admits a hidden low-rank structure on top of an unknown non-linear representation. The goal is to design an algorithm that (1) finds an ε-equilibrium policy sample efficiently without prior knowledge of the environment or the representation, and (2) permits a deep-learning friendly implementation. We leverage representation learning and present a model-based and a model-free approach to construct an effective representation from collected data. For both approaches, the algorithm achieves a sample complexity of poly$(H,d,A,1/\varepsilon)$, where H is the game horizon, d is the dimension of the feature vector, A is the size of the joint action space and ε is the optimality gap. When the number of players is large, the above sample complexity can scale exponentially with the number of players in the worst case. To address this challenge, we consider Markov Games with a factorized transition structure and present an algorithm that escapes such exponential scaling. To our best knowledge, this is the first sample-efficient algorithm for multi-agent general-sum Markov games that incorporates (non-linear) function approximation. We accompany our theoretical result with a neural network-based implementation of our algorithm and evaluate it against the wide

ly used deep RL baseline, DQN with fictitious play.

Multi-Domain Long-Tailed Learning by Augmenting Disentangled Representations

Huaxiu Yao,Xinyu Yang,Allan Zhou,Chelsea Finn

There is an inescapable long-tailed class-imbalance issue in many real-world classification problems. Existing long-tailed classification methods focus on the single-domain setting, where all examples are drawn from the same distribution. However, real-world scenarios often involve multiple domains with distinct imbalanced class distributions. We study this multi-domain long-tailed learning problem and aim to produce a model that generalizes well across all classes and domains. Towards that goal, we introduce TALLY, which produces invariant predictors by balanced augmenting hidden representations over domains and classes. Built upon a proposed selective balanced sampling strategy, TALLY achieves this by mixing the semantic representation of one example with the domain-associated nuisances of another, producing a new representation for use as data augmentation. To improve the disentanglement of semantic representations, TALLY further utilizes a domain-invariant class prototype that averages out domain-specific effects. We evaluate TALLY on four long-tailed variants of classical domain generalization benchmarks and two real-world imbalanced multi-domain datasets. The results indicate that TALLY consistently outperforms other state-of-the-art methods in both subpopulation shift and domain shift.

Surgical Fine-Tuning Improves Adaptation to Distribution Shifts

Yoonho Lee,Annie S Chen,Fahim Tajwar,Ananya Kumar,Huaxiu Yao,Percy Liang,Chelsea Finn

A common approach to transfer learning under distribution shift is to fine-tune the last few layers of a pre-trained model, preserving learned features while also adapting to the new task. This paper shows that in such settings, selectively fine-tuning a subset of layers (which we term surgical fine-tuning) matches or outperforms commonly used fine-tuning approaches. Moreover, the type of distribution shift influences which subset is more effective to tune: for example, for image corruptions, fine-tuning only the first few layers works best. We validate our findings systematically across seven real-world data tasks spanning three types of distribution shifts. Theoretically, we prove that for two-layer neural networks in an idealized setting, first-layer tuning can outperform fine-tuning all layers. Intuitively, fine-tuning more parameters on a small target dataset can cause information learned during pre-training to be forgotten, and the relevant information depends on the type of shift.

****

Diversify and Disambiguate: Out-of-Distribution Robustness via Disagreement

Yoonho Lee,Huaxiu Yao,Chelsea Finn

Real-world machine learning problems often exhibit shifts between the source and target distributions, in which source data does not fully convey the desired behavior on target inputs. Different functions that achieve near-perfect source accuracy can make differing predictions on test inputs, and such ambiguity makes robustness to distribution shifts challenging. We propose DivDis, a simple two-stage framework for identifying and resolving ambiguity in data. DivDis first learns a diverse set of hypotheses that achieve low source loss but make differing predictions on target inputs. We then disambiguate by selecting one of the discovered functions using additional information, for example, a small number of target labels. Our experimental evaluation shows improved performance in subpopulation shift and domain generalization settings, demonstrating that DivDis can scalably adapt to distribution shifts in image and text classification benchmarks.

