Although pre-trained language models (PLMs) have shown impressive performance by text-only self-supervised training, they are found lack of visual semantics or commonsense, e.g., sizes, shapes and colors of commonplace objects. Existing solutions often rely on explicit images for visual knowledge augmentation (requiring time-consuming retrieval or generation), and they also conduct the augmentation for the whole input text, without considering whether it is actually needed in specific inputs or tasks. To address these issues, we propose a novel visually-augmented fine-tuning approach that can be generally applied to various PLMs or NLP tasks, without using any retrieved or generated images, namely VAWI. Specifically, we first identify the visually-hungry words (VH-words) from input text via a token selector, where three different methods have been proposed, including syntax-, attention- and learning-based strategies. Then, we adopts a fixed CLIP text encoder to generate the visually-augmented representations of these VH-words. As it has been pre-trained by visual-language alignment task on large-scale corpus, it is capable of injecting visual semantics into the aligned text representations. Finally, the visually-augmented features will be fused and transformed into several pre-designed visual prompts based on VH-words, which can be inserted into PLMs to enrich the visual semantics in word repersentations. We conduct extensive experiments on ten NLP tasks, i.e., GLUE benchmark, CommonsenseQA, CommonGen and SNLI-VE. Experimental results show that our approach can consistently improve the performance of BERT, RoBERTa, BART and T5 at different scales, and outperform several competitive baselines significantly. Besides, the generated visual prompts of our framework can also be used for parameter-efficient tuning, which boosts the performance of T5-3B. We will make our code, data, and models publicly available.

Improving Adversarial Robustness via Frequency Regularization

Binxiao Huang,Chaofan Tao,Rui Lin,Ngai Wong

Deep neural networks (DNNs) are incredibly vulnerable to crafted, human-imperceptible adversarial perturbations. While adversarial training (AT) has proven to be an effective defense approach, the properties of AT for robustness improvement remain an open issue. In this paper, we investigate AT from a spectral perspective, providing new insights into the design of effective defenses. Our analyses show that AT induces the deep model to focus more on the low-frequency region, which retains the shape-biased representations, to gain robustness. Further, we find that the spectrum of a white-box attack is primarily distributed in regions the model focuses on, and the perturbation attacks the spectral bands where the model is vulnerable. To train a model tolerant to frequency-varying perturbation, we propose a frequency regularization (FR) such that the spectral output inferred by an attacked input stays as close as possible to its natural input counterpart. Experiments demonstrate that FR and its weight averaging (WA) extension could significantly improve the robust accuracy by 1.14% ~ 4.57%, across multiple datasets (SVHN, CIFAR-10, CIFAR-100, and Tiny ImageNet), and various attacks (PGD, C&W, and Autoattack), without any extra data.

FastFill: Efficient Compatible Model Update

Florian Jaeckle,Fartash Faghri,Ali Farhadi,Oncel Tuzel,Hadi Pouransari

In many retrieval systems the original high dimensional data (e.g., images) is mapped to a lower dimensional feature through a learned embedding model. The task of retrieving the most similar data from a gallery set to a given query data is performed through similarity comparison on features. When the embedding model is updated, it might produce features that are not comparable/compatible with features already in the gallery computed with the old model. Subsequently, all features in the gallery need to be re-computed using the new embedding model -- a computationally expensive process called backfilling. Recently, compatible representation learning methods have been proposed to avoid back-filling. Despite their relative success, there is an inherent trade-off between new model performance and its compatibility with the old model. In this work, we introduce FastFill: a compatible model update process using feature alignment and policy based partial backfilling to promptly elevate retrieval performance. We show that previous backfilling strategies suffer from decreased performance and demonstrate the importance of both the training objective and the ordering in online partial backfilling. We propose a new training method for feature alignment between old and new embedding models using uncertainty estimation. Compared to previous works, we obtain significantly improved backfilling results on a variety of datasets: mAP on ImageNet (+4.4%), Places-365 (+2.7%), and VGG-Face2 (+1.3%). Further, we demonstrate that when updating a biased model with FastFill, the minority subgroup accuracy gap promptly vanishes with a small fraction of partial backfilling.

Learnable Graph Convolutional Attention Networks

Adrián Javaloy,Pablo Sanchez Martin,Amit Levi,Isabel Valera

Existing Graph Neural Networks (GNNs) compute the message exchange between nodes by either aggregating uniformly (convolving) the features of all the neighboring nodes, or by applying a non-uniform score (attending) to the features. Recent works have shown the strengths and weaknesses of the resulting GNN architectur es, respectively, GCNs and GATs. In this work, we aim at exploiting the strengths of both approaches to their full extent. To this end, we first introduce the graph convolutional attention layer (CAT), which relies on convolutions to compute the attention scores. Unfortunately, as in the case of GCNs and GATs, we show that there exists no clear winner between the three—neither theoretically nor in practice—as their performance directly depends on the nature of the data (i.e., of the graph and features). This result brings us to the main contribution of our work, the learnable graph convolutional attention network (L-CAT): a GNN architecture that automatically interpolates between GCN, GAT and CAT in each layer, by adding only two scalar parameters. Our results demonstrate that L-CAT is able to efficiently combine different GNN layers along the network, outperforming competing methods in a wide range of datasets, and resulting in a more robust model that reduces the need of cross-validating.

Indoor Localisation for Detecting Medication Use in Parkinson's Disease

Ferdian Jovan,Catherine Morgan,Ryan McConville,Emma Tonkin,Alan Whone,Ian Craddock

Parkinson’s disease (PD) is a slowly progressive debilitating neurodegenerative disease which is prominently characterised by motor symptoms. Indoor localisation, including its in-home mobility features, could provide a digital biomarker that can be used to quantify how mobility changes as this disease progresses. To improve the effectiveness of current methods for indoor localisation, a transformer-based approach utilising multiple modalities, Received Signal Strength Indicator (RSSI) and accelerometer data from wearable devices, which provide complementary views of movement, is proposed. To properly evaluate our proposed method, we use a free-living dataset where the movements and mobility are greatly varied and unstructured as expected in real-world conditions. 12 pairs of people (one with PD, and the other a control participant) lived for five days in a smart home with various sensors. Our evaluation on such a dataset, which includes subjects with and without PD, demonstrates that our proposed network outperforms the current state-of-the-art in indoor localisation. We also show how the accurate room-level localisation predictions can be transformed into in-home mobility features (i.e. room-to-room transition duration) which can be used to effectively classify whether the PD participant is taking their medications or withholding them (increasing their symptoms)

Scaffolding a Student to Instill Knowledge

Anil Kag,Durmus Alp Emre Acar,Aditya Gangrade,Venkatesh Saligrama

We propose a novel knowledge distillation (KD) method to selectively instill teacher knowledge into a student model motivated by situations where the student's capacity is significantly smaller than that of the teachers. In vanilla KD, the teacher primarily sets a predictive target for the student to follow, and we posit that this target is overly optimistic due to the student's lack of capacity. We develop a novel scaffolding scheme where the teacher, in addition to setting a predictive target, also scaffolds the student's prediction by censoring hard-to-learn examples. Scaffolding utilizes the same information as the teacher's soft-max predictions as inputs, and in this sense, our proposal can be viewed as a natural variant of vanilla KD. We show on synthetic examples that censoring hard-examples leads to smoothening the student's loss landscape so that the student encounters fewer local minima. As a result, it has good generalization properties. Against vanilla KD, we achieve improved performance and are comparable to more intrusive techniques that leverage feature matching on benchmark datasets.

User-Interactive Offline Reinforcement Learning

Phillip Swazinna,Steffen Udluft,Thomas Runkler

Offline reinforcement learning algorithms still lack trust in practice due to the risk that the learned policy performs worse than the original policy that generated the dataset or behaves in an unexpected way that is unfamiliar to the user. At the same time, offline RL algorithms are not able to tune their most import ant hyperparameter - the proximity of the learned policy to the original policy. We propose an algorithm that allows the user to tune this hyperparameter at run time, thereby addressing both of the above mentioned issues simultaneously. This allows users to start with the original behavior and grant successively greater deviation, as well as stopping at any time when the policy deteriorates or the behavior is too far from the familiar one.

No-regret Learning in Repeated First-Price Auctions with Budget Constraints

Rui Ai,Chang Wang,Chenchen Li,Jinshan Zhang,Wenhan Huang,Xiaotie Deng

Recently the online advertising market has exhibited a gradual shift from second-price auctions to first-price auctions. Although there has been a line of works concerning online bidding strategies in first-price auctions, it still remains open how to handle budget constraints in the problem. In the present paper, we initiate the study for a buyer with budgets to learn online bidding strategies in repeated first-price auctions. We propose an RL-based bidding algorithm against the optimal non-anticipating strategy under stationary competition. Our algorithm obtains
$\widetilde O(\sqrt T)$-regret if the bids are all revealed at the end of each round. With the restriction that the buyer only sees the winning bid after each round, our modified algorithm obtains $\widetilde O(T^{\frac{7}{12}})$-regret by techniques developed from survival analysis. Our analysis extends to the more general scenario where the buyer has any bounded instantaneous utility function with regrets of the same order.

Private and Efficient Meta-Learning with Low Rank and Sparse decomposition

Soumyabrata Pal,Prateek Varshney,Gagan Madan,Abhradeep Guha Thakurta,Gaurav Aggarwal,Pradeep Shenoy,Gaurav Srivastava,Prateek Jain

Meta-learning is critical for a variety of practical ML systems -- like personalized recommendations systems -- that are required to generalize to new tasks despite a small number of task-specific training points. Existing meta-learning techniques use two complementary approaches of either learning a low-dimensional representation of points for all tasks, or task-specific fine-tuning of a global model trained using all the tasks. In this work, we propose a novel meta-learning framework that combines both the techniques to enable handling of a large number of data-starved tasks. Our framework models network weights as a sum of low-rank and sparse matrices. This allows us to capture information from multiple domains together in the low-rank part while still allowing task specific personalization using the sparse part. We instantiate and study the framework in the linear setting, where the problem reduces to that of estimating the sum of a rank-r and a k-column sparse matrix using a small number of linear measurements. We propose an alternating minimization method with hard thresholding -- AMHT-LRS -- to learn the low-rank and sparse part effectively and efficiently. For the realizable, Gaussian data setting, we show that AMHT-LRS indeed solves the problem efficiently with nearly optimal samples. We extend AMHT-LRS to ensure that it preserves privacy of each individual user in the dataset, while still ensuring strong generalization with nearly optimal number of samples. Finally, on multiple datasets, we demonstrate that the framework allows personalized models to obtain superior performance in the data-scarce regime.

ωGNNs: Deep Graph Neural Networks Enhanced by Multiple Propagation Operators

Moshe Eliasof,Lars Ruthotto,Eran Treister

Graph Neural Networks (GNNs) are limited in their propagation operators. These operators often contain non-negative elements only and are shared across channels and layers, limiting the expressiveness of GNNs. Moreover, some GNNs suffer from over-smoothing, limiting their depth. On the other hand, Convolutional Neural Networks (CNNs) can learn diverse propagation filters, and phenomena like over-smoothing are typically not apparent in CNNs.

In this paper, we bridge this gap by incorporating trainable channel-wise weighting factors ω to learn and mix multiple smoothing and sharpening propagat ion operators at each layer. Our generic method is called ωGNN, and we study two variants: ωGCN and ωGAT.

For ωGCN, we theoretically analyse its behaviour and the impact of ω on the obtained node features. Our experiments confirm these findings, demonstrating and explaining how both variants do not over-smooth.

Additionally, we experiment with 15 real-world datasets on node- and graph-classification tasks, where our ωGCN and ωGAT perform better or on par with state-of-the-art methods.

Few-bit Backward: Quantized Gradients of Activation Functions for Memory Footprint Reduction

Georgii Sergeevich Novikov,Daniel Bershatsky,Julia Gusak,Alex Shonenkov,Denis Valerievich Dimitrov,Ivan Oseledets

Memory footprint is one of the main limiting factors for large neural network training. In backpropagation, one needs to store the input to each operation in the computational graph. Every modern neural network model has quite a few pointwise nonlinearities in its architecture, and such operation induces additional memory costs which --- as we show -- can be significantly reduced by quantization of the gradients.

We propose a systematic approach to compute optimal quantization of the retained gradients of the pointwise nonlinear functions with only a few bits per each element.

We show that such approximation can be achieved by computing optimal piecewise-constant approximation of the derivative of the activation function, which can be done by dynamic programming. The drop-in replacements are implemented for all popular nonlinearities and can be used in any existing pipeline. We confirm the memory reduction and the same convergence on several open benchmarks.

SLTUNET: A Simple Unified Model for Sign Language Translation

Biao Zhang,Mathias Müller,Rico Sennrich

Despite recent successes with neural models for sign language translation (SLT), translation quality still lags behind spoken languages because of the data scarcity and modality gap between sign video and text. To address both problems, we investigate strategies for cross-modality representation sharing for SLT. We propose SLTUNET, a simple unified neural model designed to support multiple SLTrelated tasks jointly, such as sign-to-gloss, gloss-to-text and sign-to-text translation. Jointly modeling different tasks endows SLTUNET with the capability to explore the cross-task relatedness that could help narrow the modality gap. In addition, this allows us to leverage the knowledge from external resources, such as abundant parallel data used for spoken-language machine translation (MT). We show in experiments that SLTUNET achieves competitive and even state-of-the-art performance on PHOENIX-2014T and CSL-Daily when augmented with MT data and equipped with a set of optimization techniques. We further use the DGS Corpus for end-to-end SLT for the first time. It covers broader domains with a significantly larger vocabulary, which is more challenging and which we consider to allow for a more realistic assessment of the current state of SLT than the former two. Still, SLTUNET obtains improved results on the DGS Corpus. Code is available at https://github.com/bzhangGo/sltunet.

Pruning by Active Attention Manipulation

Zahra Babaiee,Lucas Liebenwein,Ramin Hasani,Daniela Rus,Radu Grosu

Structured pruning of a CNN is typically achieved by applying discrete masks on the CNN's filter weights or activation maps, post-training. Here, we present a new filter-importance-scoring concept named pruning by active attention manipulation (PAAM), that sparsifies the CNN's set of filters through a particular attention mechanism, during-training. PAAM learns continuous filter scores from the filter weights by optimizing a cost function regularized by an additive term in the scores. As the filters are not independent, we use attention to dynamically learn their correlations. Moreover, by training the pruning scores of all layers simultaneously, PAAM can account for layer inter-dependencies, which is essential to finding a performant sparse sub-network. PAAM can also train and generate a pruned network from scratch in a straightforward, one-stage training process without requiring a pre-trained network. Finally, PAAM does not need layer-specific hyperparameters and pre-defined layer budgets, since it can implicitly determine the appropriate number of filters in each layer. Our experimental results on different network architectures suggest that PAAM outperforms state-of-the-art structured-pruning methods (SOTA). On CIFAR-10 dataset, without requiring a pre-trained baseline network, we obtain 1.02% and 1.19% accuracy gain and 52.3% and 54% parameters reduction, on ResNet56 and ResNet110, respectively. Similarly, on the ImageNet dataset, PAAM achieves 1.06% accuracy gain while pruning 51.1% of the parameters on ResNet50. For Cifar-10, this is better than the SOTA with a margin of 9.5% and 6.6%, respectively, and on ImageNet with a margin of 11%.

Robustness of Unsupervised Representation Learning without Labels

Aleksandar Petrov,Marta Kwiatkowska

Unsupervised representation learning leverages large unlabeled datasets and is competitive with supervised learning. But non-robust encoders may affect downstream task robustness. Recently, robust representation encoders have become of interest. Still, all prior work evaluates robustness using a downstream classification task. Instead, we propose a family of unsupervised robustness measures, which are model- and task-agnostic and label-free. We benchmark state-of-the-art representation encoders and show that none dominates the rest. We offer unsupervised extensions to the FGSM and PGD attacks. When used in adversarial training, they improve most unsupervised robustness measures, including certified robustness. We validate our results against a linear probe and show that, for MOCOv2, adversarial training results in 3 times higher certified accuracy, a 2-fold decrease in impersonation attack success rate and considerable improvements in certified robustness.

Understanding the Generalization of Adam in Learning Neural Networks with Proper Regularization

Difan Zou,Yuan Cao,Yuanzhi Li,Quanquan Gu

Adaptive gradient methods such as Adam have gained increasing popularity in deep learning optimization. However, it has been observed in many deep learning applications such as image classification, Adam can converge to a different solution with a worse test error compared to (stochastic) gradient descent, even with a fine-tuned regularization. In this paper, we provide a theoretical explanation for this phenomenon: we show that in the nonconvex setting of learning over-parameterized two-layer convolutional neural networks starting from the same random initialization, for a class of data distributions (inspired from image data), Adam and gradient descent (GD) can converge to different global solutions of the training objective with provably different generalization errors, even with weight decay regularization. In contrast, we show that if the training objective is convex, and the weight decay regularization is employed, any optimization algorithms including Adam and GD will converge to the same solution if the training is successful. This suggests that the generalization gap between Adam and SGD in the presence of weight decay regularization is closely tied to the nonconvex landscape of deep learning optimization, which cannot be covered by the recent neural tangent kernel (NTK) based analysis.

ACQL: An Adaptive Conservative Q-Learning Framework for Offline Reinforcement Learning

Kun Wu,Yinuo Zhao,Zhiyuan Xu,Zhengping Che,Chengxiang Yin,Chi Harold Liu,Qinru Qiu,Feifei Feng,Jian Tang

Offline Reinforcement Learning (RL), which relies only on static datasets without additional interactions with the environment, provides an appealing alternative to learning a safe and promising control policy. Most existing offline RL methods did not consider relative data quality and only crudely constrained the distribution gap between the learned policy and the behavior policy in general. Moreover, these algorithms cannot adaptively control the conservative level in more fine-grained ways, like for each state-action pair, leading to a performance drop, especially over highly diversified datasets. In this paper, we propose an Adaptive Conservative Q-Learning (ACQL) framework that enables more flexible control over the conservative level of Q-function for offline RL. Specifically, we present two adaptive weight functions to shape the Q-values for collected and out-of-distribution data. Then we discuss different conditions under which the conservative level of the learned Q-function changes and define the monotonicity with respect to data quality and similarity. Motivated by the theoretical analysis, we propose a novel algorithm with the ACQL framework, using neural networks as the adaptive weight functions. To learn proper adaptive weight functions, we design surrogate losses incorporating the conditions for adjusting conservative levels and a contrastive loss to maintain the monotonicity of adaptive weight functions. We evaluate ACQL on the commonly-used D4RL benchmark and conduct extensive ablation studies to illustrate the effectiveness and state-of-the-art performance compared to existing offline DRL baselines.

Fisher-Legendre (FishLeg) optimization of deep neural networks

Jezabel R Garcia,Federica Freddi,Stathi Fotiadis,Maolin Li,Sattar Vakili,Alberto Bernacchia,Guillaume Hennequin

Incorporating second-order gradient information (curvature) into optimization can dramatically reduce the number of iterations required to train machine learning models. In natural gradient descent, such information comes from the Fisher information matrix which yields a number of desirable properties. As exact natural gradient updates are intractable for large models, successful methods such as KFAC and sequels approximate the Fisher in a structured form that can easily be inverted. However, this requires model/layer-specific tensor algebra and certain approximations that are often difficult to justify. Here, we use ideas from Legendre-Fenchel duality to learn a direct and efficiently evaluated model for the product of the inverse Fisher with any vector, in an online manner, leading to natural gradient steps that get progressively more accurate over time despite noisy gradients. We prove that the resulting “Fisher-Legendre” (FishLeg) optimizer converges to a (global) minimum of non-convex functions satisfying the PL condition, which applies in particular to deep linear networks. On standard auto-encoder benchmarks, we show empirically that FishLeg outperforms standard first-order optimization methods, and performs on par with or better than other second-order methods, especially when using small batches. Thanks to its generality, we expect our approach to facilitate the handling of a variety neural network layers in future work.