MaSS: Multi-attribute Selective Suppression

Chun-Fu Chen,Shaohan Hu,Zhonghao Shi,Prateek Gulati,Bill Moriarty,Marco Pistoia,Vincenzo Piuri,Pierangela Samarati

The recent rapid advances in the development and deployment of machine learning technologies largely depend on the vast richness of data available today, in terms of both the quantity and the rich content contained within. For example, biom

etric data such as images and voices could reveal people's attributes like age, gender, sentiment, and origin, whereas location/motion data could be used to infer people's activity levels, transportation modes, and life habits. Along with the new services and applications enabled by such technological advances, various governmental policies are put in place to regulate such data usage and protect people's privacy and rights. As a result, data owners often opt for simple data obfuscation (e.g., blur people's faces in images) or withholding data altogether, which leads to severe data quality degradation and greatly limits the data's potential utility.
Aiming for a sophisticated mechanism which gives data owners fine-grained control while retaining the maximal degree of data utility, we propose Multi-attribute Selective Suppression, or MaSS, a general framework for performing precisely targeted data surgery to simultaneously suppress any selected set of attributes while preserving the rest for downstream machine learning tasks. MaSS learns a data modifier through adversarial games between two sets of networks, where one is aimed at suppressing selected attributes, and the other ensures the retention of the rest of the attributes via general contrastive loss as well as explicit classification metrics. We carried out an extensive evaluation of our proposed method using multiple datasets from different domains including facial images, voice audio, and video clips, and obtained highly promising results in MaSS' generalizability and capability of drastically suppressing targeted attributes (e.g., reducing inference on such attributes to random guess) while imposing virtually no impact on the data's usability in other downstream ML tasks.
****

Neural Attention Memory

Hyoungwook Nam,Seung Byum Seo

Scaled dot-product attention has become the essence of state-of-the-art deep neural networks for various machine learning tasks. Though its ubiquitous accomplishments, it is inefficient for long sequence tasks and problematic for tasks requiring memory states such as compositional generalization. We propose a novel perspective of the attention mechanism by reinventing it as a memory architecture for neural networks, namely Neural Attention Memory (NAM). NAM follows the same query-key-value structure by constructing a memory matrix while reducing its computational complexity from quadratic to linear to the sequence length. NAM writes a memory matrix via the sum of outer products of value and unit key vectors, and reads it by multiplying the matrix with a unit query vector. Indeed, we show that our normalized outer-product attention mechanism is mathematically equivalent to the conventional attention mechanism. Then, we evaluate a NAM-based Transformer on long-range arena tasks and demonstrate its efficiency and efficacy. Finally, we propose two NAM-based memory-augmented neural networks, namely Long Short-Term Attention Memory (LSAM) and NAM Turing Machine (NAM-TM), and test their compositional generalization capability using four different tasks. LSAM replaces LSTM's long-term cell state with NAM memory matrix and NAM-TM implements a Turing tape data structure using NAM read/write primitives. The experimental results show that the proposed models outperform traditional Transformer and LSTM, as well as DNC. NAM opens up possibilities in diverse machine learning research problems, including hierarchical data modeling, efficient edge inference, and few-shot learning.

Meta Optimal Transport

Brandon Amos,Samuel Cohen,Giulia Luise,Ievgen Redko

We study the use of amortized optimization to predict optimal transport (OT) maps from the input measures, which we call Meta OT. This helps repeatedly solve similar OT problems between different measures by leveraging the knowledge and information present from past problems to rapidly predict and solve new problems. Otherwise, standard methods ignore the knowledge of the past solutions and suboptimally re-solve each problem from scratch. We instantiate Meta OT models in discrete and continuous (Wasserstein-2) settings between images, spherical data, and color palettes and use them to improve the computational time of standard OT solvers by multiple orders of magnitude.

****

On amortizing convex conjugates for optimal transport

Brandon Amos

This paper focuses on computing the convex conjugate operation that arises when solving Euclidean Wasserstein-2 optimal transport problems. This conjugation, which is also referred to as the Legendre-Fenchel conjugate or c-transform,is considered difficult to compute and in practice,Wasserstein-2 methods are limited by not being able to exactly conjugate the dual potentials in continuous space. To overcome this, the computation of the conjugate can be approximated with amortized optimization, which learns a model to predict the conjugate. I show that combining amortized approximations to the conjugate with a solver for fine-tuning significantly improves the quality of transport maps learned for the Wasserstein-2 benchmark by Korotin et al. (2021a) and is able to model many 2-dimensional couplings and flows considered in the literature. All of the baselines, methods, and solvers in this paper are available at http://github.com/facebookresearch/w2ot.