****

A law of adversarial risk, interpolation, and label noise

Daniel Paleka,Amartya Sanyal

In supervised learning, it has been shown that label noise in the data can be interpolated without penalties on test accuracy. We show that interpolating label noise induces adversarial vulnerability, and prove the first theorem showing the relationship between label noise and adversarial risk for any data distribution. Our results are almost tight if we do not make any assumptions on the inductive bias of the learning algorithm. We then investigate how different components of this problem affect this result including properties of the distribution. We also discuss non-uniform label noise distributions; and prove a new theorem showing uniform label noise induces nearly as large an adversarial risk as the worst poisoning with the same noise rate. Then, we provide theoretical and empirical evidence that uniform label noise is more harmful than typical real-world label noise. Finally, we show how inductive biases amplify the effect of label noise and argue the need for future work in this direction.

Lossy Image Compression with Conditional Diffusion Models

Ruihan Yang,Stephan Mandt

Denoising diffusion models have recently marked a milestone in high-quality image generation. One may thus wonder if they are suitable for neural image compression. This paper outlines an end-to-end optimized image compression framework bas ed on a conditional diffusion model, drawing on the transform-coding paradigm. Besides the latent variables inherent to the diffusion process, this paper introduces an additional discrete "content" latent variable to condition the denoising process on. This variable is equipped with a hierarchical prior for entropy coding. The remaining "texture" latent variables characterizing the diffusion process are synthesized (either stochastically or deterministically) at decoding time. We furthermore show that the performance can be tuned toward perceptual metrics of interest. Our extensive experiments involving five datasets and 16 image perceptual quality assessment metrics show that our approach not only compares favorably in terms of rate and perceptual distortion tradeoffs but also shows robust performance under all metrics while other baselines show less consistent behavior.

ASIF: coupled data turns unimodal models to multimodal without training

Antonio Norelli,Marco Fumero,Valentino Maiorca,Luca Moschella,Emanuele Rodolà,Francesco Locatello

Aligning the visual and language spaces requires to train deep neural networks from scratch on giant multimodal datasets; CLIP trains both an image and a text encoder, while LiT manages to train just the latter by taking advantage of a pretrained vision network. In this paper, we show that sparse relative representations are sufficient to align text and images without training any network. Our method relies on readily available single-domain encoders (trained with or without supervision) and a modest (in comparison) number of image-text pairs. ASIF redefines what constitutes a multimodal model by explicitly disentangling memory from processing: here the model is defined by the embedded pairs of all the entries in the multimodal dataset, in addition to the parameters of the two encoders. Experiments on standard zero-shot visual benchmarks demonstrate the typical transfer ability of image-text models. Overall, our method represents a simple yet surprisingly strong baseline for foundation multi-modal models, raising important questions on their data efficiency and on the role of retrieval in machine learning.

Momentum Boosted Episodic Memory for Improving Learning in Long-Tailed RL Environments

Dolton Milagres Fernandes,Pramod Kaushik,Harsh Shukla,Bapi Raju Surampudi

Conventional Reinforcement Learning (RL) algorithms assume the distribution of the data to be uniform or mostly uniform. However, this is not the case with most real-world applications like autonomous driving or in nature, where animals roam. Some objects are encountered frequently, and most of the remaining experiences occur rarely; the resulting distribution is called \emph{Zipfian}. Taking inspiration from the theory of \emph{complementary learning systems}, an architecture for learning from Zipfian distributions is proposed where long tail states are discovered in an unsupervised manner and states along with their recurrent activation are kept longer in episodic memory. The recurrent activations are then reinstated from episodic memory using a similarity search, giving weighted importance. The proposed architecture yields improved performance in a Zipfian task over conventional architectures. Our method outperforms IMPALA by a significant margin of 20.3\% when maps/objects occur with a uniform distribution and by 50.2\% on the rarest 20\% of the distribution.

ProtoGNN: Prototype-Assisted Message Passing Framework for Non-Homophilous Graphs

Yanfei Dong,Mohammed Haroon Dupty,Lambert Deng,Yong Liang Goh,Wee Sun Lee

Many well-known Graph Neural Network (GNN) models assume the underlying graphs are homophilous, where nodes share similar features and labels with their neighbours. They rely on message passing that iteratively aggregates neighbour's features and often suffer performance degradation on non-homophilous graphs where useful information is hardly available in the local neighbourhood. In addition, earlier studies show that in some cases GNNs are even outperformed by Multi-Layer Perceptron, indicating insufficient exploitation of node feature information. Moti vated by the two limitations, we propose ProtoGNN, a novel message passing framework that augments existing GNNs by effectively combining node features with structural information. ProtoGNN learns multiple class prototypes for each class from raw node features with the slot-attention mechanism. These prototype representations are then transferred onto the structural node features with explicit message passing to all non-training nodes irrespective of distance. This form of message passing, from training nodes to class prototypes to non-training nodes, also serves as a shortcut that bypasses local graph neighbourhoods and captures global information. ProtoGNN is a generic framework which can be applied onto any of the existing GNN backbones to improve node representations when node features are strong and local graph information is scarce. We demonstrate through extensive experiments that ProtoGNN brings performance improvement to various GNN backbones and achieves state-of-the-art on several non-homophilous datasets.

MonoFlow: A Unified Generative Modeling Framework for GAN Variants
Mingxuan Yi,Zhanxing Zhu,Song Liu

Generative adversarial networks (GANs) play a minmax two-player game via adversarial training. The conventional understanding of adversarial training is that the discriminator is trained to estimate a divergence and the generator learns to minimize this divergence. We argue that despite the fact that many variants of GANs are developed following this paradigm, the existing theoretical understanding of GANs and the practical algorithms are inconsistent. In order to gain deeper theoretical insights and algorithmic inspiration for these GAN variants, we leverage Wasserstein gradient flows which characterize the evolution of particles in the sample space. Based on this, we introduce a unified generative modeling framework – MonoFlow: the particle evolution is rescaled via an arbitrary monotonically increasing mapping. Under our framework, adversarial training can be viewed as a procedure first obtaining MonoFlow's vector field via the discriminator and then the generator learns to parameterize the flow defined by the corresponding vector field. We also reveal the fundamental difference between variational divergence minimization and adversarial training. These analysis help us to identify what types of generator loss functions can lead to the successful training of GANs and suggest that GANs may have more loss designs beyond those developed in the literature, e.g., non-saturated loss, as long as they realize MonoFlow. Consistent empirical studies are also included to validate the effectiveness of our framework.

****

The Effective coalitions of Shapley value For Integrated Gradients
ShuYang Liu,Changjie Fan,Yu Xiong,Meng Wang,Yujing Hu,Tangjie Lv,Zixuan Chen,Runze Wu,Yang Gao

Many methods aim to explain deep neural networks (DNN) by attributing the prediction of DNN to its input features, like Integrated Gradients and Deep Shap, which both have critical baseline problems. Previous studies pursue a perfect but intractable baseline value, which is hard to find and has a very high computational cost, limiting the application range of these baseline methods. In this paper, we propose to find a set of baseline values corresponding to Shapley values which are easier to be found and have a lower computation cost. To solve computation dilemma of Shapley value, we propose Effective Shapley value (ES), a proportional sampling method to well simulate the ratios between the Shapley values of features and then propose Shapley Integrated Gradients (SIG) to combine Integrated Gradients with ES, to achieve a good balance between efficiency and effectiveness. Experiment results show that our ES method can well and stably approximate the ratios between Shapley values, and our SIG method has a much better and more accurate performance than common baseline values with similar computational costs.

Cold Rao-Blackwellized Straight-Through Gumbel-Softmax Gradient Estimator
Alexander Shekhovtsov

The problem of estimating the gradient of an expectation in discrete random variables arises in many applications: learning with discrete latent representations

, training neural networks with quantized weights, activations, conditional blocks, etc.
This work contributes to the development of the popular Gumbel-Softmax family of estimator, which is based on approximating argmax with a temperature-parametrized softmax. The state-of-the art in this family, the Gumbel-Rao estimator uses internal MC samples to reduce the variance.
We show that in the limit of zero temperature the internal integration has a closed form solution. The limit estimator, called ZGR, has a favorable bias and variance, is simple to implement and computationally inexpensive and is obviously free of the temperature hyperparameter. Furthermore, ZGR is unbiased for the class of quadratic functions of categorical variables and can be decomposed into a sum of two simple but not very well performing on their own estimators: the straight through estimator and the DARN estimator. Experiments thoroughly validate the method.
****
Tree-structure segmentation for logistic regression
Adrien Ehrhardt
The decision for a financial institution to accept or deny a loan is based on the probability of a client paying back their debt in time. This probability is given by a model such as a logistic regression, and estimated based on, e.g., the clients' characteristics, their credit history, the repayment performance. Historically, different models have been developed on different markets and/or credit products and/or addressed population. We show that this amounts to modelling default as a mixture model composed of a decision tree and logistic regression on its leaves (thereafter “logistic regression tree”). We seek to optimise this practice by considering the population to which a client belongs as a latent variable, which we will estimate. After exposing the context, the notations and the problem formalisation, we will conduct estimation using a Stochastic-Expectation-Maximisation (SEM) algorithm. We will finally show the performance on simulated data, and on real retail credit data from [COMPANY], as well as real open-source data.
****
Neural Image Compression with a Diffusion-based Decoder
Noor Fathima Khanum Mohamed Ghouse,Jens Petersen,Auke J. Wiggers,Tianlin Xu,Guillaume Sautiere
Diffusion probabilistic models have recently achieved remarkable success in generating high quality image and video data. In this work, we build on this class of generative models and introduce a method for lossy compression of high resolution images. The resulting codec, which we call \emph{DIffuson-based Residual Augmentation Codec (DIRAC)}, is the first neural codec to allow smooth traversal of the rate-distortion-perception tradeoff at test time, while obtaining competitive performance with GAN-based methods in perceptual quality. Furthermore, while sampling from diffusion probabilistic models is notoriously expensive, we show that in the compression setting the number of steps can be drastically reduced.
****
Learning ReLU networks to high uniform accuracy is intractable
Julius Berner,Philipp Grohs,Felix Voigtlaender
Statistical learning theory provides bounds on the necessary number of training samples needed to reach a prescribed accuracy in a learning problem formulated over a given target class. This accuracy is typically measured in terms of a generalization error, that is, an expected value of a given loss function. However, for several applications --- for example in a security-critical context or for problems in the computational sciences --- accuracy in this sense is not sufficient. In such cases, one would like to have guarantees for high accuracy on every input value, that is, with respect to the uniform norm. In this paper we precisely quantify the number of training samples needed for any conceivable training algorithm to guarantee a given uniform accuracy on any learning problem formulated over target classes containing (or consisting of) ReLU neural networks of a prescribed architecture. We prove that, under very general assumptions, the minimal number of training samples for this task scales exponentially both in the dept

h and the input dimension of the network architecture.

Caption supervision enables robust learners: a controlled study of distributionally robust model training

Benjamin Feuer,Ameya Joshi,Chinmay Hegde

Vision language models like CLIP are robust to natural distribution shifts, in part because CLIP learns on unstructured data using a technique called caption supervision; the model inteprets image-linked texts as ground-truth labels. In a carefully controlled comparison study, we show that CNNs trained on a standard cross-entropy loss can also benefit from caption supervision, in some cases even more than VL models, on the same data. To facilitate future experiments with high-accuracy caption-supervised models, we introduce CaptionNet, one piece of which is a class-balanced, fully supervised dataset with over 50,000 new human-labeled ImageNet-compliant samples which includes web-scraped captions. In a series of experiments on CaptionNet, we show how the choice of loss function, data filtration and supervision strategy enable robust computer vision.

Active Learning for Object Detection with Evidential Deep Learning and Hierarchical Uncertainty Aggregation

Younghyun Park,Wonjeong Choi,Soyeong Kim,Dong-Jun Han,Jaekyun Moon

Despite the huge success of object detection, the training process still requires an immense amount of labeled data. Although various active learning solutions for object detection have been proposed, most existing works do not take advantage of epistemic uncertainty, which is an important metric for capturing the usefulness of the sample. Also, previous works pay little attention to the attributes of each bounding box (e.g., nearest object, box size) when computing the informativeness of an image. In this paper, we propose a new active learning strategy for object detection that overcomes the shortcomings of prior works. To make use of epistemic uncertainty, we adopt evidential deep learning (EDL) and propose a new module termed model evidence head (MEH), that makes EDL highly compatible with object detection. Based on the computed epistemic uncertainty of each bounding box, we propose hierarchical uncertainty aggregation (HUA) for obtaining the informativeness of an image. HUA realigns all bounding boxes into multiple levels based on the attributes and aggregates uncertainties in a bottom-up order, to effectively capture the context within the image. Experimental results show that our method outperforms existing state-of-the-art methods by a considerable margin.

How Sharpness-Aware Minimization Minimizes Sharpness?

Kaiyue Wen,Tengyu Ma,Zhiyuan Li

Sharpness-Aware Minimization (SAM) is a highly effective regularization technique for improving the generalization of deep neural networks for various settings. However, the underlying working of SAM remains elusive because of various intriguing approximations in the theoretical characterizations. SAM intends to penalize a notion of sharpness of the model but implements a computationally efficient variant; moreover, a third notion of sharpness was used for proving generalization guarantees. The subtle differences in these notions of sharpness can indeed lead to significantly different empirical results. This paper rigorously nails down the exact sharpness notion that SAM regularizes and clarifies the underlying mechanism. We also show that the two steps of approximations in the original motivation of SAM individually lead to inaccurate local conclusions, but their combination accidentally reveals the correct effect, when full-batch gradients are applied. Furthermore, we also prove that the stochastic version of SAM in fact regularizes the third notion of sharpness mentioned above, which is most likely to be the preferred notion for practical performance. The key mechanism behind this intriguing phenomenon is the alignment between the gradient and the top eigenvector of Hessian when SAM is applied.

On discrete symmetries of robotics systems: A group-theoretic and data-driven analysis

Daniel Ordonez-Apraez,Mario Martin,Antonio Agudo,Francesc Moreno-Noguer

In this work, we study the Morphological Symmetries of dynamical systems with one or more planes of symmetry, a predominant feature in animal biology and robotic systems, characterized by the duplication and balanced distribution of body parts. These morphological symmetries imply that the system's dynamics are symmetric (or approximately symmetric), which in turn imprints symmetries in optimal control policies and in all proprioceptive and exteroceptive measurements related to the evolution of the system's dynamics. For data-driven methods, symmetry represents an inductive bias that justifies data augmentation and the construction of symmetric function approximators. To this end, we use Group Theory to present a theoretical and practical framework allowing for (1) the identification of the system's morphological symmetry Group $\G$, (2) the characterization of how the group acts upon the system state variables and any relevant measurement living in the Euclidean space, and (3) the exploitation of data symmetries through the use of $\G$-equivariant/$\G$-invariant Neural Networks, for which we present experimental results on synthetic and real-world applications, demonstrating how symmetry constraints lead to better sample efficiency and generalization while reducing the number of trainable parameters.

The Implicit Bias of Minima Stability in Multivariate Shallow ReLU Networks

Mor Shpigel Nacson,Rotem Mulayoff,Greg Ongie,Tomer Michaeli,Daniel Soudry

We study the type of solutions to which stochastic gradient descent converges when used to train a single hidden-layer multivariate ReLU network with the quadratic loss. Our results are based on a dynamical stability analysis. In the univariate case, it was shown that linearly stable minima correspond to network functions (predictors), whose second derivative has a bounded weighted L^1 norm. Notably, the bound gets smaller as the step size increases, implying that training with a large step size leads to `smoother' predictors. Here we generalize this result to the multivariate case, showing that a similar result applies to the Laplacian of the predictor. We demonstrate the tightness of our bound on the MNIST dataset, and show that it accurately captures the behavior of the solutions as a function of the step size. Additionally, we prove a depth separation result on the approximation power of ReLU networks corresponding to stable minima of the loss. Specifically, although shallow ReLU networks are universal approximators, we prove that stable shallow networks are not. Namely, there is a function that cannot be well-approximated by stable single hidden-layer ReLU networks trained with a non-vanishing step size. This is while the same function can be realized as a stable two hidden-layer ReLU network. Finally, we prove that if a function is sufficiently smooth (in a Sobolev sense) then it can be approximated arbitrarily well using shallow ReLU networks that correspond to stable solutions of gradient descent.

Consciousness-Aware Multi-Agent Reinforcement Learning

Jianzhun Shao,Hongchang Zhang,Yun Qu,Chang Liu,Shuncheng He,Yuhang Jiang,Xiangyang Ji

In cooperative multi-agent reinforcement learning, centralized training with decentralized execution (CTDE) shows great promise for a trade-off between independent Q-learning and joint action learning. However, vanilla CTDE methods assumed a fixed number of agents could hardly adapt to real-world scenarios where dynamic team compositions typically suffer from the dilemma of dramatic partial observability variance. Specifically, agents with extensive sight ranges are prone to be affected by trivial environmental substrates, dubbed the “attention distraction” issue; ones with limited observability can hardly sense their teammates, hindering the quality of cooperation. In this paper, we propose a Consciousness-Aware Multi-Agent reinforcement learning (CAMA) approach, which roots in a divide-and-conquer strategy to facilitate stable and sustainable teamwork. Concretely, CAMA targets dividing the input entities with controlled observability masks by an Entity Dividing Module (EDM) according to their execution relevance for consciousness learning. To tackle the attention distraction issue, the highly related entities are fed to a Consciousness Enhancement Module (CEM) for consciousness-a

ware representation extraction via action prediction with an inverse model. For better out-of-sight-range cooperation, the lowly related ones are compressed to brief messages by a Consciousness Replenishment Module (CRM) with a conditional mutual information estimator. Our CAMA outperforms the SOTA methods significantly on the challenging StarCraftII, MPE, and Traffic Junction benchmarks.

Better with Less: Data-Active Pre-training of Graph Neural Networks

Jiarong Xu,Renhong Huang,XIN JIANG,Yuxuan Cao,Carl Yang,Chunping Wang,Yang Yang

Recently, pre-training on graph neural networks (GNNs) has become an active research area and is used to learn transferable knowledge for downstream tasks with unlabeled data. The success of graph pre-training models is often attributed to the massive amount of input data. In this paper, however, we identify the curse of big data phenomenon in graph pre-training: more training samples and graph datasets do not necessarily lead to better performance. Motivated by this observation, we propose a better-with-less framework for graph pre-training: few, but carefully chosen data are fed into a GNN model to enhance pre-training. This novel pre-training pipeline is called the data-active graph pre-training (APT) framework, and is composed of a graph selector and a pre-training model. The graph selector chooses the most representative and instructive data points based on the inherent properties of graphs as well as the predictive uncertainty. The proposed uncertainty, as feedback from the pre-training model, measures the confidence level of the model to the data. When fed with the chosen data, on the other hand, the pre-training model grasps an initial understanding of the new, unseen data, and at the same time attempts to remember the knowledge learnt from the previous data. Therefore, the integration and interaction between these two components form a unified framework, in which graph pre-training is performed in a progressive way. Experiment results show that the proposed APT framework is able to obtain an efficient pre-training model with fewer training data and better downstream performance.

MAST: Masked Augmentation Subspace Training for Generalizable Self-Supervised Priors

Chen Huang,Hanlin Goh,Jiatao Gu,Joshua M. Susskind

Recent Self-Supervised Learning (SSL) methods are able to learn feature representations that are invariant to different data augmentations, which can then be transferred to downstream tasks of interest. However, different downstream tasks require different invariances for their best performance, so the optimal choice of augmentations for SSL depends on the target task. In this paper, we aim to learn self-supervised features that generalize well across a variety of downstream tasks (e.g., object classification, detection and instance segmentation) without knowing any task information beforehand. We do so by Masked Augmentation Subspace Training (or MAST) to encode in the single feature space the priors from different data augmentations in a factorized way. Specifically, we disentangle the feature space into separate subspaces, each induced by a learnable mask that selects relevant feature dimensions to model invariance to a specific augmentation. We show the success of MAST in jointly capturing generalizable priors from different augmentations, using both unique and shared features across the subspaces. We further show that MAST benefits from uncertainty modeling to reweight ambiguous samples from strong augmentations that may cause similarity mismatch in each subspace. Experiments demonstrate that MAST consistently improves generalization on various downstream tasks, while being task-agnostic and efficient during SSL. We also provide interesting insights about how different augmentations are related and how uncertainty reflects learning difficulty.