Example-based Planning via Dual Gradient Fields

Mingdong Wu,fangwei zhong,Yizhou Wang,Hao Dong

Path planning is one of the key abilities of an intelligent agent. However, both the learning-based and sample-based planners remain to require explicitly defining the task by manually designing the reward function or optimisation objectives, which limits the scope of implementation. Formulating the path planning problem from a new perspective, Example-based planning is to find the most efficient path to increase the likelihood of the target distribution by giving a set of target examples. In this work, we introduce Dual Gradient Fields (DualGFs), an offline-learning example-based planning framework built upon score matching. There are two gradient fields in DualGFs: a target gradient field that guides task completion and a support gradient field that ensures moving with environmental constraints. In the learning process, instead of interacting with the environment, the agents are trained with two offline examples, i.e., the target gradients and support gradients are trained by target examples and support examples, respectively. The support examples are randomly sampled from free space, e.g., states without collisions. DualGF is a weighted mixture of the two fields, combining the merits of the two fields together. To update the mixing ratio adaptively, we further propose a fields-balancing mechanism based on Lagrangian-Relaxation. Experimental results across four tasks (navigation, tracking, particle rearrangement, and room rearrangement) demonstrate the scalability and effectiveness of our method.

****

DualAfford: Learning Collaborative Visual Affordance for Dual-gripper Manipulation

Yan Zhao,Ruihai Wu,Zhehuan Chen,Yourong Zhang,Qingnan Fan,Kaichun Mo,Hao Dong

It is essential yet challenging for future home-assistant robots to understand and manipulate diverse 3D objects in daily human environments. Towards building scalable systems that can perform diverse manipulation tasks over various 3D shapes, recent works have advocated and demonstrated promising results learning visual actionable affordance, which labels every point over the input 3D geometry with an action likelihood of accomplishing the downstream task (e.g., pushing or picking-up). However, these works only studied single-gripper manipulation tasks, yet many real-world tasks require two hands to achieve collaboratively. In this work, we propose a novel learning framework, DualAfford, to learn collaborative affordance for dual-gripper manipulation tasks. The core design of the approach is to reduce the quadratic problem for two grippers into two disentangled yet interconnected subtasks for efficient learning. Using the large-scale PartNet-Mobility and ShapeNet datasets, we set up four benchmark tasks for dual-gripper manipulation. Experiments prove the effectiveness and superiority of our method over three baselines. We will release code and data upon acceptance.

GraphCG: Unsupervised Discovery of Steerable Factors in Graphs

Shengchao Liu,Chengpeng Wang,Weili Nie,Hanchen Wang,Jiarui Lu,Bolei Zhou,Jian Tang

Deep generative models have been widely developed for graph data such as molecular graphs and point clouds. Yet, much less investigation has been carried out on understanding the learned latent space of deep graph generative models. Such understandings can open up a unified perspective and provide guidelines for essential tasks like controllable generation. To this end, this work develops a method called GraphCG for unsupervised discovery of steerable factors in latent space of deep graph generative models. We first examine the representation space of the recent deep generative models trained for graph data, and observe that the learned representation space is not perfectly disentangled. Thus, our method is designed for discovering steerable factors of graph data in a model-agnostic and task-agnostic manner. Specifically, GraphCG learns the semantic-rich directions via maximizing the corresponding mutual information, where the edited graph along the same direction will possess certain steerable factors. We conduct experiments on two types of graph data, molecular graphs and point clouds. Both the quantitative and qualitative results show the effectiveness of GraphCG for discovering steerable factors.

Molecular Geometry Pretraining with SE(3)-Invariant Denoising Distance Matching

Shengchao Liu,Hongyu Guo,Jian Tang

Molecular representation pretraining is critical in various applications for drug and material discovery due to the limited number of labeled molecules, and most existing work focuses on pretraining on 2D molecular graphs. However, the power of pretraining on 3D geometric structures has been less explored. This is owing to the difficulty of finding a sufficient proxy task that can empower the pretraining to effectively extract essential features from the geometric structures. Motivated by the dynamic nature of 3D molecules, where the continuous motion of a molecule in the 3D Euclidean space forms a smooth potential energy surface, we propose GeoSSL, a 3D coordinate denoising pretraining framework to model such an energy landscape. Further by leveraging an SE(3)-invariant score matching method, we propose GeoSSL-DDM in which the coordinate denoising proxy task is effectively boiled down to denoising the pairwise atomic distances in a molecule. Our comprehensive experiments confirm the effectiveness and robustness of our proposed method.

SIMPLE: Specialized Model-Sample Matching for Domain Generalization

Ziyue Li,Kan Ren,XINYANG JIANG,Yifei Shen,Haipeng Zhang,Dongsheng Li

In domain generalization (DG), most existing methods aspire to fine-tune a specific pretrained model through novel DG algorithms. In this paper, we propose an alternative direction, i.e., to efficiently leverage a pool of pretrained models without fine-tuning. Through extensive empirical and theoretical evidence, we demonstrate that (1) pretrained models have possessed generalization to some extent while there is no single best pretrained model across all distribution shifts, and (2) out-of-distribution (OOD) generalization error depends on the fitness between the pretrained model and unseen test distributions. This analysis motivates us to incorporate diverse pretrained models and to dispatch the best matched models for each OOD sample by means of recommendation techniques. To this end, we propose SIMPLE, a specialized model-sample matching method for domain generalization. First, the predictions of pretrained models are adapted to the target domain by a linear label space transformation. A matching network aware of model specialty is then proposed to dynamically recommend proper pretrained models to predict each test sample. The experiments on DomainBed show that our method achieves significant performance improvements (up to 12.2% for individual dataset and 3.9% on average) compared to state-of-the-art (SOTA) methods and further achieves 6.1% gain via enlarging the pretrained model pool. Moreover, our method is highly efficient and achieves more than 1000 times training speedup compared to the conventional DG methods with fine-tuning a pretrained model. Code and supplemental materials are available at https://seqml.github.io/simple.

The Augmented Image Prior: Distilling 1000 Classes by Extrapolating from a Single Image
Yuki M Asano,Aaqib Saeed
What can neural networks learn about the visual world when provided with only a single image as input? While any image obviously cannot contain the multitudes of all existing objects, scenes and lighting conditions -- within the space of all $256^{3\cdot224\cdot224}$ possible 224-sized square images, it might still provide a strong prior for natural images. To analyze this ``augmented image prior'' hypothesis, we develop a simple framework for training neural networks from scratch using a single image and augmentations using knowledge distillation from a supervised pretrained teacher. With this, we find the answer to the above question to be: `surprisingly, a lot'. In quantitative terms, we find accuracies of 94%/74% on CIFAR-10/100, 69\% on ImageNet, and by extending this method to video and audio, 51% on Kinetics-400 and 84\% on SpeechCommands. In extensive analyses spanning 13 datasets, we disentangle the effect of augmentations, choice of data and network architectures and also provide qualitative evaluations that include lucid ``panda neurons'' in networks that have never even seen one.
****
Protein structure generation via folding diffusion
Kevin Eric Wu,Kevin K Yang,Rianne van den Berg,James Zou,Alex Xijie Lu,Ava P Amini
The ability to computationally generate novel yet physically foldable protein structures could lead to new biological discoveries and new treatments targeting yet incurable diseases. Despite recent advances in protein structure prediction, directly generating diverse, novel protein structures from neural networks remains difficult. In this work, we present a new diffusion-based generative model that designs protein backbone structures via a procedure that mirrors the native folding process. We describe protein backbone structure as a series of consecutive angles capturing the relative orientation of the constituent amino acid residues, and generate new structures by denoising from a random, unfolded state towards a stable folded structure. Not only does this mirror how proteins biologically twist into energetically favorable conformations, the inherent shift and rotational invariance of this representation crucially alleviates the need for complex equivariant networks. We train a denoising diffusion probabilistic model with a simple transformer backbone and demonstrate that our resulting model unconditionally generates highly realistic protein structures with complexity and structural patterns akin to those of naturally-occurring proteins. As a useful resource, we release the first open-source codebase and trained models for protein structure diffusion.
****
Delving into Semantic Scale Imbalance
Yanbiao Ma,Licheng Jiao,Fang Liu,Yuxin Li,Shuyuan Yang,Xu Liu
Model bias triggered by long-tailed data has been widely studied. However, measure based on the number of samples cannot explicate three phenomena simultaneously: (1) Given enough data, the classification performance gain is marginal with additional samples. (2) Classification performance decays precipitously as the number of training samples decreases when there is insufficient data. (3) Model trained on sample-balanced datasets still has different biases for different classes. In this work, we define and quantify the semantic scale of classes, which is equivalent to the feature diversity of classes. It is exciting to find experimentally that there is a marginal effect of semantic scale, which perfectly describes the first two phenomena. Further, the quantitative measurement of semantic scale imbalance is proposed, which can accurately reflect model bias on multiple datasets, even on sample-balanced data, revealing a novel perspective for the study of class imbalance. Due to the prevalence of semantic scale imbalance, we propose semantic-scale-balanced learning, including a general loss improvement scheme and a dynamic re-weighting training framework that overcomes the challenge of calculating semantic scales in real-time during iterations. Comprehensive experiments show that dynamic semantic-scale-balanced learning consistently enables

the model to perform superiorly on large-scale long-tailed and non-long-tailed datasets, which is a good starting point for mitigating the prevalent but unnoticed model bias.