Graph-based Deterministic Policy Gradient for Repetitive Combinatorial Optimization Problems

Zhongyuan Zhao,Ananthram Swami,Santiago Segarra

We propose an actor-critic framework for graph-based machine learning pipelines with non-differentiable blocks, and apply it to repetitive combinatorial optimization problems (COPs) under hard constraints. Repetitive COP refers to problems to be solved repeatedly on graphs of the same or slowly changing topology but rapidly changing node or edge weights. Compared to one-shot COPs, repetitive COPs often rely on fast heuristics to solve one instance of the problem before the next one arrives, at the cost of a relatively large optimality gap. Through numerical experiments on several discrete optimization problems, we show that our approach can learn reusable node or edge representations to reduce the optimality gap of fast heuristics for independent repetitive COPs, and can optimize the long-term objectives for repetitive COPs embedded in graph-based Markov decision processes. Lower Bounds on the Depth of Integral ReLU Neural Networks via Lattice Polytopes

Christian Alexander Haase,Christoph Hertrich,Georg Loho

We prove that the set of functions representable by ReLU neural networks with integer weights strictly increases with the network depth while allowing arbitrary width. More precisely, we show that $\lceil\log_2(n)\rceil$ hidden layers are indeed necessary to compute the maximum of n numbers, matching known upper bounds. Our results are based on the known duality between neural networks and Newton polytopes via tropical geometry. The integrality assumption implies that these Newton polytopes are lattice polytopes. Then, our depth lower bounds follow from a parity argument on the normalized volume of faces of such polytopes.

Contextual Transformer for Offline Reinforcement Learning

Runji Lin,Ye Li,Xidong Feng,Zhaowei Zhang,XIAN HONG WU FUNG,Haifeng Zhang,Jun Wang,Yali Du,Yaodong Yang

Recently, the pretrain-tuning paradigm in large-scale sequence models has made significant progress in Natural Language Processing and Computer Vision. However, such a paradigm is still hindered by intractable challenges in Reinforcement Learning (RL), including the lack of self-supervised large-scale pretraining methods based on offline data and efficient fine-tuning/prompt-tuning over unseen downstream tasks. In this work, we explore how prompts can help sequence-modeling-based offline Reinforcement Learning (offline-RL) algorithms. Firstly, we propose prompt tuning for offline RL, where a context vector sequence is concatenated with the input to guide the conditional generation. As such, we can pretrain a model on the offline dataset with supervised loss and learn a prompt to guide the policy to play the desired actions. Secondly, we extend the framework to the Meta-RL setting and propose Contextual Meta Transformer (CMT), which leverages the context among different tasks as the prompt to improve the performance on unseen tasks. We conduct extensive experiments across three different offline-RL settings: offline single-agent RL on the D4RL dataset, offline Meta-RL on the MuJoCo benchmark, and offline MARL on the SMAC benchmark. The results validate the strong performance, and generality of our methods.

Two-Dimensional Weisfeiler-Lehman Graph Neural Networks for Link Prediction

Yang Hu,Xiyuan Wang,Zhouchen Lin,Pan Li,Muhan Zhang

Link prediction is one important application of graph neural networks (GNNs). Most existing GNNs for link prediction are based on one-dimensional Weisfeiler-Lehman (1-WL) test. 1-WL-GNNs first compute node representations by iteratively passing neighboring node features to the center, and then obtain link representations by aggregating the pairwise node representations. As pointed out by previous works, this two-step procedure results in low discriminating power, as 1-WL-GNNs by nature learn node-level representations instead of link-level. In this paper, we study a completely different approach which can directly obtain node pair (link) representations based on \textit{two-dimensional Weisfeiler-Lehman (2-WL) tests}. 2-WL tests directly use links (2-tuples) as message passing units instead of nodes, and thus can directly obtain link representations. We theoretically analyze the expressive power of 2-WL tests to discriminate non-isomorphic links, and prove their superior link discriminating power than 1-WL. Based on different 2-WL variants, we propose a series of novel 2-WL-GNN models for link prediction. Experiments on a wide range of real-world datasets demonstrate their competitive performance to state-of-the-art baselines and superiority over plain 1-WL-GNNs.

Wasserstein Auto-encoded MDPs: Formal Verification of Efficiently Distilled RL Policies with Many-sided Guarantees

Florent Delgrange,Ann Nowe,Guillermo Perez

Although deep reinforcement learning (DRL) has many success stories, the large-scale deployment of policies learned through these advanced techniques in safety-critical scenarios is hindered by their lack of formal guarantees. Variational Markov Decision Processes (VAE-MDPs) are discrete latent space models that provide a reliable framework for distilling formally verifiable controllers from any RL policy. While the related guarantees address relevant practical aspects such as the satisfaction of performance and safety properties, the VAE approach suffers from several learning flaws (posterior collapse, slow learning speed, poor dynamics estimates), primarily due to the absence of abstraction and representation guarantees to support latent optimization. We introduce the Wasserstein auto-encoded MDP (WAE-MDP), a latent space model that fixes those issues by minimizing a penalized form of the optimal transport between the behaviors of the agent executing the original policy and the distilled policy, for which the formal guarantees apply. Our approach yields bisimulation guarantees while learning the distilled policy, allowing concrete optimization of the abstraction and representation model quality. Our experiments show that, besides distilling policies up to 10 times faster, the latent model quality is indeed better in general. Moreover, we present experiments from a simple time-to-failure verification algorithm on the latent space. The fact that our approach enables such simple verification techniques highlights its applicability.

Towards graph-level anomaly detection via deep evolutionary mapping

Xiaoxiao Ma,Jian Yang,Jia Wu,Quan Z. Sheng

Graph-level anomaly detection aims at depicting anomalous individual graphs in a graph set. Due to its significance in various real-world application fields, such as identifying rare molecules in chemistry and detecting potential frauds in online social networks, graph-level anomaly detection has received great attention. In distinction from node- and edge-level anomaly detection that is devoted to identifying anomalies on a single graph, graph-level anomaly detection faces more significant challenges because both the intra- and inter-graph structural and attribute patterns need to be taken into account to distinguish anomalies that exhibit deviating structures, rare attributes or the both. Although deep graph representation learning shows effectiveness in fusing high-level representations and capturing characters of individual graphs, most of the existing works are defective in graph-level anomaly detection because of their limited capability in exploring information across graphs, the imbalanced data distribution of anomalies, and low interpretability of the black-box graph neural networks (GNNs). To bridge these gaps, we propose a novel deep evolutionary graph mapping framework named GmapAD, which can adaptively map each graph into a new feature space based on its similarity to a set of representative nodes chosen from the graph set. By automatically adjusting the candidate nodes using a specially designed evolutionary algorithm, anomalies and normal graphs are mapped to separate areas in the new feature space where a clear boundary between them can be learned. The selected candidate nodes can therefore be regarded as a benchmark for explaining anomalies because anomalies are more dissimilar/similar to the benchmark than normal graphs. Through our extensive experiments on nine real-world datasets, we demonstrate that exploring both intra- and inter-graph structural and attribute information are critical to spot anomalous graphs, and our framework outperforms the state of the art on all datasets used in the experiments.

Global Explainability of GNNs via Logic Combination of Learned Concepts

Steve Azzolin,Antonio Longa,Pietro Barbiero,Pietro Lio,Andrea Passerini

While instance-level explanation of GNN is a well-studied problem with plenty of approaches being developed, providing a global explanation for the behaviour of a GNN is much less explored, despite its potential in interpretability and debu gging. Existing solutions either simply list local explanations for a given class, or generate a synthetic prototypical graph with maximal score for a given class, completely missing any combinatorial aspect that the GNN could have learned. In this work, we propose GLGExplainer (Global Logic-based GNN Explainer), the first Global Explainer capable of generating explanations as arbitrary Boolean combinations of learned graphical concepts. GLGExplainer is a fully differentiable architecture that takes local explanations as inputs and combines them into a logic formula over graphical concepts, represented as clusters of local explanations.

Contrary to existing solutions, GLGExplainer provides accurate and human-interpretable global explanations that are perfectly aligned with ground-truth explanations (on synthetic data) or match existing domain knowledge (on real-world data). Extracted formulas are faithful to the model predictions, to the point of providing insights into some occasionally incorrect rules learned by the model, making GLGExplainer a promising diagnostic tool for learned GNNs.

BO-Muse: A Human expert and AI teaming framework for accelerated experimental design

Sunil Gupta,Alistair Shilton,Shannon Ryan,Arun Kumar Anjanapura Venkatesh,Majid Abdolshah,Hung Le,Santu Rana,Julian Berk,Mahad Rashid,Svetha Venkatesh

In this paper we introduce BO-Muse, a new approach to human-AI teaming for the optimisation of expensive blackbox functions. Inspired by the intrinsic difficulty of extracting expert knowledge and distilling it back into AI models and by observations of human behaviour in real-world experimental design, our algorithm lets the human expert take the lead in the experimental process. The human expert can use their domain expertise to its full potential, while the AI plays the role of a muse, injecting novelty and searching for areas of weakness to break the human out of over-exploitation induced by cognitive entrenchment. With mild assumptions, we show that our algorithm converges sub-linearly, at a rate faster than the AI or human alone. We validate our algorithm using synthetic data and with human experts performing real-world experiments.

****

Coordination Scheme Probing for Generalizable Multi-Agent Reinforcement Learning

Hao Ding,Chengxing Jia,Cong Guan,Feng Chen,Lei Yuan,Zongzhang Zhang,Yang Yu

Coordinating with previously unknown teammates without joint learning is a crucial need for real-world multi-agent applications, such as human-AI interaction. An active research topic on this problem is ad hoc teamwork, which improves agents' coordination ability in zero-shot settings. However, previous works can only solve the problem of a single agent's coordination with different teams, which is not in line with arbitrary group-to-group coordination in complex multi-agent scenarios. Moreover, they commonly suffer from limited adaptation ability within an episode in a zero-shot setting. To address these problems, we introduce the Coordination Scheme Probing (CSP) approach that applies a disentangled scheme probing module to represent and classify the newly arrived teammates beforehand with limited pre-collected episodic data and makes multi-agent control accordingly. To achieve generalization, CSP learns a meta-policy with multiple sub-policies that follow distinguished coordination schemes in an end-to-end fashion and automatically reuses it to coordinate with unseen teammates. Empirically, we show that the proposed method achieves remarkable performance compared to existing ad hoc teamwork and policy generalization methods in various multi-agent cooperative scenarios.

Generalization error bounds for Neural Networks with ReLU activation

Harsh Pandey,Amitabha Bagchi,Srikanta J. Bedathur,Arindam Bhattacharya

We show rigorous bounds on the generalization error for Neural Networks with ReLU activation under the condition that the network size doesn't grow with the training set size. In order to prove these bounds we weaken the notion of uniform stability of a learning algorithm in a probabilistic way by positing the notion of almost sure (a.s.) support stability and proving that if an algorithm has low enough a.s. support stability its generalization error tends to 0 as the trainin g set size increases. Further we show that for Stochastic Gradient Descent to be almost surely support stable we only need the loss function to be locally Lipschitz and locally smooth with probability 1, thereby showing low generalization error with weaker conditions than have been used in the literature. We then show that Neural Networks with ReLU activation and a doubly differentiable loss function possess these properties, thereby proving low generalization error. The caveat is that the size of NN must not grow with the size of the training set. Finally we present experimental evidence to validate our theoretical results.

Two Birds, One Stone: An Equivalent Transformation for Hyper-relational Knowledge Graph Modeling

Yu Liu,Shu Yang,Jingtao Ding,quanming yao,Yong Li

By representing knowledge in a primary triple associated with additional attribute value qualifiers, hyper-relational knowledge graph (HKG) that generalizes triple based knowledge graph (KG) has been attracting research attention recently. Compared with KG, HKG is enriched with the semantic difference between the primary triple and additional qualifiers as well as the structural connection between entities in hyper-relational graph structure. However, to model HKG, existing studies mainly focus on either semantic information or structural information therein, fail to capture both simultaneously. To tackle this issue, in this paper, we propose an equivalent transformation for HKG modeling, referred to as TransEQ. Specifically, the equivalent transformation transforms a HKG to a KG, which considers both semantic and structural characteristics. Then a generalized encoder-decoder framework is developed to bridge the modeling research between KG and HKG. In the encoder part, KG-based graph neural networks are leveraged for structural modeling; while in the decoder part, various HKG-based scoring functions are exploited for semantic modeling. Especially, we design the sharing embedding mechanism in the encoder-decoder framework with semantic relatedness captured. We further theoretically prove that TransEQ preserves complete information in the equivalent transformation, and also achieves full expressivity. Finally, extensive experiments on three benchmarks demonstrate the superior performance of TransEQ in terms of both effectiveness and efficiency. On the largest benchmark WikiPeople, TransEQ significantly improves the state-of-the-art models by 15% on MRR.

Gradient Gating for Deep Multi-Rate Learning on Graphs

T. Konstantin Rusch,Benjamin Paul Chamberlain,Michael W. Mahoney,Michael M. Bronstein,Siddhartha Mishra

We present Gradient Gating (G^2), a novel framework for improving the performance of Graph Neural Networks (GNNs). Our framework is based on gating the output of GNN layers with a mechanism for multi-rate flow of message passing information across nodes of the underlying graph. Local gradients are harnessed to further modulate message passing updates. Our framework flexibly allows one to use any basic GNN layer as a wrapper around which the multi-rate gradient gating mechanism is built. We rigorously prove that G^2 alleviates the oversmoothing problem and allows the design of deep GNNs. Empirical results are presented to demonstrate that the proposed framework achieves state-of-the-art performance on a variety of graph learning tasks, including on large-scale heterophilic graphs.

****

MAESTRO: Open-Ended Environment Design for Multi-Agent Reinforcement Learning

Mikayel Samvelyan,Akbir Khan,Michael D Dennis,Minqi Jiang,Jack Parker-Holder,Jakob Nicolaus Foerster,Roberta Raileanu,Tim Rocktäschel

Open-ended learning methods that automatically generate a curriculum of increasingly challenging tasks serve as a promising avenue toward generally capable reinforcement learning agents. Existing methods adapt curricula independently over either environment parameters (in single-agent settings) or co-player policies (in multi-agent settings). However, the strengths and weaknesses of co-players can manifest themselves differently depending on environmental features. It is thus crucial to consider the dependency between the environment and co-player when shaping a curriculum in multi-agent domains. In this work, we use this insight and extend Unsupervised Environment Design (UED) to multi-agent environments. We t hen introduce Multi-Agent Environment Design Strategist for Open-Ended Learning (MAESTRO), the first multi-agent UED approach for two-player zero-sum settings. MAESTRO efficiently produces adversarial, joint curricula over both environments and co-players and attains minimax-regret guarantees at Nash equilibrium. Our experiments show that MAESTRO outperforms a number of strong baselines on competitive two-player games, spanning discrete and continuous control settings.

Capturing the Motion of Every Joint: 3D Human Pose and Shape Estimation with Independent Tokens

Sen Yang,Wen Heng,Gang Liu,GUOZHONG LUO,Wankou Yang,Gang YU

In this paper we present a novel method to estimate 3D human pose and shape from monocular videos. This task requires directly recovering pixel-alignment 3D human pose and body shape from monocular images or videos, which is challenging due to its inherent ambiguity. To improve precision, existing methods highly rely on the initialized mean pose and shape as prior estimates and parameter regression with an iterative error feedback manner. In addition, video-based approaches model the overall change over the image-level features to temporally enhance the single-frame feature, but fail to capture the rotational motion at the joint level, and cannot guarantee local temporal consistency. To address these issues, we propose a novel Transformer-based model with a design of independent tokens. First, we introduce three types of tokens independent of the image feature: \textit{joint rotation tokens, shape token, and camera token}.

By progressively interacting with image features through Transformer layers, these tokens learn to encode the prior knowledge of human 3D joint rotations, body shape, and position information from large-scale data, and are updated to estimate SMPL parameters conditioned on a given image. Second, benefiting from the proposed token-based representation, we further use a temporal model to focus on capturing the rotational temporal information of each joint, which is empirically conducive to preventing large jitters in local parts. Despite being conceptually simple, the proposed method attains superior performances on the 3DPW and Human3.6M datasets. Using ResNet-50 and Transformer architectures, it obtains 42.0 mm error on the PA-MPJPE metric of the challenging 3DPW, outperforming state-of-the-art counterparts by a large margin. Code will be publicly available\footnote{\url{https://github.com/yangsenius/INT_HMR_Model}}.

Almost Linear Constant-Factor Sketching for ℓ_1 and Logistic Regression

Alexander Munteanu,Simon Omlor,David Woodruff

We improve upon previous oblivious sketching and turnstile streaming results for ℓ_1 and logistic regression, giving a much smaller sketching dimension achieving $O(1)$-approximation and yielding an efficient optimization problem in the sketch space. Namely, we achieve for any constant $c>0$ a sketching dimension of $\tilde{O}(d^{1+c})$ for ℓ_1 regression and $\tilde{O}(\mu d^{1+c})$ for logistic regression, where μ is a standard measure that captures the complexity of compressing the data. For ℓ_1-regression our sketching dimension is near-linear and improves previous work which either required $\Omega(\log d)$-approximation with this sketching dimension, or required a larger $\operatorname{poly}(d)$ number of rows. Similarly, for logistic regression previous work had worse $\operatorname{poly}(\mu d)$ factors in its sketching dimension. We also give a tradeoff that yields a $1+\varepsilon$ approximation in input sparsity time by increasing the total size to $(d\log(n)/\varepsilon)^{O(1/\varepsilon)}$ for ℓ_1 and to $(\mu d\log(n)/\varepsilon)^{O(1/\varepsilon)}$ for logistic regression. Finally, we show that our sketch can be extended to approximate a regularized version of logistic regression where the data-dependent regularizer corresponds to the variance of the individual logistic losses.

Neural-based classification rule learning for sequential data

Marine Collery,Philippe Bonnard,François Fages,Remy Kusters

Discovering interpretable patterns for classification of sequential data is of key importance for a variety of fields, ranging from genomics to fraud detection or more generally interpretable decision-making.

In this paper, we propose a novel differentiable fully interpretable method to discover both local and global patterns (i.e. catching a relative or absolute temporal dependency) for rule-based binary classification.
It consists of a convolutional binary neural network with an interpretable neural filter and a training strategy based on dynamically-enforced sparsity.
We demonstrate the validity and usefulness of the approach on synthetic datasets and on an open-source peptides dataset.
Key to this end-to-end differentiable method is that the expressive patterns used in the rules are learned alongside the rules themselves.
****
Q-learning Decision Transformer: Leveraging Dynamic Programming for Conditional Sequence Modelling in Offline RL
Taku Yamagata,Ahmed Khalil,Raul Santos-Rodriguez
Recent works have shown that tackling offline reinforcement learning (RL) with a conditional policy produces promising results. The Decision Transformer (DT) combines the conditional policy approach and a transformer architecture, showing competitive performance against several benchmarks. However, DT lacks stitching ability -- one of the critical abilities for offline RL to learn the optimal policy from sub-optimal trajectories. This issue becomes particularly significant when the offline dataset only contains sub-optimal trajectories.
On the other hand, the conventional RL approaches based on Dynamic Programming (such as Q-learning) do not have the same limitation; however, they suffer from unstable learning behaviours, especially when they rely on function approximation in an off-policy learning setting. In this paper, we propose the Q-learning Decision Transformer (QDT) to address the shortcomings of DT by leveraging the benefits of Dynamic Programming (Q-learning). It utilises the Dynamic Programming results to relabel the return-to-go in the training data to then train the DT with the relabelled data. Our approach efficiently exploits the benefits of these two approaches and compensates for each other's shortcomings to achieve better performance. We empirically show these in both simple toy environments and the more complex D4RL benchmark, showing competitive performance gains.