DAG Matters! GFlowNets Enhanced Explainer for Graph Neural Networks

Wenqian Li,Yinchuan Li,Zhigang Li,Jianye HAO,Yan Pang

Uncovering rationales behind predictions of graph neural networks (GNNs) has received increasing attention over the years. Existing literature mainly focus on selecting a subgraph, through combinatorial optimization, to provide faithful explanations. However, the exponential size of candidate subgraphs limits the applicability of state-of-the-art methods to large-scale GNNs. We enhance on this through a different approach: by proposing a generative structure – GFlowNets-based GNN Explainer (GFlowExplainer), we turn the optimization problem into a step-by-step generative problem. Our GFlowExplainer aims to learn a policy that generates a distribution of subgraphs for which the probability of a subgraph is proportional to its’ reward. The proposed approach eliminates the influence of node sequence and thus does not need any pre-training strategies. We also propose a new cut vertex matrix to efficiently explore parent states for GFlowNets structure, thus making our approach applicable in a large-scale setting. We conduct extensive experiments on both synthetic and real datasets, and both qualitative and quantitative results show the superiority of our GFlowExplainer.

A MULTI-SCALE STRUCTURE-PRESERVING HETEROLOGOUS IMAGE TRANSFORMATION ALGORITHM BASED ON CONDITIONAL ADVERSARIAL NETWORK LEARNING

Rui Xiang,Guo-yo Wang,Pan Yu

Image transformation model learning is a basic technology for image enhancement, image super-resolution, image generation, multimodal image fusion, etc. which uses deep convolutional networks as a representation model for arbitrary functions, and uses fitting optimization with paired image training sets to solve the transformation model between images in the different sets. Affected by the complex and diverse changes of the 3D shape of the actual scene and the pixel-level optical properties of materials, the solution of the heterologous image conversion model is an ill-posed problem. In recent years, most of the proposed conditional adversarial learning methods for image transformation networks only consider the overall consistency loss constraint of the image, and the generated images often contain some pseudo-features or local structural deformations. In order to solve this problem, using the idea of multi-scale image coding and perception, this paper proposes a multi-scale structure-preserving heterologous image transformation method based on conditional adversarial network learning. First, using the idea of multi-scale coding and reconstruction, a multi-scale, step by step generator lightweight network structure is designed. Then, two image multi-scale structure loss functions are proposed, and combined with the existing overall consistency loss, a loss function for generative adversarial learning is designed. Finally, test experiments are performed on the KAIST-MPD-set1 dataset. The experimental results show that, compared with the state-of-the-art algorithms, the proposed algorithm can better suppress the local structural distortion, and has significant advantages in evaluation indicators such as RMSE, LPIPS, PSNR, and SSIM.

****

Metro: Memory-Enhanced Transformer for Retrosynthetic Planning via Reaction Tree

Songtao Liu,Zhitao Ying,Zuobai Zhang,Peilin Zhao,Jian Tang,Lu Lin,Dinghao Wu

Retrosynthetic planning plays a critical role in drug discovery and organic chemistry. Starting from a target molecule as the root node, it aims to find a complete reaction tree subject to the constraint that all leaf nodes belong to a set of starting materials. The multi-step reactions are crucial because they determine the flow chart in the production of the Organic Chemical Industry. However, existing datasets lack curation of tree-structured multi-step reactions and fail to provide such reaction trees, limiting models' understanding of organic molecule transformations. In this work, we first develop a benchmark curated for the retrosynthetic planning task, which consists of 124,869 reaction trees retrieved from the public USPTO-full dataset. On top of that, we propose Metro: Memory-Enh anced Transformer for RetrOsynthetic planning. Specifically, the dependency among molecules in the reaction tree is captured as context information for multi-step retrosynthesis predictions through transformers with a memory module. Extensive experiments show that Metro dramatically outperforms existing single-step retrosynthesis models by at least 10.7% in top-1 accuracy. The experiments demonstrate the superiority of exploiting context information in the retrosynthetic planning task. Moreover, the proposed model can be directly used for synthetic accessibility analysis, as it is trained on reaction trees with the shortest depths. Our work is the first step towards a brand new formulation for retrosynthetic planning in the aspects of data construction, model design, and evaluation.

In the ZONE: Measuring difficulty and progression in curriculum generation

Rose E Wang,Jesse Mu,Dilip Arumugam,Natasha Jaques,Noah Goodman

A common strategy in curriculum generation for reinforcement learning is to train a teacher network to generate tasks that fall within a student network's ``zone of proximal development'' (ZPD). These are tasks that are not too easy and not too hard for the student. Albeit intuitive, ZPD is not well understood computationally. We propose ZONE, a novel computational framework that operationalizes ZPD. It formalizes ZPD through the language of Bayesian probability theory, revealing that tasks should be selected by difficulty (the student's success probability on the task) and learning progression (the degree of change in the student's model parameters). ZONE operationalizes ZPD with two techniques that we apply on top of existing algorithms. One is REJECT, which rejects tasks outside a difficulty scope and the other is GRAD, which prioritizes tasks that maximize the student's gradient norm. Compared to the original algorithms, the ZONE techniques improve the student’s generalization performance on discrete Minigrid environments and continuous control Mujoco domains with up to $9 \times$ higher success. ZONE also accelerates the student's learning by training on up to $10\times$ less data.