****
ϵ-Invariant Hierarchical Reinforcement Learning for Building Generalizable Policy
Yihan Li,Tianren Zhang,Jinsheng Ren,Feng Chen
Goal-conditioned Hierarchical Reinforcement Learning (HRL) has shown remarkable potential for solving complex control tasks. However, existing methods struggle in tasks that require generalization since the learned subgoals are highly task-specific and therefore hardly reusable. In this paper, we propose a novel HRL framework called \textit{ϵ-Invariant HRL} that uses abstract, task-agnostic subgoals reusable across tasks, resulting in a more generalizable policy. Although such subgoals are reusable, a transition mismatch problem caused by the inevitable incorrect value evaluation of subgoals can lead to non-stationary learning and even collapse. We mitigate this mismatch problem by training the high-level policy to be adaptable to the stochasticity manually injected into the low-level policy. As a result, our framework can leverage reusable subgoals to constitute a hierarchical policy that can effectively generalize to unseen new tasks. Theoretical analysis and experimental results in continuous control navigation tasks and challenging zero-shot generalization tasks show that our approach significantly outperforms state-of-the-art methods.
****
Learning Control by Iterative Inversion
Gal Leibovich,Guy Jacob,Or Avner,Gal Novik,Aviv Tamar
We formulate learning for control as an inverse problem - inverting a dynamical system to give the actions which yield desired behavior. The key challenge in this formulation is a distribution shift in the inputs to the function to be inverted - the learning agent can only observe the forward mapping (its actions' consequences) on trajectories that it can execute, yet must learn the inverse mapping for inputs-outputs that correspond to a different, desired behavior. We propos

e a general recipe for inverse problems with a distribution shift that we term $\textit{iterative inversion}$ - learn the inverse mapping under the current input distribution (policy), then use it on the desired output samples to obtain a new input distribution, and repeat.

As we show, iterative inversion can converge to the desired inverse mapping, but under rather strict conditions on the mapping itself.

We next apply iterative inversion to learn control. Our input is a set of demonstrations of desired behavior, given as video embeddings of trajectories (without actions), and our method iteratively learns to imitate trajectories generated by the current policy, perturbed by random exploration noise. We find that constantly adding the demonstrated trajectory embeddings as input to the policy when generating trajectories to imitate, a-la iterative inversion, we effectively steer the learning towards the desired trajectory distribution. To the best of our knowledge, this is the first exploration of learning control from the viewpoint of inverse problems, and the main advantage of our approach is simplicity - it does not require rewards, and only employs supervised learning, which can be easily scaled to use state-of-the-art trajectory embedding techniques and policy representations. Indeed, with a VQ-VAE embedding, and a transformer-based policy, we demonstrate non-trivial continuous control on several tasks. Further, we report an improved performance on imitating diverse behaviors compared to reward based methods.

****

DetectBench: An Object Detection Benchmark for OOD Generalization Algorithms

Fan Wu,Nanyang Ye,Lanqing HONG,Chensheng Peng,Bikang Pan,Huaihai Lyu,Heyuan Shi

The consensus about practical machine learning tasks, such as object detection, is still the test data are drawn from the same distribution as the training data, which is known as IID (Independent and Identically Distributed). However, it can not avoid being confronted with OOD (Out-of-Distribution) scenarios in real practice. It is risky to apply an object detection algorithm without figuring out its OOD generalization performance. On the other hand, a plethora of OOD generalization algorithms has been proposed to amortize the gap between the in-house and open-world performances of machine learning systems. However, their effectiveness was only demonstrated in the image classification tasks. It is still an opening question of how these algorithms perform on complex and practical tasks. In this paper, we first specify the setting of OOD-OD (OOD generalization object detection). Then, we propose DetectBench consisting of four OOD-OD benchmark datasets to evaluate various object detection and OOD generalization algorithms. From extensive experiments on DetectBench, we find that existing OOD generalization algorithms fail dramatically when applied to the more practical object detection tasks. This raises questions over the current progress on a large number of these algorithms and whether they can be effective in practice beyond simple toy examples. For future work, we sincerely hope that DetectBench can serve as a foothold for OOD-OD research.

Generalization Bounds with Arbitrary Complexity Measures

Paul Viallard,Rémi Emonet,Amaury Habrard,Emilie Morvant,Valentina Zantedeschi

In statistical learning theory, generalization bounds usually involve a complexity measure that is constrained by the considered theoretical framework. This limits the scope of such analysis, as in practical algorithms, other forms of regularization are used. Indeed, the empirical work of Jiang et al. (2019) shows that (I) common complexity measures (such as the VC-dimension) do not correlate with the generalization gap and that (ii) there exist arbitrary complexity measures that are better correlated with the generalization gap, but come without generalization guarantees. In this paper, we bridge the gap between this line of empirical works and generalization bounds of statistical learning theory. To do so, we leverage the framework of disintegrated PAC-Bayes bounds to derive a generalization bound that involves an arbitrary complexity measure. Our bound stands in probability jointly over the hypotheses and the learning sample, which allows us to improve the correlation between generalization gap and complexity, as the latter can be set to fit both the hypothesis class and the task.

Learning To Invert: Simple Adaptive Attacks for Gradient Inversion in Federated Learning

Ruihan Wu,Xiangyu Chen,Chuan Guo,Kilian Q Weinberger

Gradient inversion attack enables recovery of training samples from model updates in federated learning (FL) and constitutes a serious threat to data privacy. To mitigate this vulnerability, prior work proposed both principled defenses based on differential privacy, as well as heuristic defenses based on gradient compression as countermeasures. These defenses have so far been very effective, in particular those based on gradient compression that allow the model to maintain high accuracy while greatly reducing the attack's effectiveness. In this work, we argue that such findings do not accurately reflect the privacy risk in FL, and show that existing defenses can be broken by a simple adaptive attack that trains a model using auxiliary data to learn how to invert gradients on both vision and language tasks.

****

Leveraging Unlabeled Data to Track Memorization

Mahsa Forouzesh,Hanie Sedghi,Patrick Thiran

Deep neural networks may easily memorize noisy labels present in real-world data, which degrades their ability to generalize. It is therefore important to track and evaluate the robustness of models against noisy label memorization. We propose a metric, called $\textit{susceptibility}$, to gauge such memorization for neural networks. Susceptibility is simple and easy to compute during training. Moreover, it does not require access to ground-truth labels and it only uses unlabeled data. We empirically show the effectiveness of our metric in tracking memorization on various architectures and datasets and provide theoretical insights into the design of the susceptibility metric. Finally, we show through extensive experiments on datasets with synthetic and real-world label noise that one can utilize susceptibility and the overall training accuracy to distinguish models that maintain a low memorization on the training set and generalize well to unseen clean data.

CCIL: Context-conditioned imitation learning for urban driving

Ke Guo,Wei Jing,Wenxi Liu,Junbo Chen,Jia Pan

Imitation learning is a promising solution to the challenging autonomous urban driving task as experienced human drivers can effortlessly tackle highly complex driving scenarios. Behavior cloning is the most widely applied imitation learning approach in autonomous driving due to its exemption from potentially risky online interactions, but it suffers from the covariate shift issue. To mitigate this problem, we propose a context-conditioned imitation learning approach that learns a policy to map the context state into the ego vehicle's state instead of the typical formulation from both ego and context state to the ego action. Besides, to make full use of the spatial and temporal relations in the context to infer the ego future states, we design a novel policy network based on the Transformer, whose attention mechanism has demonstrated excellent performance in capturing relations. Finally, during evaluation, a linear quadratic controller is employed to produce smooth planning based on the predicted states from the policy network. Experiments on the real-world large-scale Lyft and nuPlan datasets demonstrate that our method can surpass the state-of-the-art method significantly.

Improving Continual Learning by Accurate Gradient Reconstructions of the Past

Erik Daxberger,Siddharth Swaroop,Kazuki Osawa,Rio Yokota,Richard E Turner,José Miguel Hernández-Lobato,Mohammad Emtiyaz Khan

Knowledge reuse is essential for continual learning, and current methods attempt to realize it through regularization or experience replay. These two strategies have complementary strengths, e.g., regularization methods are compact, but replay methods can mimic batch training more accurately. At present, little has been done to find principled ways to combine the two methods and current heuristics can give suboptimal performance. Here, we provide a principled approach to comb ine and improve them by using a recently proposed principle of adaptation, where the goal is to reconstruct the “gradients of the past”, i.e., to mimic batch training by estimating gradients from past data. Using this principle, we design a prior that provably gives better gradient reconstructions by utilizing two types of replay and a quadratic weight-regularizer. This improves performance on standard benchmarks such as Split CIFAR, Split TinyImageNet, and ImageNet-1000. Our work shows that a good combination of replay and regularizer-based methods can be very effective in reducing forgetting, and can sometimes even completely eliminate it.

Group-wise Verifiable Distributed Computing for Machine Learning under Adversarial Attacks

Sangwoo Hong,Heecheol Yang,Youngseok Yoon,Jungwoo Lee

Distributed computing has been a promising solution in machine learning to accelerate the training procedure on large-scale dataset by utilizing multiple workers in parallel. However, there remain two major issues that still need to be addressed: i) adversarial attacks from malicious workers, and ii) the effect of slow workers known as stragglers. In this paper, we tackle both problems simultaneously by proposing Group-wise Verifiable Coded Computing (GVCC), which leverages coding techniques and group-wise verification to provide robustness to adversarial attacks and resiliency to straggler effects in distributed computing. The key idea of GVCC is to verify a group of computation results from workers at a time, while providing resilience to stragglers through encoding tasks assigned to workers with Group-wise Verifiable Codes. Experimental results show that GVCC outperforms the existing methods in terms of overall processing time and verification time for executing matrix multiplication, which is a key computational component in machine learning and deep learning.

Extending graph transformers with quantum computed aggregation

Slimane Thabet,Romain Fouilland,Loic Henriet

Recently, efforts have been made in the community to design new Graph Neural Networks (GNN), as limitations of Message Passing Neural Networks became more apparent. This led to the appearance of Graph Transformers using global graph features such as Laplacian Eigenmaps. In our paper, we introduce a GNN architecture where the aggregation weights are computed using the long-range correlations of a quantum system. These correlations are generated by translating the graph topology into the interactions of a set of qubits in a quantum computer. The recent development of quantum processing units enables the computation of a new family of global graph features that would be otherwise out of reach for classical hardware. We give some theoretical insights about the potential benefits of this approach, and benchmark our algorithm on standard datasets. Although not being adapted to all datasets, our model performs similarly to standard GNN architectures, and paves a promising future for quantum enhanced GNNs.

****

Policy-Based Self-Competition for Planning Problems

Jonathan Pirnay,Quirin Göttl,Jakob Burger,Dominik Gerhard Grimm

AlphaZero-type algorithms may stop improving on single-player tasks in case the value network guiding the tree search is unable to approximate the outcome of an episode sufficiently well. One technique to address this problem is transforming the single-player task through self-competition. The main idea is to compute a scalar baseline from the agent’s historical performances and to reshape an episode’s reward into a binary output, indicating whether the baseline has been exceeded or not. However, this baseline only carries limited information for the agent about strategies how to improve. We leverage the idea of self-competition and directly incorporate a historical policy into the planning process instead of its scalar performance. Based on the recently introduced Gumbel AlphaZero (GAZ), we propose our algorithm GAZ ‘Play-to-Plan’ (GAZ PTP), in which the agent learns to find strong trajectories by planning against possible strategies of its past self. We show the effectiveness of our approach in two well-known combinatorial optimization problems, the Traveling Salesman Problem and the Job-Shop Scheduli ng Problem. With only half of the simulation budget for search, GAZ PTP consistently outperforms all selected single-player variants of GAZ.

Can Fair Federated Learning reduce the need for personalization?

Alex Iacob,Pedro Porto Buarque de Gusmao,Nicholas Donald Lane

Federated Learning (FL) allows edge devices to collaboratively train machine learning models without sharing local data. Since the data distribution varies across client partitions, the performance of the federated model on local data also varies. To solve this, fair FL approaches attempt to reduce the accuracy disparity between local partitions by emphasizing clients with larger losses during training; while local adaptation personalizes the federated model by re-training on local data to provide a device participation incentive in cases where a federated model underperforms relative to one trained locally---their accuracy difference is less than zero. This paper evaluates Q-Fair Federated Learning (Q-FFL) in this relative domain and determines whether it provides a better starting point for personalization or supplants it. Contrary to expectation, Q-FFL does not significantly reduce the number of underperforming clients in a language task while doubling them in an image recognition task. Furthermore, fairness levels which maintain average accuracy provide no benefit to relative accuracy in federated or adapted models. We postulate that Q-FFL is unsuitable for our goal since clients with highly accurate local models require the federated model to have a disproportionate local partition accuracy to receive a benefit. Instead, we propose using knowledge distillation during FL training to create models with a higher local accuracy floor without forfeiting the ceiling. Our preliminary evaluation shows a 50% reduction in underperforming clients in the language task with no increase in underperforming clients for the image task. Thus, we argue that this simple change represents a more promising avenue for reducing the need for personalization than fairness.

Out-of-Distribution Detection based on In-Distribution Data Patterns Memorization with Modern Hopfield Energy

Jinsong Zhang,Qiang Fu,Xu Chen,Lun Du,Zelin Li,Gang Wang,xiaoguang Liu,Shi Han,Dongmei Zhang

Out-of-Distribution (OOD) detection is essential for safety-critical applications of deep neural networks. OOD detection is challenging since DNN models may produce very high logits value even for OOD samples. Hence, it is of great difficulty to discriminate OOD data by directly adopting Softmax on output logits as the confidence score. Differently, we detect the OOD sample with Hopfield energy in a store-then-compare paradigm. In more detail, penultimate layer outputs on the training set are considered as the representations of in-distribution (ID) data. Thus they can be transformed into stored patterns that serve as anchors to measure the discrepancy of unseen data for OOD detection. Starting from the energy function defined in Modern Hopfield Network for the discrepancy score calculation, we derive a simplified version SHE with theoretical analysis. In SHE, we utilize only one stored pattern to present each class, and these patterns can be obtained by simply averaging the penultimate layer outputs of training samples within this class. SHE has the advantages of hyperparameterfree
and high computational efficiency. The evaluations of nine widely-used OOD datasets show the promising performance of such a simple yet effective approach and its superiority over State-of-the-Art models. Code is available at https://github.com/zjs975584714/SHE ood detection.

Scaling Pareto-Efficient Decision Making via Offline Multi-Objective RL

Baiting Zhu,Meihua Dang,Aditya Grover

The goal of multi-objective reinforcement learning (MORL) is to learn policies that simultaneously optimize multiple competing objectives. In practice, an agent's preferences over the objectives may not be known apriori, and hence, we require policies that can generalize to arbitrary preferences at test time. In this work, we propose a new data-driven setup for offline MORL, where we wish to learn a preference-agnostic policy agent using only a finite dataset of offline demon strations of other agents and their preferences. The key contributions of this work are two-fold. First, we introduce D4MORL, (D)atasets for MORL that are specifically designed for offline settings. It contains 1.8 million annotated demonstrations obtained by rolling out reference policies that optimize for randomly sampled preferences on 6 MuJoCo environments with 2-3 objectives each. Second, we propose Pareto-Efficient Decision Agents (PEDA), a family of offline MORL algorithms that builds and extends Decision Transformers via a novel preference-and-return-conditioned policy. Empirically, we show that PEDA closely approximates the behavioral policy on the D4MORL benchmark and provides an excellent approximation of the Pareto-front with appropriate conditioning, as measured by the hypervolume and sparsity metrics.

Learning from Asymmetrically-corrupted Data in Regression for Sensor Magnitude

Takayuki Katsuki,Takayuki Osogami

This paper addresses a regression problem in which output label values represent the results of sensing the magnitude of a phenomenon. A low value of such labels can either mean that the actual magnitude of the phenomenon has been low or that the sensor has made an incomplete observation. This leads to a bias toward lower values in labels and its resultant learning because labels for incomplete observations are recorded as lower than those for typical observations, even if both have monitored similar phenomena. Moreover, because an incomplete observation does not provide any tags indicating incompleteness, we cannot eliminate or impute them. To address this issue, we propose a learning algorithm that explicitly models the incomplete observations to be corrupted with an asymmetric noise that always has a negative value. We show that our algorithm is unbiased with a regression learned from the uncorrupted data that does not involve incomplete observations. We demonstrate the advantages of our algorithm through numerical experiments.

NAGphormer: A Tokenized Graph Transformer for Node Classification in Large Graphs

Jinsong Chen,Kaiyuan Gao,Gaichao Li,Kun He

The graph Transformer emerges as a new architecture and has shown superior performance on various graph mining tasks. In this work, we observe that existing graph Transformers treat nodes as independent tokens and construct a single long sequence composed of all node tokens so as to train the Transformer model, causing it hard to scale to large graphs due to the quadratic complexity on the number of nodes for the self-attention computation. To this end, we propose a Neighborhood Aggregation Graph Transformer (NAGphormer) that treats each node as a sequence containing a series of tokens constructed by our proposed Hop2Token module. For each node, Hop2Token aggregates the neighborhood features from different hops into different representations and thereby produces a sequence of token vectors as one input. In this way, NAGphormer could be trained in a mini-batch manner and thus could scale to large graphs. Moreover, we mathematically show that as compared to a category of advanced Graph Neural Networks (GNNs), the decoupled Graph Convolutional Network, NAGphormer could learn more informative node representations from the multi-hop neighborhoods. Extensive experiments on benchmark datasets from small to large are conducted to demonstrate that NAGphormer consistently outperforms existing graph Transformers and mainstream GNNs. Code is available at https://github.com/JHL-HUST/NAGphormer.

Bayesian Oracle for bounding information gain in neural encoding models

Konstantin-Klemens Lurz,Mohammad Bashiri,Edgar Y. Walker,Fabian H. Sinz

In recent years, deep learning models have set new standards in predicting neural population responses. Most of these models currently focus on predicting the mean response of each neuron for a given input. However, neural variability around this mean is not just noise and plays a central role in several theories on neural computation. To capture this variability, we need models that predict full response distributions for a given stimulus. However, to measure the quality of such models, commonly used correlation-based metrics are not sufficient as they mainly care about the mean of the response distribution. An interpretable alternative evaluation metric for likelihood-based models is \textit{Information Gain} (IG) which evaluates the likelihood of a model relative to a lower and upper bound. However, while a lower bound is usually easy to obtain, constructing an upper bound turns out to be challenging for neural recordings with relatively low numbers of repeated trials, high (shared) variability, and sparse responses. In this work, we generalize the jack-knife oracle estimator for the mean---commonly used for correlation metrics---to a flexible Bayesian oracle estimator for IG based on posterior predictive distributions. We describe and address the challenges that arise when estimating the lower and upper bounds from small datasets. We then show that our upper bound estimate is data-efficient and robust even in the case of sparse responses and low signal-to-noise ratio. We further provide the derivation of the upper bound estimator for a variety of common distributions including the state-of-the-art zero-inflated mixture models, and relate IG to common mean-based metrics. Finally, we use our approach to evaluate such a mixture model resulting in 90% IG performance.

Near Optimal Private and Robust Linear Regression

Xiyang Liu,Prateek Jain,Weihao Kong,Sewoong Oh,Arun Suggala

We study the canonical statistical estimation problem of linear regression from n i.i.d. examples under (ε,δ)-differential privacy when a fraction of response variables are adversarially corrupted. We propose a variant of the popular differentially private stochastic gradient descent (DP-SGD) algorithm with two innovations: a full-batch gradient descent to improve sample complexity and a novel adaptive clipping to guarantee robustness. When there is no adversarial corruption, this algorithm improves upon the existing state-of-the-art approach and achieves near optimal sample complexity. Under label-corruption, this is the first efficient linear regression algorithm to provably guarantee both (ϵ,δ)-DP and robustness. Synthetic experiments confirm the superiority of our approach.

Inverse Learning with Extremely Sparse Feedback for Recommendation

Guanyu Lin,Yu Zheng,Chen Gao,Jianxin Chang,Yanan Niu,Yang Song,Zhiheng Li,Depeng Jin,Yong Li

Negative sampling is widely used in modern recommender systems, where negative data is randomly sampled from the whole item pool. However, such a strategy often introduces false-positive noises. Existing approaches about de-noising recommendation mainly focus on positive instances while ignoring the noise in the large amount of sampled negative feedback. In this paper, we propose a meta learning method to annotate the unlabeled data from loss and gradient perspectives, which considers the noises on both positive and negative instances. Specifically, we first propose $\textit{inverse dual loss}$ (IDL) to boost the true label learning and prevent the false label learning, based on the loss of unlabeled data towards true and false labels during the training process. To achieve more robust sampling on hard instances, we further propose $\textit{inverse gradient}$ (IG) to explore the correct updating gradient and adjust the updating based on meta learning. We conduct extensive experiments on a benchmark and an industrially collected dataset where our proposed method can significantly improve AUC by 9.25% against state-of-the-art methods. Further analysis verifies the proposed inverse learning is model-agnostic and can well annotate the labels combined with different recommendation backbones. The source code along with the best hyper-parameter settings is available at this link: https://anonymous.4open.science/r/InverseLearning-4F4F.

Instance-Specific Augmentation: Capturing Local Invariances

Ning Miao,Tom Rainforth,Emile Mathieu,Yann Dubois,Yee Whye Teh,Adam Foster,Hyunjik Kim

We introduce InstaAug, a method for automatically learning input-specific augmentations from data. Previous data augmentation methods have generally assumed ind

ependence between the original input and the transformation applied to that input. This can be highly restrictive, as the invariances that the augmentations are based on are themselves often highly input dependent; e.g., we can change a leaf from green to yellow while maintaining its label, but not a lime. InstaAug instead allows for input dependency by introducing an invariance module that maps inputs to tailored transformation distributions. It can be simultaneously trained alongside the downstream model in a fully end-to-end manner, or separately learned for a pre-trained model. We empirically demonstrate that InstaAug learns meaningful input-dependent augmentations for a wide range of transformation classes, which in turn provides better performance on both supervised and self-supervised tasks.

Spectral Subgraph Localization

Judith Hermanns,Amit Boyarski,Petros Petsinis,Alex M. Bronstein,Davide Mottin,Panagiotis Karras

Several graph mining problems are based on some variant of the subgraph isomorphism problem: Given two graphs, G and Q, does G contain a subgraph isomorphic to Q? As this problem is NP-hard, many methods avoid addressing it explicitly. In this paper, we propose a method that solves the problem by localizing, i.e., finding the position of, Q in G, by means of an alignment among graph spectra. Finding a node correspondence from Q to G thereafter is relegated to a separate task, as an instance of the graph alignment problem. We demonstrate that our spectral approach outperforms a baseline based on the state-of-the-art method for graph alignment in terms of accuracy on real graphs and scales to hundreds of nodes as no other method does.
****

Dynamical Signatures of Learning in Recurrent Networks

Marius Schneider,Andreea Lazar

Recurrent neural networks (RNNs) are powerful computational tools that operate best near the edge of chaos, where small perturbations in neuronal firing are transmitted between neurons with minimal amplification or loss. In this article, we depart from the observation that both stimulus and noise can be seen as perturbations to the intrinsic dynamics of a recurrent network, however stimulus information must be reliably preserved, while noise must be discarded. First, we show that self-organizing recurrent networks (SORNs) that learn the spatio-temporal structure of their inputs, increase their recurrent memory by preferentially propagating the relevant stimulus-specific structured signals, while becoming more robust to random perturbation. We find that the computational advantages gained through self-supervised learning are accompanied by a shift from critical to ordered dynamics, and that this dynamical shift varies with the structure of the stimulus. Next, we show that SORNs with subcritical dynamics can outperform their random RNNs counterparts with critical dynamics, on a range of tasks, including a temporal MNIST and a sequential shape-rotation task. Interestingly, when a shape is rotated, both the invariant (shape) and the variant (motion direction) aspects of the stimulus sequence are improved through learning in the subcritical SORNs. We propose that the shift in criticality is a signature of specialization and we expect it to be found in all cases in which general-purpose recurrent networks acquire self-correcting properties by internalizing the statistical structure of their inputs.
****

Shifts 2.0: Extending The Dataset of Real Distributional Shifts

Andrey Malinin,andreas athanasopoulos,Muhamed Barakovic,Meritxell Bach Cuadra,Mark Gales,Cristina Granziera,Mara Graziani,Nikolay Kartashev,Konstantinos Kyriakopoulos,Po-Jui Lu,Nataliia Molchanova,Antonis Nikitakis,Vatsal Raina,Francesco La Rosa,Eli Sivena,Vasileios Tsarsitalidis,Efi Tsompopoulou,Elena Volf

Distributional shift, or the mismatch between training and deployment data, is a significant obstacle to the usage of machine learning in high-stakes industrial applications, such as autonomous driving and medicine. This creates a need to be able to assess how robustly ML models generalize as well as the quality of their uncertainty estimates. Standard ML datasets do not allow these properties to be assessed, as the training, validation and test data are often identically distributed. Recently, a range of dedicated benchmarks have appeared, featuring both distributionally matched and shifted data. The Shifts dataset stands out in terms of the diversity of tasks and data modalities it features. Unlike most benchmarks, which are dominated by 2D image data, Shifts contains tabular weather forecasting, machine translation, and vehicle motion prediction tasks. This enables models to be assessed on a diverse set of industrial-scale tasks and either universal or directly applicable task-specific conclusions to be reached. In this paper, we extend the Shifts Dataset with two datasets sourced from industrial, high-risk applications of high societal importance. Specifically, we consider the tasks of segmentation of white matter Multiple Sclerosis lesions in 3D magnetic resonance brain images and the estimation of power consumption in marine cargo vessels. Both tasks feature ubiquitous distributional shifts and strict safety requirements due to the high cost of errors. These new datasets will allow researchers to explore robust generalization and uncertainty estimation in new situations. This work provides a description of the dataset and baseline results for both tasks.

Λ-DARTS: Mitigating Performance Collapse by Harmonizing Operation Selection among Cells

Sajad Movahedi,Melika Adabinejad,Ayyoob Imani,Arezou Keshavarz,Mostafa Dehghani,Azadeh Shakery,Babak N Araabi

Differentiable neural architecture search (DARTS) is a popular method for neural architecture search (NAS), which performs cell-search and utilizes continuous relaxation to improve the search efficiency via gradient-based optimization. The main shortcoming of DARTS is performance collapse, where the discovered architecture suffers from a pattern of declining quality during search. Performance collapse has become an important topic of research, with many methods trying to solve the issue through either regularization or fundamental changes to DARTS.

However, the weight-sharing framework used for cell-search in DARTS and the convergence of architecture parameters has not been analyzed yet. In this paper, we provide a thorough and novel theoretical and empirical analysis on DARTS and its point of convergence.

We show that DARTS suffers from a specific structural flaw due to its weight-sharing framework that limits the convergence of DARTS to saturation points of the softmax function. This point of convergence gives an unfair advantage to layers closer to the output in choosing the optimal architecture, causing performance collapse. We then propose two new regularization terms that aim to prevent performance collapse by harmonizing operation selection via aligning gradients of layers.

Experimental results on six different search spaces and three different datasets show that our method (Λ-DARTS) does indeed prevent performance collapse, providing justification for our theoretical analysis and the proposed remedy.

Efficient Hyperparameter Optimization Through Tensor Completion

Aaman Rebello,Kriton Konstantinidis,Yao Lei Xu,Danilo Mandic

Hyperparameter optimization is a prerequisite for state-of-the-art performance in machine learning, with current strategies including Bayesian optimisation, Hyperband, and evolutionary methods. Whereas such methods have been shown to improve performance, none of these is designed to explicitly take advantage of the underlying data structure. To this end, we introduce a completely different approach for hyperaparameter optimization, based on low-rank tensor completion. This is achieved by first forming a multi-dimensional tensor which comprises performance scores for different combinations of hyperparameters. Based on the realistic underlying assumption that the so-formed tensor has a low rank structure, this then allows for reliable estimates of the unobserved validation scores of combinations of hyperparameters to be obtained through tensor completion, and from only a fraction of known elements. Through extensive experimentation on various datasets and learning models, the proposed method is shown to exhibit competitive or superior performance to the state-of-the-art hyperparameter optimization strate gies. Distinctive advantages of the proposed method include its ability to simultaneously handle any hyperparameter type (e.g., kind of optimizer, number of neurons, number of layer, etc.), its relative simplicity compared to the competing methods, as well as the ability to suggest multiple optimal combinations of hyperparameters.

Learning Vortex Dynamics for Fluid Inference and Prediction

Yitong Deng,Hong-Xing Yu,Jiajun Wu,Bo Zhu

We propose a novel differentiable vortex particle (DVP) method to infer and predict fluid dynamics from a single video. Lying at its core is a particle-based latent space to encapsulate the hidden, Lagrangian vortical evolution underpinning the observable, Eulerian flow phenomena. Our differentiable vortex particles are coupled with a learnable, vortex-to-velocity dynamics mapping to effectively capture the complex flow features in a physically-constrained, low-dimensional space. This representation facilitates the learning of a fluid simulator tailored to the input video that can deliver robust, long-term future predictions. The value of our method is twofold: first, our learned simulator enables the inference of hidden physics quantities (e.g., velocity field) purely from visual observation; secondly, it also supports future prediction, constructing the input video's sequel along with its future dynamics evolution. We compare our method with a range of existing methods on both synthetic and real-world videos, demonstrating improved reconstruction quality, visual plausibility, and physical integrity.

Discovering Generalizable Multi-agent Coordination Skills from Multi-task Offline Data

Fuxiang Zhang,Chengxing Jia,Yi-Chen Li,Lei Yuan,Yang Yu,Zongzhang Zhang

Cooperative multi-agent reinforcement learning (MARL) faces the challenge of adapting to multiple tasks with varying agents and targets. Previous multi-task MARL approaches require costly interactions to simultaneously learn or fine-tune policies in different tasks. However, the situation that an agent should generalize to multiple tasks with only offline data from limited tasks is more in line with the needs of real-world applications. Since offline multi-task data contains a variety of behaviors, an effective data-driven approach is to extract informative latent variables that can represent universal skills for realizing coordination across tasks. In this paper, we propose a novel Offline MARL algorithm to Discover coordInation Skills (ODIS) from multi-task data. ODIS first extracts task-invariant coordination skills from offline multi-task data and learns to delineate different agent behaviors with the discovered coordination skills. Then we train a coordination policy to choose optimal coordination skills with the centralized training and decentralized execution paradigm. We further demonstrate that the discovered coordination skills can assign effective coordinative behaviors, thus significantly enhancing generalization to unseen tasks. Empirical results in cooperative MARL benchmarks, including the StarCraft multi-agent challenge, show that ODIS obtains superior performance in a wide range of tasks only with offline data from limited sources.

On student-teacher deviations in distillation: does it pay to disobey?

Vaishnavh Nagarajan,Aditya Krishna Menon,Srinadh Bhojanapalli,Hossein Mobahi,Sanjiv Kumar

Knowledge distillation has been widely-used to improve the performance of a ``student'' network by hoping to mimic the soft probabilities of a  ``teacher'' network. Yet, for self-distillation to work, the student {\em must} deviate from the teacher in some manner \citep{stanton21does}. We conduct a variety of experiments across image and language classification datasets to more precisely understand the nature of student-teacher deviations and how they relate to accuracy gains. Our first key empirical observation is that in a majority of our settings, the student underfits points that the teacher finds hard. Next, we find that student-teacher deviations during the \textit{initial} phase training are \textit{not}

crucial to get the benefits of distillation --- simply switching to distillation in the middle of training can recover a significant fraction of distillation's accuracy gains.
We then provide two parallel theoretical perspectives of student-teacher deviations, one casting distillation as a regularizer in eigenspace, and another as a denoiser of gradients. In both these views, we argue how our empirically reported student-teacher deviations may emerge, and how they may relate to generalization. Importantly, our analysis bridges key gaps between existing theory and practice by focusing on gradient descent and avoiding label noise assumptions.

Merging Models Pre-Trained on Different Features with Consensus Graph
Tengfei Ma,Trong Nghia Hoang,Jie Chen
Learning global models effectively on private and decentralized datasets has become an increasingly important challenge of machine learning when applied in practice. Federated Learning (FL) has recently emerged as a solution paradigm to address this challenge. In particular, the FL clients agree to a common model parameterization in advance, which can then be updated collaboratively via synchronous aggregation of their local model updates. However, such strong requirement of modeling homogeneity and synchronicity across clients makes FL inapplicable to many practical learning scenarios that cannot afford such requirements. For example, in distributed sensing, a network of heterogeneous sensors sample from different data modalities of the same phenomenon. Each sensor thus requires its own specialized model. Local learning therefore needs to happen in isolation but inference still requires merging the local models for better performance.

To enable this, we investigate a feature fusion approach that extracts local feature representations from local models and incorporates them into a global representation to train a more holistic predictive model. We study two key aspects of this feature incorporation. First, we develop an alignment algorithm that draws accurate correspondence between feature components which are arbitrarily arranged across clients. Next, we propose learning a consensus graph that captures the high-order interactions between these feature components, which reveals how data with heterogeneous features can be stitched together coherently to train a better model. The proposed framework is demonstrated on four real-life data sets including monitoring and predicting power grids and traffic networks.
****
Unsupervised Performance Predictor for Architecture Search
Xiangning Xie,Yanan Sun,Yuqiao Liu
Performance predictors can directly predict the performance value of given neural architectures without training, thus broadly being studied to alleviate the prohibitive cost of Neural Architecture Search (NAS). However, existing performance predictors still require training a large number of architectures from scratch to get their performance labels as the training dataset, which is still computationally expensive. To solve this issue, we develop an unsupervised performance predictor called USPP, which can avoid costly dataset construction by using existing fully-trained architectures. Specifically, a progressive domain-invariant feature extraction method is proposed to assist in extracting domain-invariant features due to the great transferability challenge caused by the rich domain-specific features. Furthermore, a learnable representation (denoted as operation embedding) is designed to replace the fixed encoding of the operations to transfer more knowledge about operations to the target search space. In experiments, we train the predictor by the labeled architectures in NAS-Bench-101 and predict the architectures in the DARTS search space. Compared with other state-of-the-art NAS methods, the proposed USPP only costs 0.02 GPU days but finds the architecture with 97.86% on CIFAR-10 and 96.50% top-1 accuracy on ImageNet.

Efficient recurrent architectures through activity sparsity and sparse back-propagation through time
Anand Subramoney,Khaleelulla Khan Nazeer,Mark Schöne,Christian Mayr,David Kappel
Recurrent neural networks (RNNs) are well suited for solving sequence tasks in r

esource-constrained systems due to their expressivity and low computational requirements. However, there is still a need to bridge the gap between what RNNs are capable of in terms of efficiency and performance and real-world application requirements. The memory and computational requirements arising from propagating the activations of all the neurons at every time step to every connected neuron, together with the sequential dependence of activations, contribute to the inefficiency of training and using RNNs. We propose a solution inspired by biological neuron dynamics that makes the communication between RNN units sparse and discrete. This makes the backward pass with backpropagation through time (BPTT) computationally sparse and efficient as well. We base our model on the gated recurrent unit (GRU), extending it with units that emit discrete events for communication triggered by a threshold so that no information is communicated to other units in the absence of events. We show theoretically that the communication between units, and hence the computation required for both the forward and backward passes, scales with the number of events in the network. Our model achieves efficiency without compromising task performance, demonstrating competitive performance compared to state-of-the-art recurrent network models in real-world tasks, including language modeling. The dynamic activity sparsity mechanism also makes our model well suited for novel energy-efficient neuromorphic hardware. Code is available at https://github.com/KhaleelKhan/EvNN/.

Quality-Similar Diversity via Population Based Reinforcement Learning

Shuang Wu,Jian Yao,Haobo Fu,Ye Tian,Chao Qian,Yaodong Yang,QIANG FU,Yang Wei

Diversity is a growing research topic in Reinforcement Learning (RL). Previous research on diversity has mainly focused on promoting diversity to encourage exploration and thereby improve quality (the cumulative reward), maximizing diversity subject to quality constraints, or jointly maximizing quality and diversity, known as the quality-diversity problem. In this work, we present the quality-similar diversity problem that features diversity among policies of similar qualities. In contrast to task-agnostic diversity, we focus on task-specific diversity defined by a set of user-specified Behavior Descriptors (BDs). A BD is a scalar function of a trajectory (e.g., the fire action rate for an Atari game), which delivers the type of diversity the user prefers. To derive the gradient of the user-specified diversity with respect to a policy, which is not trivially available, we introduce a set of BD estimators and connect it with the classical policy gradient theorem. Based on the diversity gradient, we develop a population-based RL algorithm to adaptively and efficiently optimize the population diversity at multiple quality levels throughout training. Extensive results on MuJoCo and Atari demonstrate that our algorithm significantly outperforms previous methods in terms of generating user-specified diverse policies across different quality levels.

PREDICTION OF TOURISM FLOW WITH SPARSE DATA INCORPORATING TOURIST GEOLOCATIONS

Julian Lemmel,Zahra Babaiee,Marvin Kleinlehner,Ivan Majic,Philipp Neubauer,Johannes Scholz,Radu Grosu,Sophie Neubauer

Modern tourism in the 21st century is facing numerous challenges. One of these challenges is the rapidly growing number of tourists in space-limited regions such as historical city centers, museums, or geographical bottlenecks like narrow valleys. In this context, a proper and accurate prediction of tourism volume and tourism flow within a certain area is important and critical for visitor management tasks such as sustainable treatment of the environment and prevention of overcrowding. Static flow control methods like conventional low-level controllers or limiting access to overcrowded venues could not solve the problem yet. In this paper, we empirically evaluate the performance of state-of-the-art deep-learning methods such as RNNs, GNNs, and Transformers as well as the classic statistical ARIMA method. Granular limited data supplied by a tourism region is extended by exogenous data such as geolocation trajectories of individual tourists, weath er and holidays. In the field of visitor flow prediction with sparse data, we are thereby capable of increasing the accuracy of our predictions, incorporating modern input feature handling as well as mapping geolocation data on top of discrete POI data.

Modeling the Uncertainty with Maximum Discrepant Students for Semi-supervised 2D Pose Estimation

Jiaqi Wu,Junbiao Pang,Qingming Huang

Semi-supervised pose estimation is a practically challenging task for computer vision. Although numerous excellent semi-supervised classification methods have emerged, these methods typically use confidence to evaluate the quality of pseudo-labels, which is difficult to achieve in pose estimation tasks. For example, in pose estimation, confidence represents only the possibility that a position of the heatmap is a keypoint, not the quality of that prediction. In this paper, we propose a simple yet efficient framework to estimate the quality of pseudo-labels in semi-supervised pose estimation tasks from the perspective of modeling the uncertainty of the pseudo-labels. Concretely, under the dual mean-teacher framework, we construct the two maximum discrepant students (MDSs) to effectively push two teachers to generate different decision boundaries for the same sample. Moreover, we create multiple uncertainties to assess the quality of the pseudo-labels. Experimental results demonstrate that our method improves the performance of semi-supervised pose estimation on three datasets.

UTS: When Monotonic Value Factorisation Meets Non-monotonic and Stochastic Targets

Zeyang Liu,Lipeng Wan,Xue Sui,Xingyu Chen,Xuguang Lan

Extracting decentralised policies from joint action-values is an attractive way to exploit centralised learning. It is possible to apply monotonic value factorisation to guarantee consistency between the centralised and decentralised policies. However, the best strategy for training decentralised policies when the target joint action-values are non-monotonic and stochastic is still unclear. We propose a novel value factorisation method named uncertainty-based target shaping (UTS) to solve this problem. UTS employs networks that estimate the reward and the following state's embedding, where the large prediction error indicates that the target is stochastic. By replacing deterministic targets for the suboptimal with the best per-agent values, we enforce that all shaped targets become a subset of the space that can be represented by monotonic value factorisation. Empirical results show that UTS outperforms state-of-the-art baselines on multiple benchmarks, including matrix games, predator-prey, and challenging tasks in the StarCraft II micromanagement.

Meta-learning with Auto-generated Tasks for Predicting Human Behaviour in Normal Form Games

Shaofei Chen,Jiaxing Chen,Peng Li,William Yuan,Zhen Zhen Hu

In recent years, machine learning methods have been successfully applied to predict human behaviour in strategic settings. However, as available data of human behaviour is not always large enough and people's reasoning processes in different types of games are various, it is challenging to acquire a satisfied prediction model. In this paper, we employ a meta-learning method to improve learning performance in predicting human behaviour in normal form games. In particular, we first design a deep neural network that captures mixed human behaviour features to model and be learned to get a underlying behavioural predictor. Then, using a dataset of experimental human behaviour, we apply unsupervised learning to generate tasks and use meta-learning to improve the learning proficiency. Experimental results show that our proposed meta-learning method with the designed neural network and auto-generated tasks considerably increases the prediction accuracy and significantly exceeds the previous state-of-the-art.