Object Tracking by Hierarchical Part-Whole Attention

Jinkun Cao,Jiangmiao Pang,Xinshuo Weng,Rawal Khirodkar,Kris M. Kitani

We present in this paper that hierarchical representations of objects can provide an informative and low-noisy proxy to associate objects of interest in multi-object tracking. This is aligned with our intuition that we usually only need to compare a little region of the body of target objects to distinguish them from other objects. We build the hierarchical representation in levels of (1) target body parts, (2) the whole target body, and (3) the union area of the target and other objects of overlap. Furthermore, with the spatio-temporal attention mechanism by transformer, we can solve the tracking in a global fashion and keeps the process online. We design our method by combining the representation with the transformer and name it Hierarchical Part-Whole Attention, or HiPWA for short. The experiments on multiple datasets suggest its good effectiveness. Moreover, previous methods mostly focus on leveraging transformers to exploit long temporal context during association which requires heavy computation resources. But HiPWA focuses on a more informative representation of objects on every single frame instead. So it is more robust with the length of temporal context and more computationally economic.

Understanding the Training Dynamics in Federated Deep Learning via Aggregation Weight Optimization

Zexi Li,Tao Lin,Xinyi Shang,Chao Wu

From the server's perspective, federated learning (FL) learns a global model by iteratively sampling a cohort of clients and updating the global model with the sum local gradient of the cohort. We find this process is analogous to mini-batch SGD of centralized training. In mini-batch SGD, a model is learned by iteratively sampling a batch of data and updating the model with the sum gradient of the batch. In this paper, we delve into the training dynamics in FL by learning from the experience of optimization and generalization in mini-batch SGD. Specifically, we focus on two aspects: \emph{client coherence} (refers to sample coherenc e in mini-batch SGD) and \emph{global weight shrinking regularization} (refers to weight decay in mini-batch SGD). We find the roles of the two aspects are both determined by the aggregation weights assigned to each client during global model updating. Thus, we use aggregation weight optimization on the server as a tool to study how client heterogeneity and the number of local epochs affect the global training dynamics in FL. Besides, we propose an effective method for \textbf{Fed}erated \textbf{A}ggregation \textbf{W}eight \textbf{O}ptimization, named as \textsc{\textbf{FedAWO}}. Extensive experiments verify that our method can improve the generalization of the global model by a large margin on different datasets and models.

BiBench: Benchmarking and Analyzing Network Binarization

Haotong Qin,Mingyuan Zhang,Yifu Ding,Aoyu Li,Zhongang Cai,Ziwei Liu,Fisher Yu,Xianglong Liu

Neural network binarization emerges as one of the most promising compression approaches with extraordinary computation and memory savings by minimizing the bit-width of weight and activation. However, despite being a generic technique, recent works reveal that applying binarization in a wide range of realistic scenarios involving diverse tasks, architectures, and hardware is not trivial. Moreover, common challenges, such as severe degradation in accuracy and limited efficiency gains, suggest that specific attributes of binarization are not thoroughly studied and adequately understood. To close this gap, we present BiBench, a rigorously designed benchmark with in-depth analysis for network binarization. We first carefully scrutinize the requirements of binarization in the actual production setting. We thus define the evaluation tracks and metrics for a fair and systematic investigation. We then perform a comprehensive evaluation with a rich collection of milestone binarization algorithms. Our benchmark results show binarization still faces severe accuracy challenges but diminishing improvements brought by newer state-of-the-art binarization algorithms, even at the expense of efficiency. Moreover, the actual deployment of certain binarization operations reveals a surprisingly large deviation from their theoretical consumption. Finally, we provide suggestions based on our benchmark results and analysis, devoted to establishing a paradigm for accurate and efficient binarization among existing techniques. We hope BiBench paves the way towards more extensive adoption of network binarization and serves as a foundation for future research.