FairGrad: Fairness Aware Gradient Descent

Gaurav Maheshwari,Michaël Perrot

We address the problem of group fairness in classification, where the objective is to learn models that do not unjustly discriminate against subgroups of the population. Most existing approaches are limited to simple binary tasks or involve difficult to implement training mechanisms. This reduces their practical applicability. In this paper, we propose FairGrad, a method to enforce fairness based on a reweighting scheme that iteratively learns group specific weights based on whether they are advantaged or not. FairGrad is easy to implement and can accommodate various standard fairness definitions. Furthermore, we show that it is competitive with standard baselines over various datasets including ones used in natural language processing and computer vision.

Better Teacher Better Student: Dynamic Prior Knowledge for Knowledge Distillation

Martin Zong,Zengyu Qiu,Xinzhu Ma,Kunlin Yang,Chunya Liu,Jun Hou,Shuai Yi,Wanli Ouyang

Knowledge distillation (KD) has shown very promising capabilities in transferring learning representations from large models (teachers) to small models (students). However, as the capacity gap between students and teachers becomes larger, existing KD methods fail to achieve better results. Our work shows that the 'prior knowledge' is vital to KD, especially when applying large teachers. Particularly, we propose the dynamic prior knowledge (DPK), which integrates part of teacher's features as the prior knowledge before the feature distillation. This means that our method also takes the teacher's feature as `input', not just `target'. Besides, we dynamically adjust the ratio of the prior knowledge during the training phase according to the feature gap, thus guiding the student in an appropriate difficulty. To evaluate the proposed method, we conduct extensive experiments on two image classification benchmarks (i.e. CIFAR100 and ImageNet) and an object detection benchmark (\i.e. MS COCO). The results demonstrate the superiority of our method in performance under varying settings. Besides, our DPK makes the performance of the student model positively correlated with that of the teacher model, which means that we can further boost the accuracy of students by applying larger teachers. More importantly, DPK provides a fast solution in teacher model selection for any given model. Our codes will be publicly available for reproducibility.

Flow Straight and Fast: Learning to Generate and Transfer Data with Rectified Flow

Xingchao Liu,Chengyue Gong,qiang liu

We present rectified flow, a simple approach to learning (neural) ordinary differential equation (ODE) models to transport between two empirically observed distributions π_0 and π_1, hence providing a unified solution to generative modeling and domain transfer, among various other tasks involving distribution transport. The idea of rectified flow is to learn the ODE to follow the straight paths connecting the points drawn from π_0 and π_1 as much as possible. This is achieved by solving a straightforward nonlinear least squares optimization problem, which can be easily scaled to large models without introducing extra parameters beyond standard supervised learning. The straight paths are the shortest paths between two points, and can be simulated exactly without time discretization and hence yield computationally efficient models. We show that, by learning a rectified flow from data, we effectively turn an arbitrary coupling of π_0 and π_1 to a new deterministic coupling with provably non-increasing convex transport costs. In addition, with a ``reflow" procedure that iteratively learns a new rectified flow from the data bootstrapped from the previous one, we obtain a sequence of flows with increasingly straight paths, which can be simulated accurately with coarse time discretization in the inference phase. In empirical studies, we show that rectified flow performs superbly on image generation, image-to-image translation, and domain adaptation. In particular, on image gen eration and translation, our method yields nearly straight flows that give high quality results even with \emph{a single Euler discretization step}. Code is available at \url{https://github.com/gnobitab/RectifiedFlow}.

Inequality phenomenon in l_{∞}-adversarial training, and its unrealized threats

Ranjie Duan,YueFeng Chen,Yao Zhu,Xiaojun Jia,Rong Zhang,Hui Xue'

The appearance of adversarial examples raises attention from both academia and industry. Along with the attack-defense arms race, adversarial training is the most effective against adversarial examples.

However, we find inequality phenomena occur during the l_{∞}-adversarial training, that few features dominate the prediction made by the adversarially trained model. We systematically evaluate such inequality phenomena by extensive experiments and find such phenomena become more obvious when performing adversarial training with increasing adversarial strength (evaluated by ϵ). We hypothesize such inequality phenomena make l_{∞}-adversarially trained model less reliable than the standard trained model when few ``important features" are influenced. To validate our hypothesis, we proposed two simple attacks that either perturb or replace important features with noise or occlusion. Experiments show that l_{∞}-adversarially trained model can be easily attacked when the few important features are influenced.

Our work shed light on the limitation of the practicality of l_{∞}-adversarial training.

Tensor-Based Sketching Method for the Low-Rank Approximation of Data Streams.

Cuiyu Liu,Xiao Chuanfu,Mingshuo Ding,Chao Yang

Low-rank approximation in data streams is a fundamental and significant task in computing science, machine learning and statistics. Multiple streaming algorithms have emerged over years and most of them are inspired by randomized algorithms, more specifically, sketching methods. However, many algorithms are not able to leverage information of data streams and consequently suffer from low accuracy. Existing data-driven methods improve accuracy but the training cost is expensive in practice. In this paper, from a subspace perspective, we propose a tensor-based sketching method for low-rank approximation of data streams. The proposed algorithm fully exploits the structure of data streams and obtains quasi-optimal sketching matrices by performing tensor decomposition on training data. A series of experiments are carried out and show that the proposed tensor-based method can be more accurate and much faster than the previous work.

CRISP: Curriculum based Sequential neural decoders for Polar code family

S Ashwin Hebbar,Viraj Vivek Nadkarni,Ashok Vardhan Makkuva,Suma Bhat,Sewoong Oh,Pramod Viswanath

Polar codes are widely used state-of-the-art codes for reliable communication that have recently been included in the 5^{th} generation wireless standards (5G). However, there still remains room for design of polar decoders that are both efficient and reliable in the short blocklength regime. Motivated by recent successes of data-driven channel decoders, we introduce a novel $\textbf{ C}$ur${\textbf{RI}}$culum based $\textbf{S}$equential neural decoder for $\textbf{P}$olar codes (CRISP).

We design a principled curriculum, guided by information-theoretic insights, to train CRISP and show that it outperforms the successive-cancellation (SC) decoder and attains near-optimal reliability performance on the $\text{Polar}(16,32)$ and $\text{Polar}(22,64)$ codes.

The choice of the proposed curriculum is critical in achieving the accuracy gains of CRISP, as we show by comparing against other curricula. More notably, CRISP can be readily extended to Polarization-Adjusted-Convolutional (PAC) codes, where existing SC decoders are significantly less reliable. To the best of our knowledge, CRISP constructs the first data-driven decoder for PAC codes and attains near-optimal performance on the $\text{PAC}(16,32)$ code.

A Mathematical Framework for Characterizing Dependency Structures of Multimodal Learning

Weida Wang,Tao Shi,Yaoyuan Liang,Xiangxiang Xu,Fei Ma,Shao-Lun Huang,Lizhong Zheng

Dependency structures between modalities have been utilized explicitly and implicitly in multimodal learning to enhance classification performance, particularly when the training samples are insufficient. Recent efforts have concentrated on developing suitable dependence structures and applying them in deep neural networks, but the interplay between the training sample size and various structures has not received enough attention. To address this issue, we propose a mathematical framework that can be utilized to characterize conditional dependency structures in analytic ways. It provides an explicit description of the sample size in learning various structures in a non-asymptotic regime. Additionally, it demonstrates how task complexity and a fitness evaluation of conditional dependence structures affect the results. Furthermore, we develop an autonomous updated coefficient algorithm auto-CODES based on the theoretical framework and conduct experiments on multimodal emotion recognition tasks using the MELD and IEMOCAP datasets. The experimental results validate our theory and show the effectiveness of the proposed algorithm.

Language Models are Realistic Tabular Data Generators

Vadim Borisov,Kathrin Sessler,Tobias Leemann,Martin Pawelczyk,Gjergji Kasneci

Tabular data is among the oldest and most ubiquitous forms of data. However, the generation of synthetic samples with the original data’s characteristics remains a significant challenge for tabular data. While many generative models from the computer vision domain, such as variational autoencoders or generative adversarial networks, have been adapted for tabular data generation, less research has been directed towards recent transformer-based large language models (LLMs), which are also generative in nature. To this end, we propose GReaT (Generation of Realistic Tabular data), which exploits an auto-regressive generative LLM to sample synthetic and yet highly realistic tabular data. Furthermore, GReaT can model tabular data distributions by conditioning on any subset of features; the remaining features are sampled without additional overhead. We demonstrate the effectiveness of the proposed approach in a series of experiments that quantify the validity and quality of the produced data samples from multiple angles. We find that GReaT maintains state-of-the-art performance across numerous real-world and synthetic data sets with heterogeneous feature types coming in various sizes.

Data augmentation alone can improve adversarial training

Lin Li,Michael W. Spratling

Adversarial training suffers from the issue of robust overfitting, which seriously impairs its generalization performance. Data augmentation, which is effective at preventing overfitting in standard training, has been observed by many previous works to be ineffective in mitigating overfitting in adversarial training. This work proves that, contrary to previous findings, data augmentation alone can significantly boost accuracy and robustness in adversarial training. We find that the hardness and the diversity of data augmentation are important factors in combating robust overfitting. In general, diversity can improve both accuracy and robustness, while hardness can boost robustness at the cost of accuracy within a certain limit and degrade them both over that limit. To mitigate robust overfitting, we first propose a new crop transformation Cropshift with improved diversity compared to the conventional one (Padcrop). We then propose a new data augmentation scheme, based on Cropshift, with much improved diversity and well-balanced hardness. Empirically, our augmentation method achieves the state-of-the-art accuracy and robustness for data augmentations in adversarial training. Furthermore, it matches, or even exceeds when combined with weight averaging, the performance of the best contemporary regularization methods for alleviating robust overfitting.

Learning Diffusion Bridges on Constrained Domains

Xingchao Liu,Lemeng Wu,Mao Ye,qiang liu

Diffusion models have achieved promising results on generative learning recently. However, because diffusion processes are most naturally applied on the unconstrained Euclidean space R^d, key challenges arise for developing diffusion based models for learning data on constrained and structured domains. We present a simple and unified framework to achieve this that can be easily adopted to various types of domains, including product spaces of any type (be it bounded/unbounded, continuous/discrete, categorical/ordinal, or their mix). In our model, the diffusion process is driven by a drift force that is a sum of two terms: one singular force designed by $Doob's~ h$-$transform$ that ensures all outcomes of the process to belong to the desirable domain, and one non-singular neural force field that is trained to make sure the outcome follows the data distribution statistically. Experiments show that our methods perform superbly on generating tabular data, images, semantic segments and 3D point clouds.

Revisiting Uncertainty Estimation for Node Classification: New Benchmark and Insights

Gleb Bazhenov,Denis Kuznedelev,Andrey Malinin,Artem Babenko,Liudmila Prokhorenkova

Uncertainty estimation is an important task that can be essential for high-risk applications of machine learning. This problem is especially challenging for node-level prediction in graph-structured data, as the samples (nodes) are interdependent. Recently, several studies addressed node-level uncertainty estimation. However, there is no established benchmark for evaluating these methods in a unified setup covering diverse distributional shift. In this paper, we address this problem and propose such a benchmark together with a technique for the controllable generation of data splits with various types of distributional shift. Importantly, besides the standard feature-based distributional shift, we also consider shifts specifically designed for graph-structured data. In summary, our benchmark consists of several graph datasets equipped with various distributional shift on which we evaluate the robustness of models and uncertainty estimation performance. This allows us to compare existing solutions in a unified setup. Moreover, we decompose the current state-of-the-art Dirichlet-based framework and perform an ablation study on its components. In our experiments, we demonstrate that when faced with complex yet realistic distributional shift, most models fail to maintain high classification performance and consistency of uncertainty estimates with prediction errors. However, ensembling techniques help to partially overcome significant drops in performance and achieve better results than distinct models. Among single-pass models, Natural Posterior Network with GNN encoder achieves the best performance.

****

CUTS: Neural Causal Discovery from Irregular Time-Series Data

Yuxiao Cheng,Runzhao Yang,Tingxiong Xiao,Zongren Li,Jinli Suo,Kunlun He,Qionghai Dai

Causal discovery from time-series data has been a central task in machine learning. Recently, Granger causality inference is gaining momentum due to its good explainability and high compatibility with emerging deep neural networks. However, most existing methods assume structured input data and degenerate greatly when encountering data with randomly missing entries or non-uniform sampling frequencies, which hampers their applications in real scenarios. To address this issue, here we present CUTS, a neural Granger causal discovery algorithm to jointly impute unobserved data points and build causal graphs, via plugging in two mutually boosting modules in an iterative framework: (i) Latent data prediction stage: designs a Delayed Supervision Graph Neural Network (DSGNN) to hallucinate and register unstructured data which might be of high dimension and with complex distribution; (ii) Causal graph fitting stage: builds a causal adjacency matrix with imputed data under sparse penalty. Experiments show that CUTS effectively infers causal graphs from irregular time-series data, with significantly superior performance to existing methods. Our approach constitutes a promising step towards applying causal discovery to real applications with non-ideal observations.

****

PAVI: Plate-Amortized Variational Inference

Louis Rouillard,Thomas Moreau,Demian Wassermann

Given observed data and a probabilistic generative model, Bayesian inference aims at obtaining the distribution of a model’s latent parameters that could have yielded the data. This task is challenging for large population studies where thousands of measurements are performed over a cohort of hundreds of subjects, resulting in a massive latent parameter space. This large cardinality renders off-the-shelf Variational Inference (VI) computationally impractical.

In this work, we design structured VI families that can efficiently tackle large population studies. Our main idea is to share the parameterization and learning across the different i.i.d. variables in a generative model --symbolized by the model’s plates. We name this concept plate amortization, and illustrate the powerful synergies it entitles, resulting in expressive, parsimoniously parameterized and orders of magnitude faster to train large scale hierarchical variational distributions.

We illustrate the practical utility of PAVI through a challenging Neuroimaging example featuring a million latent parameters, demonstrating a significant step towards scalable and expressive Variational Inference.

Near-optimal Coresets for Robust Clustering

Lingxiao Huang,Shaofeng H.-C. Jiang,Jianing Lou,Xuan Wu

We consider robust clustering problems in $\mathbb{R}^d$, specifically k-clustering problems (e.g., k-Median and k-Means) with m \emph{outliers}, where the cost for a given center set $C \subset \mathbb{R}^d$ aggregates the distances from C to all but the furthest m data points, instead of all points as in classical clustering. We focus on the ϵ-coreset for robust clustering, a small proxy of the dataset that preserves the clustering cost within ϵ-relative error for all center sets. Our main result is an ϵ-coreset of size $O(m + \mathrm{poly}(k \epsilon^{-1}))$ that can be constructed in near-linear time. This significantly improves previous results, which either suffers an exponential dependence on $(m + k)$ [Feldman and Schulman, SODA'12], or has a weaker bi-criteria guarantee [Huang et al., FOCS'18]. Furthermore, we show this dependence in m is nearly-optimal, and the fact that it is isolated from other factors may be crucial for dealing with large number of outliers. We construct our coresets by adapting to the outlier setting a recent framework [Braverman et al., FOCS'22] which was designed for capacity-constrained clustering, overcoming a new challenge that the participating terms in the cost, particularly the excluded m outlier points, are dependent on the center set C. We validate our coresets on various datasets, and we observe a superior size-accuracy tradeoff compared with popular baselines including uniform sampling and sensitivity sampling. We also achieve a significant speedup of existing approximation algorithms for robust clustering using our coresets.

****

CLUTR: Curriculum Learning via Unsupervised Task Representation Learning

Abdus Salam Azad,Izzeddin Gur,Aleksandra Faust,Pieter Abbeel,Ion Stoica

Reinforcement Learning (RL) algorithms are often known for sample inefficiency and difficult generalization. Recently, Unsupervised Environment Design (UED) emerged as a new paradigm for zero-shot generalization by simultaneously learning a task distribution and agent policies on the sampled tasks. This is a non-stationary process where the task distribution evolves along with agent policies; creating an instability over time. While past works demonstrated the potential of such approaches, sampling effectively from the task space remains an open challenge, bottlenecking these approaches. To this end, we introduce CLUTR: a novel curriculum learning algorithm that decouples task representation and curriculum learning into a two-stage optimization. It first trains a recurrent variational autoencoder on randomly generated tasks to learn a latent task manifold. Next, a teacher agent creates a curriculum by optimizing a minimax REGRET-based objective o n a set of latent tasks sampled from this manifold. By keeping the task manifold fixed, we show that CLUTR successfully overcomes the non-stationarity problem and improves stability. Our experimental results show CLUTR outperforms PAIRED, a principled and popular UED method, in terms of generalization and sample efficiency in the challenging CarRacing and navigation environments: showing an 18x improvement on the F1 CarRacing benchmark. CLUTR also performs comparably to the non-UED state-of-the-art for CarRacing, outperforming it in nine of the 20 tracks. CLUTR also achieves a 33% higher solved rate than PAIRED on a set of 18 out-of-distribution navigation tasks.

Test-time Adaptation for Segmentation via Image Synthesis

Mihir Prabhudesai,Anirudh Goyal,Sujoy Paul,Mehdi S. M. Sajjadi,Sjoerd van Steenkiste,Gaurav Aggarwal,Thomas Kipf,Deepak Pathak,Katerina Fragkiadaki

We consider the problem of segmenting scenes into constituent objects and their parts. Current supervised visual detectors, though impressive within their training distribution, often fail to segment out-of-distribution scenes into their constituent entities. Recent test-time adaptation methods use auxiliary self-supervised losses to adapt the network parameters to each test example independently and have shown promising results towards generalization outside the training distribution for the task of image classification. In our work, we find evidence that these losses can be insufficient for instance segmentation tasks, without also considering architectural inductive biases. For image segmentation, recent slot-centric generative models break such dependence on supervision by attempting to segment scenes into entities in a self-supervised manner by reconstructing pixels. Drawing upon these two lines of work, we propose Generating Fast and Slow Networks (GFS-Nets), a semi-supervised instance segmentation model equipped with a slot-centric image or point-cloud rendering component that is adapted per scene at test time through gradient descent on reconstruction or novel view synthesis objectives. We show that test-time adaptation greatly improves segmentation in out-of-distribution scenes. We evaluate GFS-Nets in several 3D and 2D scene segmentation benchmarks and show substantial out-of-distribution performance improvements against state-of-the-art supervised feed forward detectors and self-supervised domain adaptation models.

****

On the Importance of In-distribution Class Prior for Out-of-distribution Detection

Xue Jiang,Feng Liu,Zhen Fang,Hong Chen,Tongliang Liu,Feng Zheng,Bo Han

Given a pre-trained in-distribution (ID) model, the task of inference-time out-of-distribution (OOD) detection methods aims to recognize upcoming OOD data in inference time. However, some representative methods share an unproven assumption that the probability that OOD data belong to every ID class should be the same, i.e., probabilities that OOD data belong to ID classes form a uniform distribution. In this paper, we theoretically and empirically show that this assumption makes these methods incapable of recognizing OOD data when the ID model is trained with class-imbalanced data. Fortunately, by analyzing the causal relations between ID/OOD classes and features, we identify several common scenarios where probabilities that OOD data belong to ID classes should be the ID-class-prior distribution. Based on the above finding, we propose two effective strategies to modify previous inference-time OOD detection methods: 1) if they explicitly use the uniform distribution, we can replace the uniform distribution with the ID-class-prior distribution; 2) otherwise, we can reweight their scores according to the similarity between the ID-class-prior distribution and the softmax outputs of the pre-trained model. Extensive experiments show that both strategies significantly improve the accuracy of recognizing OOD data when the ID model is pre-trained with imbalanced data. As a highlight, when evaluating on the iNaturalist dataset, our method can achieve ~36% increase on AUROC and ~61% decrease on FPR95, compared with the original Energy method, reflecting the importance of ID-class prior in the OOD detection, which lights up a new road to study this problem.

Quantized Compressed Sensing with Score-Based Generative Models

Xiangming Meng,Yoshiyuki Kabashima

We consider the general problem of recovering a high-dimensional signal from noisy quantized measurements. Quantization, especially coarse quantization such as 1-bit sign measurements, leads to severe information loss and thus a good prior knowledge of the unknown signal is helpful for accurate recovery. Motivated by the power of score-based generative models (SGM, also known as diffusion models) in capturing the rich structure of natural signals beyond simple sparsity, we propose an unsupervised data-driven approach called quantized compressed sensing with SGM (QCS-SGM), where the prior distribution is modeled by a pre-trained SGM. To perform posterior sampling, an annealed pseudo-likelihood score called ${\textit{noise perturbed pseudo-likelihood score}}$ is introduced and combined with the prior score of SGM. The proposed QCS-SGM applies to an arbitrary number of quantization bits. Experiments on a variety of baseline datasets demonstrate that the proposed QCS-SGM significantly outperforms existing state-of-the-art algorithms by a large margin for both in-distribution and out-of-distribution samples. Moreover, as a posterior sampling method, QCS-SGM can be easily used to obtain confidence intervals or uncertainty estimates of the reconstructed results. $\textit{The code is available at}$ https://github.com/mengxiangming/QCS-SGM.

Unbiased Representation of Electronic Health Records for Patient Outcome Prediction

Lucas Jing Liu,Victor Ortiz,Javier A Neyra,Jin Chen

Fairness is one of the newly emerging focuses for building trustworthy artificial intelligence (AI) models. One of the reasons resulting in an unfair model is the algorithm bias towards different groups of samples. A biased model may benefit certain groups but disfavor others. As a result, leaving the fairness problem unresolved might have a significant negative impact, especially in the context of healthcare applications. Integrating both domain-specific and domain-invariant representations, we propose a masked triple attention transformer encoder (MTATE) to learn unbiased and fair data representations of different subpopulations. Specifically, MTATE includes multiple domain classifiers and uses three attention mechanisms to effectively learn the representations of diverse subpopulations.

In the experiment on real-world healthcare data, MTATE performed the best among the compared models regarding overall performance and fairness.

****

Valid P-Value for Deep Learning-driven Salient Region

Miwa Daiki,Vo Nguyen Le Duy,Ichiro Takeuchi

Various saliency map methods have been proposed to interpret and explain predictions of deep learning models. Saliency maps allow us to interpret which parts of the input signals have a strong influence on the prediction results. However, since a saliency map is obtained by complex computations in deep learning models, it is often difficult to know how reliable the saliency map itself is. In this study, we propose a method to quantify the reliability of a saliency region in the form of p-values. Our idea is to consider a saliency map as a selected hypothesis by the trained deep learning model and employ the selective inference framework. The proposed method provably provides a valid p-value for the detected salient region, i.e., we can provably control the false positive rate of the detected salient region. We demonstrate the validity of the proposed method through numerical examples in synthetic and real datasets. Furthermore, we develop a Keras-based framework for conducting the proposed selective inference for a wide class of CNNs without additional implementation cost.

****

Unsupervised Semantic Segmentation with Self-supervised Object-centric Representations

Andrii Zadaianchuk,Matthaeus Kleindessner,Yi Zhu,Francesco Locatello,Thomas Brox

In this paper, we show that recent advances in self-supervised representation learning enable unsupervised object discovery and semantic segmentation with a performance that matches the state of the field on supervised semantic segmentation 10 years ago. We propose a methodology based on unsupervised saliency masks and self-supervised feature clustering to kickstart object discovery followed by training a semantic segmentation network on pseudo-labels to bootstrap the system on images with multiple objects. We show that while being conceptually simple our proposed baseline is surprisingly strong. We present results on PASCAL VOC that go far beyond the current state of the art (50.0 mIoU), and we report for the first time results on MS COCO for the whole set of 81 classes: our method discovers 34 categories with more than 20% IoU, while obtaining an average IoU of 19.6 for all 81 categories.

****

Pre-training Protein Structure Encoder via Siamese Diffusion Trajectory Prediction

Zuobai Zhang,Minghao Xu,Aurelie Lozano,Vijil Chenthamarakshan,Payel Das,Jian Tang

Due to the determining role of protein structures on diverse protein functions, pre-training representations of proteins on massive unlabeled protein structures has attracted rising research interests. Among recent efforts on this direction, mutual information (MI) maximization based methods have gained the superiority on various downstream benchmark tasks. The core of these methods is to design correlated views that share common information about a protein. Previous view designs focus on capturing structural motif co-occurrence on the same protein structure, while they cannot capture detailed atom/residue interactions. To address this limitation, we propose the Siamese Diffusion Trajectory Prediction (SiamDiff) method. SiamDiff builds a view as the trajectory that gradually approaches protein native structure from scratch, which facilitates the modeling of atom/residue interactions underlying the protein structural dynamics. Specifically, we employ the multimodal diffusion process as a faithful simulation of the structure-sequence co-diffusion trajectory, where rich patterns of protein structural changes are embedded. On such basis, we design a principled theoretical framework to maximize the MI between correlated multimodal diffusion trajectories. We study the effectiveness of SiamDiff on both residue-level and atom-level structures. On the EC and ATOM3D benchmarks, we extensively compare our method with previous protein structure pre-training approaches. The experimental results verify the consistently superior or competitive performance of SiamDiff on all benchmark tasks compared to existing baselines. The source code will be made public upon acceptance.

Indiscriminate Poisoning Attacks on Unsupervised Contrastive Learning

Hao He,Kaiwen Zha,Dina Katabi

Indiscriminate data poisoning attacks are quite effective against supervised learning. However, not much is known about their impact on unsupervised contrastive learning (CL). This paper is the first to consider indiscriminate poisoning attacks of contrastive learning. We propose Contrastive Poisoning (CP), the first effective such attack on CL. We empirically show that Contrastive Poisoning, not only drastically reduces the performance of CL algorithms, but also attacks supervised learning models, making it the most generalizable indiscriminate poisoning attack. We also show that CL algorithms with a momentum encoder are more robust to indiscriminate poisoning, and propose a new countermeasure based on matrix completion. Code is available at: https://github.com/kaiwenzha/contrastive-poisoning.

Decompositional Generation Process for Instance-Dependent Partial Label Learning

Congyu Qiao,Ning Xu,Xin Geng

Partial label learning (PLL) is a typical weakly supervised learning problem, where each training example is associated with a set of candidate labels among which only one is true. Most existing PLL approaches assume that the incorrect labels in each training example are randomly picked as the candidate labels and model the generation process of the candidate labels in a simple way. However, these approaches usually do not perform as well as expected due to the fact that the generation process of the candidate labels is always instance-dependent. Therefore, it deserves to be modeled in a refined way. In this paper, we consider ins tance-dependent PLL and assume that the generation process of the candidate labels could decompose into two sequential parts, where the correct label emerges first in the mind of the annotator but then the incorrect labels related to the feature are also selected with the correct label as candidate labels due to uncertainty of labeling. Motivated by this consideration, we propose a novel PLL method that performs Maximum A Posterior(MAP) based on an explicitly modeled generation process of candidate labels via decomposed probability distribution models. Extensive experiments on manually corrupted benchmark datasets and real-world datasets validate the effectiveness of the proposed method.

Multimodal Masked Autoencoders Learn Transferable Representations

Xinyang Geng,Hao Liu,Lisa Lee,Dale Schuurmans,Sergey Levine,Pieter Abbeel

Building scalable models to learn from diverse, multimodal data remains an open challenge.

For vision-language data, the dominant approaches are based on contrastive learning objectives that train a separate encoder for each modality. While effective, contrastive learning approaches introduce sampling bias depending on the data augmentations used, which can degrade performance on downstream tasks. Moreover, these methods are limited to paired image-text data, and cannot leverage widely-available unpaired data. In this paper, we investigate whether a large multimodal model trained purely via masked token prediction, without using modality-specific encoders or contrastive learning, can learn transferable representations for downstream tasks. We propose a simple and scalable network architecture, the Multimodal Masked Autoencoder (M3AE), which learns a unified encoder for both vision and language data via masked token prediction. We provide an empirical study of M3AE trained on a large-scale image-text dataset, and find that M3AE is able to learn generalizable representations that transfer well to downstream tasks. Surprisingly, we find that M3AE benefits from a higher text mask ratio (50-90%), in contrast to BERT whose standard masking ratio is 15%, due to the joint training of two data modalities. We also provide qualitative analysis showing that the learned representation incorporates meaningful information from both image and language. Lastly, we demonstrate the scalability of M3AE with larger model size and training time, and its flexibility to train on both paired image-text data as well as unpaired data.

Adversarial Causal Augmentation for Graph Covariate Shift

Yongduo Sui,Xiang Wang,Jiancan Wu,An Zhang,Xiangnan He,Tat-Seng Chua

Out-of-distribution (OOD) generalization on graphs is drawing widespread attention. However, existing efforts mainly focus on the OOD issue of correlation shift. While another type, covariate shift, remains largely unexplored but is the focus of this work. From a data generation view, causal features are stable substructures in data, which play key roles in OOD generalization. While their complementary parts, environments, are unstable features that often lead to various distribution shifts. Correlation shift establishes spurious statistical correlations between environments and labels. In contrast, covariate shift means that there exist unseen environmental features in test data. Existing strategies of graph invariant learning and data augmentation suffer from limited environments or unstable causal features, which greatly limits their generalization ability on covariate shift. In view of that, we propose a novel graph augmentation strategy: Adversarial Causal Augmentation (AdvCA), to alleviate the covariate shift. Specifically, it adversarially augments the data to explore diverse distributions of the environments. Meanwhile, it keeps the causal features invariant across diverse environments. It maintains the environmental diversity while ensuring the invariance of the causal features, thereby effectively alleviating the covariate shift. Extensive experimental results with in-depth analyses demonstrate that AdvCA can outperform 14 baselines on synthetic and real-world datasets with various covariate shifts.

Learning from conflicting data with hidden contexts

Tianren Zhang,Yizhou Jiang,Xin Su,Shangqi Guo,Chongkai Gao,Feng Chen

Classical supervised learning assumes a stable relation between inputs and outputs. However, this assumption is often invalid in real-world scenarios where the input-output relation in the data depends on some hidden contexts. We formulate a more general setting where the training data is sampled from multiple unobservable domains, while different domains may possess semantically distinct input-output maps. Training data exhibits inherent conflict in this setting, rendering vanilla empirical risk minimization problematic. We propose to tackle this problem by introducing an allocation function that learns to allocate conflicting data to different prediction models, resulting in an algorithm that we term LEAF. We draw an intriguing connection between our approach and a variant of the Expectation-Maximization algorithm. We provide theoretical justifications for LEAF on its identifiability, learnability, and generalization error. Empirical results demonstrate the efficacy and potential applications of LEAF in a range of regression and classification tasks on both synthetic data and real-world datasets.

Building a Subspace of Policies for Scalable Continual Learning

Jean-Baptiste Gaya,Thang Doan,Lucas Caccia,Laure Soulier,Ludovic Denoyer,Roberta Raileanu

The ability to continuously acquire new knowledge and skills is crucial for autonomous agents. Existing methods are typically based on either fixed-size models that struggle to learn a large number of diverse behaviors, or growing-size models that scale poorly with the number of tasks. In this work, we aim to strike a better balance between scalability and performance by designing a method whose size grows adaptively depending on the task sequence. We introduce Continual Subspace of Policies (CSP), a new approach that incrementally builds a subspace of policies for training a reinforcement learning agent on a sequence of tasks. The subspace's high expressivity allows CSP to perform well for many different tasks while growing more slowly than the number of tasks. Our method does not suffer from forgetting and also displays positive transfer to new tasks. CSP outperforms a number of popular baselines on a wide range of scenarios from two challenging domains, Brax (locomotion) and Continual World (robotic manipulation). Interactive visualizations of the subspace can be found at https://share.streamlit.io/continual-subspace/policies/main.

Complexity-Based Prompting for Multi-step Reasoning

Yao Fu,Hao Peng,Ashish Sabharwal,Peter Clark,Tushar Khot

We study the task of prompting large-scale language models to perform multi-step reasoning. Existing work shows that when prompted with a chain of thoughts (CoT), sequences of short sentences describing intermediate reasoning steps towards a final answer, large language models can generate new reasoning chains and predict answers for new inputs. A central question is which reasoning examples make the most effective prompts. In this work, we propose complexity-based prompting, a simple and effective example selection scheme for multi-step reasoning. We show that prompts with higher reasoning complexity, i.e., chains with more reasoning steps, achieve substantially better performance on math word reasoning tasks over strong baselines. We further extend our complexity-based criteria from prompting (selecting inputs) to decoding (selecting outputs), where we sample multiple reasoning chains from the model, then choose the majority of generated answers from complex reasoning chains (over simple chains). When used to prompt GPT-3, our approach substantially improves multi-step reasoning accuracy, with an 8.6% absolute improvement on GSM8K, and 6.4% on MathQA. Compared with existing example selection schemes like manual tuning or retrieval-based selection, selection based on reasoning complexity is intuitive, easy to implement, and annotation-efficient. Further results demonstrate the robustness of performance gains from complex prompts under format perturbation and distribution shift.

****

Not All Tasks Are Born Equal: Understanding Zero-Shot Generalization

Jing Zhou,Zongyu Lin,Yanan Zheng,Jian Li,Zhilin Yang

Recent work has achieved remarkable zero-shot performance with multi-task prompted pretraining, but little has been understood.
For the first time, we show that training on a small number of key tasks beats using all the training tasks, while removing these key tasks substantially hurts performance. We also find that these key tasks are mostly question answering (QA) tasks.
These novel findings combined deepen our understanding about zero-shot generalization---training on certain tasks such as QA encodes general knowledge transferable to a wide range of tasks.
In addition, to automate this procedure, we devise a method to identify and upsample key training tasks without observing the test tasks based on cross validation. Empirically, our approach achieves improved results across various model scales and tasks.

MA2QL: A Minimalist Approach to Fully Decentralized Multi-Agent Reinforcement Learning

Kefan Su,Siyuan Zhou,Chuang Gan,Xiangjun Wang,Zongqing Lu

Decentralized learning has shown great promise for cooperative multi-agent reinforcement learning (MARL). However, non-stationarity remains a significant challenge in fully decentralized learning. In the paper, we tackle the non-stationarity problem in the simplest and fundamental way and propose multi-agent alternate Q-learning (MA2QL), where agents take turns to update their Q-functions by Q-learning. MA2QL is a minimalist approach to fully decentralized cooperative MARL but is theoretically grounded. We prove that when each agent guarantees ε-convergence at each turn, their joint policy converges to a Nash equilibrium. In practice, MA2QL only requires minimal changes to independent Q-learning (IQL). We empirically evaluate MA2QL on a variety of cooperative multi-agent tasks. Results show MA2QL consistently outperforms IQL, which verifies the effectiveness of MA2QL, despite such minimal changes.

Representation Interference Suppression via Non-linear Value Factorization for Indecomposable Markov Games

Lipeng Wan,Xu He,Zeyang Liu,Kai Li,Mengchen Zhao,Dong Li,Bo An,Jianye HAO,Xuguang Lan

Value factorization is an efficient approach for centralized training with decentralized execution in cooperative multi-agent reinforcement learning tasks. As the simplest implementation of value factorization, Linear Value Factorization (LVF) attracts wide attention. In this paper, firstly, we investigate the applicable conditions of LVF, which is important but usually neglected by previous works. We prove that due to the representation limitation, LVF is only perfectly applicable to an extremely narrow class of tasks, which we define as the decomposable Markov game. Secondly, to handle the indecomposable Markov game where the LVF is inapplicable, we turn to value factorization with complete representation capability (CRC) and explore the general form of the value factorization function that satisfies both Independent Global Max (IGM) and CRC conditions. A common problem of these value factorization functions is the representation interference among true Q values with shared local Q value functions. As a result, the policy could be trapped in local optimums due to the representation interference on the optimal true Q values. Thirdly, to address the problem, we propose a novel value factorization method, namely Q Factorization with Representation Interference Suppression (QFRIS). QFRIS adaptively reduces the gradients of the local Q value functions contributed by the non-optimal true Q values. Our method is evaluated on various benchmarks. Experimental results demonstrate the good convergence of QFIRS.

SDAC: Efficient Safe Reinforcement Learning with Low-Biased Distributional Actor-Critic

Dohyeong Kim,Kyungjae Lee,Songhwai Oh

To apply reinforcement learning (RL) to real-world practical applications, agent

s are required to adhere to the safety guidelines of their respective domains.
Safe RL can effectively handle the guidelines by maximizing returns while maintaining safety satisfaction.
In this paper, we develop a safe distributional RL method based on the trust region method which has the capability of satisfying safety constraints consistently.
However, importance sampling required for the trust region method can hinder performance due to its significant variance, and policies may not meet the safety guidelines due to the estimation bias of distributional critics.
Hence, we enhance safety performance through the following approaches.
First, we propose novel surrogates for the trust region method expressed with Q-functions using the reparameterization trick.
Second, we utilize distributional critics trained with a target distribution where bias-variance can be traded off.
In addition, if an initial policy violates safety constraints, there can be no policy satisfying safety constraints within the trust region.
Thus, we propose a gradient integration method which is guaranteed to find a policy satisfying multiple constraints from an unsafe initial policy.
From extensive experiments, the proposed method shows minimal constraint violations while achieving high returns compared to existing safe RL methods.
Furthermore, we demonstrate the benefit of safe RL for problems in which the reward function cannot be easily specified.

So-TVAE: Sentiment-oriented Transformer-based Variational Autoencoder Network for Live Video Commenting
Fengyi Fu,Shancheng Fang,Weidong Chen,Yan Song,Zhendong Mao,Yongdong Zhang
Automatic live video commenting is with increasing attention due to its significance in narration generation, topic explanation, etc. However, the sentiment consideration of the generated comments is missing from the current methods. Thus, in this paper, we introduce and investigate a task, namely sentiment-guided automatic live video commenting, which aims to generate live video comments based on sentiment guidance. To address this problem, we propose a Sentiment-oriented Transformer-based Variational Autoencoder (So-TVAE) network, which consists of a sentiment-oriented diversity encoder module and a batch-attention module. Specifically, our sentiment-oriented diversity encoder elegantly combines VAE and random mask mechanism to achieve semantic diversity under sentiment guidance, which is then fused with cross-modal features to generate live video comments. Furthermore, a batch attention module is also proposed in this paper to alleviate the problem of missing sentimental samples, caused by the data imbalance, which is common in live videos as the popularity of video varies. Extensive experiments on Livebot and VideoIC datasets demonstrate that the proposed So-TVAE outperforms the state-of-the-art methods in terms of the quality and diversity of generated comments. Related codes will be released.

SoTeacher: Toward Student-oriented Teacher Network Training for Knowledge Distillation
Chengyu Dong,Liyuan Liu,Jingbo Shang
How to train an ideal teacher for knowledge distillation is still an open problem. It has been widely observed that a best-performing teacher does not necessarily yield the best-performing student, suggesting a fundamental discrepancy between the current practice in teacher training and the distillation objective. To fill this gap, we explore the feasibility of training a teacher that is oriented toward student performance with empirical risk minimization. Our analyses are inspired by the recent findings that the effectiveness of knowledge distillation hinges on the teacher’s capability to approximate the true label distribution of training inputs. We theoretically established that (1) the empirical risk minimizer can provably approximate the true label distribution of training data if the loss function is a proper scoring rule and the hypothesis function is locally-Lipschitz continuous around training inputs; and (2) when data augmentation is employed for training, an additional constraint is required that the minimizer has

to produce consistent predictions across augmented views of the same training input. In light of our theory, we propose a teacher training method SoTeacher which renovates the empirical risk minimization by incorporating Lipschitz regularization and consistency regularization. Experiments on two benchmark datasets confirm that SoTeacher can improve student performance significantly and consistently across various knowledge distillation algorithms and teacher-student pairs.

GuardHFL: Privacy Guardian for Heterogeneous Federated Learning

Hanxiao Chen,Meng Hao,Hongwei Li,Guangxiao Niu,Guowen Xu,Tianwei Zhang,Xilin Zhang

Heterogeneous federated learning (HFL) enables clients with different computation and communication capabilities to collaboratively train their own customized models via a query-response paradigm on auxiliary datasets. However, such paradigm raises serious privacy issues due to the leakage of highly sensitive query samples and response predictions. Although existing secure querying solutions may be extended to enhance the privacy of HFL with non-trivial adaptation, they suffer from two key limitations: (1) lacking customized protocol designs and (2) relying on heavy cryptographic primitives, which could lead to poor performance. In this work, we put forth GuardHFL, the first-of-its-kind efficient and privacy-preserving HFL framework. GuardHFL is equipped with a novel HFL-friendly secure querying scheme that is built on lightweight secret sharing and symmetric-key techniques. Its core is a set of customized multiplication and comparison protocols, which substantially boost the execution efficiency. Extensive evaluations demonstrate that GuardHFL outperforms the state-of-the-art works by up to two orders of magnitude in efficiency.