Contextual Image Masking Modeling via Synergized Contrasting without View Augmentation for Faster and Better Visual Pretraining

Shaofeng Zhang,Feng Zhu,Rui Zhao,Junchi Yan

We propose a new contextual masking image modeling (MIM) approach called contrasting-aided contextual MIM (ccMIM), under the MIM paradigm for visual pretraining. Specifically, we adopt importance sampling to select the masked patches with richer semantic information for reconstruction, instead of random sampling as done in previous MIM works. As such, the resulting patch reconstruction task from the remaining less semantic patches could be more difficult and helps to learn. To speed up the possibly slowed convergence due to our more difficult reconstruction task, we further propose a new contrastive loss that aligns the tokens of the vision transformer extracted from the selected masked patches and the remaining ones, respectively. The hope is that it serves as a regularizer for patch feature learning such that the image-level global information could be captured in both masked and unmasked patches, and notably such a single-view contrasting avoids the tedious image augmentation step required in recent efforts of introducing contrastive learning to MIM (to speedup convergence and discriminative ability). Meanwhile, the attention score from the contrastive global feature can also carry effective semantic clues to in turn guide our above masking patch selection scheme. In consequence, our contextual MIM and contrastive learning are synergetically performed in a loop (semantic patch selection-token alignment contrasting) to boost the best of the two worlds: fast convergence and strong performance on downstream tasks without ad-hoc augmentations, which are verified by empirical results on ImageNet-1K for both classification and dense vision tasks.

Patch-Level Contrasting without Patch Correspondence for Accurate and Dense Contrastive Representation Learning

Shaofeng Zhang,Feng Zhu,Rui Zhao,Junchi Yan

We propose ADCLR: \underline{A}ccurate and \underline{D}ense \underline{C}ontrastive \underline{R}epresentation \underline{L}earning, a novel self-supervised learning framework for learning accurate and dense vision representation. To extract spatial-sensitive information, ADCLR introduces query patches for contrasting in addition with global contrasting. Compared with previous dense contrasting methods, ADCLR mainly enjoys three merits: i) achieving both global-discriminative and spatial-sensitive representation, ii) model-efficient (no extra parameters in addition to the global contrasting baseline), and iii) correspondence-free and thus simpler to implement. Our approach achieves new state-of-the-art performance for contrastive methods. On classification tasks, for ViT-S, ADCLR achieves 78.1\% top-1 accuracy on ImageNet with linear probing, outperforming our baseline (DINO) without our devised techniques as plug-in, by 1.1\%. For ViT-B, ADCLR achieves 79.8\%, 84.0\% accuracy on ImageNet by linear probing and finetune, outperforming DINO by 0.6\%, 0.4\% accuracy. For dense tasks, on MS-COCO, ADCLR achieves significant improvements of 44.3\% AP on object detection, 39.7\% AP on instance segmentation, outperforming previous SOTA method SelfPatch by 2.2\% and 1.2\%, respectively. On ADE20K, ADCLR outperforms SelfPatch by 1.0\% mIoU, 1.2\% mAcc on the segmentation task.

Continuous-Discrete Convolution for Geometry-Sequence Modeling in Proteins

Hehe Fan,Zhangyang Wang,Yi Yang,Mohan Kankanhalli

The structure of proteins involves 3D geometry of amino acid coordinates and 1D sequence of peptide chains. The 3D structure exhibits irregularity because amino acids are distributed unevenly in Euclidean space and their coordinates are continuous variables. In contrast, the 1D structure is regular because amino acids are arranged uniformly in the chains and their sequential positions (orders) are discrete variables. Moreover, geometric coordinates and sequential orders are in two types of spaces and their units of length are incompatible. These inconsistencies make it challenging to capture the 3D and 1D structures while avoiding the impact of sequence and geometry modeling on each other. This paper proposes a Continuous-Discrete Convolution (CDConv) that uses irregular and regular approaches to model the geometry and sequence structures, respectively. Specifically, CDConv employs independent learnable weights for different regular sequential displacements but directly encodes geometric displacements due to their irregularity. In this way, CDConv significantly improves protein modeling by reducing the impact of geometric irregularity on sequence modeling. Extensive experiments on a range of tasks, including protein fold classification, enzyme reaction classification, gene ontology term prediction and enzyme commission number prediction, demonstrate the effectiveness of the proposed CDConv.