Decentralized Policy Optimization

Kefan Su,Zongqing Lu

The study of decentralized learning or independent learning in cooperative multi-agent reinforcement learning has a history of decades. Recently empirical studies show that independent PPO (IPPO) can obtain good performance, close to or even better than the methods of centralized training with decentralized execution, in several benchmarks. However, decentralized actor-critic with convergence guarantee is still open. In this paper, we propose decentralized policy optimization (DPO), a decentralized actor-critic algorithm with monotonic improvement and convergence guarantee. We derive a novel decentralized surrogate for policy optimization such that the monotonic improvement of joint policy can be guaranteed by each agent independently optimizing the surrogate. In practice, this decentralized surrogate can be realized by two adaptive coefficients for policy optimization at each agent. Empirically, we compare DPO with IPPO in a variety of cooperative multi-agent tasks, covering discrete and continuous action spaces, and fully and partially observable environments. The results show DPO outperforms IPPO in most tasks, which can be the evidence for our theoretical results.

Identification of the Adversary from a Single Adversarial Example

Minhao Cheng,Rui Min,Haochen Sun

Deep neural networks have been shown vulnerable to adversarial examples. Even though many defence methods have been proposed to enhance the robustness, it is still a long way toward providing an attack-free method to build a trustworthy machine learning system. In this paper, instead of enhancing the robustness, we take the investigator's perspective and propose a new framework to trace the first compromised model in a forensic investigation manner. Specifically, we focus on the following setting: the machine learning service provider provides models for a set of customers. However, one of the customers conducted adversarial attacks to fool the system. Therefore, the investigator's objective is to identify the first compromised model by collecting and analyzing evidence from only available adversarial examples. To make the tracing viable, we design a random mask watermarking mechanism to differentiate adversarial examples from different models. First, we propose a tracing approach in the data-limited case where the original example is also available. Then, we design a data-free approach to identify the adversary without accessing the original example. Finally, the effectiveness of our proposed framework is evaluated by extensive experiments with different model architectures, adversarial attacks, and datasets.

Similarity of Neural Architectures Based on Input Gradient Transferability
Jaehui Hwang,Dongyoon Han,Byeongho Heo,Song Park,Sanghyuk Chun,Jong-Seok Lee

In this paper, we aim to design a quantitative similarity function between two neural architectures. Specifically, we define a model similarity using input gradient transferability. We generate adversarial samples of two networks and measure the average accuracy of the networks on adversarial samples of each other. If two networks are highly correlated, then the attack transferability will be high, resulting in high similarity. Using the similarity score, we investigate two topics: (1) Which network component contributes to the model diversity? (2) How does model diversity affect practical scenarios? We answer the first question by providing feature importance analysis and clustering analysis. The second question is validated by two different scenarios: model ensemble and knowledge distillation. Our findings show that model diversity takes a key role when interacting with different neural architectures. For example, we found that more diversity leads to better ensemble performance. We also observe that the relationship between teacher and student networks and distillation performance depends on the choice of the base architecture of the teacher and student networks. We expect our analysis tool helps a high-level understanding of differences between various neural architectures as well as practical guidance when using multiple architectures.

Image Segmentation using Transfer Learning with DeepLabv3 to Facilitate Photogrammetric Limb Scanning
Isaac A Cabrera,Yixuan Zhou,Eric K Ngo,Ramesh Rao,Albert Lin

In this paper, we explore the use of deep learning (DL) in conjunction with photogrammetry for scanning amputated limbs. Combining these two technologies can expand the scope of prosthetic telemedicine by facilitating low-cost limb scanning using cell phones. Previous research identified image segmentation as one of the main limitations of using photogrammetry for limb scanning. Based on those limitations, this work sought to answer two main research questions: (1) Can a neural network be trained to identify and segment an amputated limb automatically? (2) Will segmenting 2D limb images using neural networks impact the accuracy of 3D models generated via photogrammetry? To answer the first question, transfer learning was applied to a neural network with the DeepLabv3 architecture. After training, the model was able to successfully identify and segment limb images with an IoU of 79.9%. To answer the second question, the fine-tuned DL model was applied to a dataset of 22 scans comprising 6312 limb images, then 3D models were rendered utilizing Agisoft Metashape. The Mean Absolute Error (MAE) of models rendered from images segmented with DL was 0.57 mm ± 0.63 mm when compared to models rendered from ground truth images. These results are important because segmentation with DL makes photogrammetry for limb scanning feasible on a large clinical scale. Future work should focus on generalizing the segmentation model for different types of amputations and imaging conditions.

****

G-Censor: Graph Contrastive Learning with Task-Oriented Counterfactual Views
tianqianjin lin,Yangyang Kang,Zhuoren Jiang,Xurui Li,Changlong Sun,cui huang,Xiaozhong Liu

Graph Contrastive learning (GCL) has achieved great success in learning representations from unlabeled graph-structure data. However, how to automatically obtain the optimal contrastive views w.r.t specific downstream tasks is little studied. Theoretically, a downstream task can be causally correlated to particular sub-structures in graphs. The existing GCL methods may fail to enhance model performance on a given task when the task-related semantics are incomplete/preserved in the positive/negative views. To address this problem, we propose G-CENSOR, i.e., Graph Contrastive lEarniNg with taSk-oriented cOunteRfactual views, a model-agnostic framework designed for node property prediction tasks. G-CENSOR can simu

ltaneously generate the optimal task-oriented counterfactual positive/negative views for raw ego-graphs and train graph neural networks (GNNs) with a contrastive objective between the raw ego-graphs and their corresponding counterfac-tual views. Extensive experiments on eight real-world datasets demonstrate that G-CENSOR can consistently outperform existing state-of-the-art GCL methods to improve the task performance and generalizability of a series of typical GNNs. To the best of our knowledge, this is a pioneer investigation to explore task-oriented graph contrastive learning from a counterfactual perspective in node property prediction tasks. We will release the source code after the review process.

Unsupervised 3D Object Learning through Neuron Activity aware Plasticity
Beomseok Kang,Biswadeep Chakraborty,Saibal Mukhopadhyay

We present an unsupervised deep learning model for 3D object classification. Conventional Hebbian learning, a well-known unsupervised model, suffers from loss of local features leading to reduced performance for tasks with complex geometric objects. We present a deep network with a novel Neuron Activity Aware (NeAW) Hebbian learning rule that dynamically switches the neurons to be governed by Hebbian learning or anti-Hebbian learning, depending on its activity. We analytically show that NeAW Hebbian learning relieves the bias in neuron activity, allowing more neurons to attend to the representation of the 3D objects. Empirical results show that the NeAW Hebbian learning outperforms other variants of Hebbian learning and shows higher accuracy over fully supervised models when training data is limited.
****

Visually-Augmented Language Modeling
Weizhi Wang,Li Dong,Hao Cheng,Haoyu Song,Xiaodong Liu,Xifeng Yan,Jianfeng Gao,Furu Wei

Human language is grounded on multimodal knowledge including visual knowledge like colors, sizes, and shapes. However, current large-scale pre-trained language models rely on the text-only self-supervised training with massive text data, which precludes them from utilizing relevant visual information when necessary. To address this, we propose a novel pre-training framework, named VaLM, to Visually-augment text tokens with retrieved relevant images for Language Modeling. Specifically, VaLM builds on a novel latent text-image alignment method via an image retrieval module to fetch corresponding images given a textual context. With the visually-augmented context, VaLM uses a visual knowledge fusion layer to enable multimodal grounded language modeling by attending on both text context and visual knowledge in images. We evaluate VaLM on various visual knowledge intensive commonsense reasoning tasks, which require visual information to excel. The experimental results illustrate that VaLM outperforms all strong language-only and vision-language baselines with substantial gains on reasoning object commonsense including color, size, and shape.

Multi-Layered 3D Garments Animation
Yidi Shao,Chen Change Loy,Bo Dai

Most existing 3D garment animation datasets are restricted to human bodies with single-layered garments. Even though cases with upper shirts and lower pants are included, only a few overlap areas among such garment combinations exist. Moreover, they often regard human body movement as the only driving factor that causes garment animation. Approaches developed on top of these datasets thus tend to model garments as functions of human body parameters such as body shape and pose. While such treatment leads to promising performance on existing datasets, it leaves a gap between experimental environments and real scenarios, where a body can wear multiple layered garments and the corresponding garment dynamics can be affected by environmental factors and garment attributes. Consequently, existing approaches often struggle to generalize to multi-layered garments and realistic scenarios. To facilitate the advance of 3D garment animation toward handling more challenging cases, this paper presents a new large-scale synthetic dataset called LAYERS, covering 4,900 different combinations of multi-layered garments with 700k frames in total. The animation of these multi-layered garments follows th e laws of physics and is affected by not only human body movements but also random environmental wind and garment attributes. To demonstrate the quality of LAYERS, we further propose a novel method, LayersNet, for 3D garment animation, which represents garments as unions of particles and subsequently adopts a neural network to animate garments via particle-based simulation. In this way, the interactions between different parts of one garment, different garments on the same body, and garments against various driving factors, can be naturally and uniformly handled via the interactions of particles. Through comprehensive experiments, LayersNet demonstrates superior performance in terms of animation accuracy and generality over baselines. The proposed dataset, LAYERS, as well as the proposed method, LayersNet, will be publicly available.

Unsupervised Learning of Structured Representations via Closed-Loop Transcription

Shengbang Tong,Xili Dai,Yubei Chen,Mingyang Li,ZENGYI LI,Brent Yi,Yann LeCun,Yi Ma

This paper proposes an unsupervised method for learning a unified representation that serves both discriminative and generative purposes. While most existing unsupervised learning approaches focus on a representation for only one of these two goals, we show that a unified representation can enjoy the mutual benefits of having both. Such a representation is attainable by generalizing the recently proposed closed-loop transcription framework, known as CTRL, to the unsupervised setting. This entails solving a constrained maximin game over a rate reduction objective that expands features of all samples while compressing features of augmentations of each sample. Through this process, we see discriminative low-dimensional structures emerge in the resulting representations. Under comparable experimental conditions and network complexities, we demonstrate that these structured representations enable classification performance close to state-of-the-art unsupervised discriminative representations, and conditionally generated image quality significantly higher than that of state-of-the-art unsupervised generative models.

Closed Boundary Learning for NLP Classification Tasks with the Universum Class

Hanzhang Zhou,Zijian Feng,Kezhi Mao,Edmond Y.M. Lo,Lihui Chen

The Universum class, often known as the other class or the miscellaneous class, is defined as a collection of samples that do not belong to any class of interest. It is a typical class that exists in many classification-based tasks in natural language processing (NLP), such as relation extraction, named entity recognition, sentiment analysis, etc. During data labeling, a significant number of samples are annotated as Universum because there are always some samples that exist in the dataset but do not belong to preset target classes and are not of interest in the task. The Universum class exhibits very different properties, namely heterogeneity and lack of representativeness in training data; however, existing methods often treat the Universum class equally with the classes of interest. Although the Universum class only contains uninterested samples, improper treatment will result in the misclassification of samples of interest. In this work, we propose a closed boundary learning method that treats the Universum class and classes of interest differently. We apply closed decision boundaries to classes of interest and designate the area outside all closed boundaries in the feature space as the space of the Universum class. Specifically, we formulate the closed boundaries as arbitrary shapes, propose a strategy to estimate the probability of the Universum class according to its unique property rather than the within-class sample distribution, and propose a boundary learning loss to learn decision boundaries based on the balance of misclassified samples inside and outside the boundary. We evaluate our method on 6 state-of-the-art works in 3 different tasks, and the performance of all 6 works is improved. Our code will be released on GitHub.

Solving Constrained Variational Inequalities via a First-order Interior Point-based Method

Tong Yang,Michael Jordan,Tatjana Chavdarova

We develop an interior-point approach to solve constrained variational inequality (cVI) problems. Inspired by the efficacy of the alternating direction method of multipliers (ADMM) method in the single-objective context, we generalize ADMM to derive a first-order method for cVIs, that we refer to as ADMM-based interior-point method for constrained VIs (ACVI). We provide convergence guarantees for ACVI in two general classes of problems: (i) when the operator is ξ-monotone, and (ii) when it is monotone, some constraints are active and the game is not purely rotational. When the operator is in addition L-Lipschitz for the latter case, we match known lower bounds on rates for the gap function of $\mathcal{O}(1/\sqrt{K})$ and $\mathcal{O}(1/K)$ for the last and average iterate, respectively. To the best of our knowledge, this is the first presentation of a first-order interior-point method for the general cVI problem that has a global convergence guarantee. Moreover, unlike previous work in this setting, ACVI provides a means to solve cVIs when the constraints are nontrivial. Empirical analyses demonstrate clear advantages of ACVI over common first-order methods. In particular, (i) cyclical behavior is notably reduced as our methods approach the solution from the analytic center, and (ii) unlike projection-based methods that zigzag when near a constraint, ACVI efficiently handles the constraints.

MeGraph: Graph Representation Learning on Connected Multi-scale Graphs

Honghua Dong,Jiawei Xu,Yu Yang,Rui Zhao,Chun Yuan,Xiu Li,Chris J. Maddison,Lei Han

We present MeGraph, a novel network architecture for graph-structured data. Given any input graph, we create multi-scale graphs using graph pooling. Then, we connect them into a mega graph by bridging inter-graph edges according to the graph pooling results. Instead of universally stacking graph convolutions over the mega graph, we apply general graph convolutions over intra-graph edges, while the convolutions over inter-graph edges follow a bidirectional pathway to deliver the information along the hierarchy for one turn. Graph convolution and graph pooling are two core elementary operations of MeGraph. In our implementation, we adopt the graph full network (GFuN) and propose the stridden edge contraction pooling (S-EdgePool) with adjustable pooling ratio, which are extended from conventional graph convolution and edge contraction pooling. The MeGraph model enables information exchange across multi-scale graphs, repeatedly, for deeper understanding of wide-range correlations in graphs. This distinguishes MeGraph from many recent hierarchical graph neural networks like Graph U-Nets. We conduct comprehensive empirical studies on tens of public datasets, in which we observe consistent performance gains comparing to baselines. Specifically, we establish 5 new graph theory benchmark tasks that require long-term inference and deduction to solve, where MeGraph demonstrates dominated performance compared with popular graph neural networks.

Learning Reduced Fluid Dynamics

zherong pan,Xifeng Gao,Kui Wu

Predicting the state evolution of ultra high-dimensional, time-reversible fluid dynamic system is a crucial but computationally expensive task. Model-reduction has been proven to be an effective method to reduce the computational cost by learning a low-dimensional state embedding. However, existing reduced models are irrespective of either the time reversible property or the nonlinear dynamics, leading to sub-optimal performance. We propose a model-based approach to identify locally optimal, model-reduced, time reversible, nonlinear fluid dynamic systems. Our main idea is to use stochastic Riemann optimization to obtain a high-quality a reduced fluid model by minimizing the expected trajectory-wise model-reduction error over a given distribution of initial conditions. To this end, our method formulates the reduced fluid dynamics as an invertible state transfer function parameterized by the reduced subspace. We further show that the reduced trajectories are differentiable with respect to the subspace bases over the entire Grassmannian manifold, under proper choices of timestep sizes and numerical integrators. Finally, we propose a loss function measuring the trajectory-wise discrepa ncy between the original and reduced models. By tensor precomputation, we show that gradient information of such loss functions can be evaluated efficiently over a long trajectory without time-integrating the high-dimensional dynamic system. Through evaluations on a row of simulation benchmarks, we show that our method lower the discrepancy by 45%-97% over conventional reduced models.

****

Symmetric Pruning in Quantum Neural Networks

Xinbiao Wang,Junyu Liu,Tongliang Liu,Yong Luo,Yuxuan Du,Dacheng Tao

Many fundamental properties of a quantum system are captured by its Hamiltonian and ground state. Despite the significance, ground states preparation (GSP) is classically intractable for large-scale Hamiltonians. Quantum neural networks (QNNs), which exert the power of modern quantum machines, have emerged as a leading protocol to conquer this issue. As such, the performance enhancement of QNNs becomes the core in GSP. Empirical evidence showed that QNNs with handcraft symmetric ans\"atze generally experience better trainability than those with asymmetric ans\"atze, while theoretical explanations remain vague. To fill this knowledge gap, here we propose the effective quantum neural tangent kernel (EQNTK) and connect this concept with over-parameterization theory to quantify the convergence of QNNs towards the global optima. We uncover that the advance of symmetric ans\"atze attributes to their large EQNTK value with low effective dimension, which requests few parameters and quantum circuit depth to reach the over-parameterization regime permitting a benign loss landscape and fast convergence. Guided by EQNTK, we further devise a symmetric pruning (SP) scheme to automatically tailor a symmetric ansatz from an over-parameterized and asymmetric one to greatly improve the performance of QNNs when the explicit symmetry information of Hamiltonian is unavailable. Extensive numerical simulations are conducted to validate the analytical results of EQNTK and the effectiveness of SP.

Managing Temporal Resolution in Continuous Value Estimation: A Fundamental Trade-off

Zichen Zhang,Johannes Kirschner,Junxi Zhang,Francesco Zanini,Alex Ayoub,Masood Dehghan,Dale Schuurmans

A default assumption in reinforcement learning and optimal control is that experience arrives at discrete time points on a fixed clock cycle. Many applications, however, involve continuous systems where the time discretization is not fixed but instead can be managed by a learning algorithm. By analyzing Monte-Carlo value estimation for LQR systems in both finite-horizon and infinite-horizon settings, we uncover a fundamental trade-off between approximation and statistical error in value estimation. Importantly, these two errors behave differently with respect to time discretization, which implies that there is an optimal choice for the temporal resolution that depends on the data budget. These findings show how adapting the temporal resolution can provably improve value estimation quality in LQR systems from finite data. Empirically, we demonstrate the trade-off in numerical simulations of LQR instances and several non-linear environments.

On the Robustness of Randomized Ensembles to Adversarial Perturbations

Hassan Dbouk,Naresh Shanbhag

Randomized ensemble classifiers (RECs), where one classifier is randomly selected during inference, have emerged as an attractive alternative to traditional ensembling methods for realizing adversarially robust classifiers with limited compute requirements. However, recent works have shown that existing methods for constructing RECs are more vulnerable than initially claimed, casting major doubts on their efficacy and prompting fundamental questions such as: "When are RECs useful?", "What are their limits?", and "How do we train them?". In this work, we first demystify RECs as we derive fundamental results regarding their theoretical limits, necessary and sufficient conditions for them to be useful, and more. Leveraging this new understanding, we propose a new boosting
algorithm (BARRE) for training robust RECs, and empirically demonstrate its effectiveness at defending against strong ℓ_∞ norm-bounded adversaries across various network architectures and datasets. Our code is submitted as part of

the supplementary material, and will be publicly released on GitHub

Minimum Variance Unbiased N:M Sparsity for the Neural Gradients

Brian Chmiel,Itay Hubara,Ron Banner,Daniel Soudry

In deep learning, fine-grained N:M sparsity reduces the data footprint and bandwidth of a General Matrix multiply (GEMM) up to x2, and doubles throughput by skipping computation of zero values. So far, it was mainly only used to prune weights to accelerate the forward and backward phases. We examine how this method can be used also for the neural gradients (i.e. loss gradients with respect to the intermediate neural layer outputs). To this end, we first establish a tensor-level optimality criteria. Previous works aimed to minimize the mean-square-error (MSE) of each pruned block. We show that while minimization of the MSE works fine for pruning the weights and activations, it catastrophically fails for the neural gradients. Instead, we show that accurate pruning of the neural gradients requires an unbiased minimum-variance pruning mask. We design such specialized masks, and find that in most cases, 1:2 sparsity is sufficient for training, and 2:4 sparsity is usually enough when this is not the case. Further, we suggest combining several such methods together in order to potentially speed up training even more. A reference implementation is supplied in the supplementary material.

Incremental Learning of Structured Memory via Closed-Loop Transcription

Shengbang Tong,