ELODI: Ensemble Logit Difference Inhibition for Positive-Congruent Training

Yue Zhao,Yantao Shen,Yuanjun Xiong,Shuo Yang,Wei Xia,Zhuowen Tu,Bernt Schiele,Stefano Soatto

Negative flips are errors introduced in a classification system when a legacy model is updated. Existing methods to reduce the negative flip rate (NFR) either do so at the expense of overall accuracy by forcing a new model to imitate the old models, or use ensembles, which multiply inference cost prohibitively. We analyze the role of ensembles in reducing NFR and observe that they remove negative flips that are typically not close to the decision boundary, but often exhibit large deviations in the distance among their logits. Based on the observation, we present a method, called Ensemble Logit Difference Inhibition ELODI, to train a classification system that achieves paragon performance in both error rate and NFR, at the inference cost of a single model. The method distills a homogeneous ensemble to a single student model which is used to update the classification system. ELODI also introduces a generalized distillation objective, Logit Difference Inhibition (LDI), which penalizes changes in the logits between the reference

ensemble and the student single model.
On multiple image classification benchmarks, model updates with ELODI demonstrate superior accuracy retention and NFR reduction.

Model-agnostic Measure of Generalization Difficulty

Akhilan Boopathy,Kevin Liu,Jaedong Hwang,Shu Ge,Asaad Mohammedsaleh,Ila R Fiete

The measure of a machine learning algorithm is the difficulty of the tasks it can perform, and sufficiently difficult tasks are critical drivers of strong machine learning models. However, quantifying the generalization difficulty of machine learning benchmarks has remained challenging. We propose what is to our knowledge the first model-agnostic measure of the inherent generalization difficulty of tasks. Our inductive bias complexity measure quantifies the total information required to generalize well on a task minus the information provided by the data. It does so by measuring the fractional volume occupied by hypotheses that generalize on a task given that they fit the training data. It scales exponentially with the intrinsic dimensionality of the space over which the model must generalize but only polynomially in resolution per dimension, showing that tasks which require generalizing over many dimensions are drastically more difficult than tasks involving more detail in fewer dimensions. Our measure can be applied to compute and compare supervised learning, reinforcement learning and meta-learning task difficulties against each other. We show that applied empirically, it formally quantifies intuitively expected trends, e.g. that in terms of required inductive bias, MNIST $<$ CIFAR10 $<$ Imagenet and fully observable Markov decision processes (MDPs) $<$ partially observable MDPs. Further, we show that classification of complex images $<$ few-shot meta-learning with simple images. Our measure provides a quantitative metric to guide the construction of more complex tasks requiring greater inductive bias, and thereby encourages the development of more sophisticated architectures and learning algorithms with more powerful generalization capabilities.

Efficient Exploration via Fragmentation and Recall

Jaedong Hwang,Zhang-Wei Hong,Eric R Chen,Akhilan Boopathy,Pulkit Agrawal,Ila R Fiete

Efficient exploration and model-building are critical for learning in large state- spaces. However, agents typically face problems like getting stuck locally during exploration and catastrophic forgetting in their construction of models when the environments are heterogeneous. Here, we propose and apply the concept of Fragmentation-and-Recall to solve spatial (FarMap) and reinforcement learning problems (FarCuriosity). Agents construct local maps or local models, respectively, which are used to predict the current observation. High surprisal points lead to a fragmentation event. At fracture points, we store the current map or model fragment in a long-term memory (LTM) and initialize a new fragment. On the other hand, Fragments are recalled (and thus reused) from LTM if the observations of their fracture points match the agent’s current observation during exploration. The set of fracture points defines a set of intrinsic potential subgoals. Agents choose their next subgoal from the set of near and far potential subgoals in the current fragment or LTM, respectively. Thus, local maps and model fragments guide exploration locally and avoid catastrophic forgetting in learning heterogeneous environments, while LTM promotes exploration more globally. We evaluate FarMap and FarCuriosity on complex procedurally-generated spatial environments and on reinforcement learning benchmarks and demonstrate that the proposed methods are more efficient at exploration and memory use, and in harvesting extrinsic rewards, respectively.

Hedge Your Actions: Flexible Reinforcement Learning for Complex Action Spaces

Norio Kosaka,Ayush Jain,Xinhu Li,Kyung-Min Kim,Joseph J Lim

Real-world decision-making is often associated with large and complex action representations, which can even be unsuited for the task. For instance, the items in recommender systems have generic representations that apply to each user differently, and the actuators of a household robot can be high-dimensional and noisy

. Prior works in discrete and continuous action space reinforcement learning (RL) define a retrieval-selection framework to deal with problems of scale. The retrieval agent outputs in the space of action representations to retrieve a few samples for a selection critic to evaluate. But, learning such retrieval actors becomes increasingly inefficient as the complexity in the action space rises. Thus, we propose to treat the retrieval task as one of listwise RL to propose a list of action samples that enable the selection phase to maximize the environment reward. By hedging its action proposals, we show that our agent is more flexible and sample efficient than conventional approaches while learning under a complex action space. Results are also present on \url{https://sites.google.com/view/complexaction}.
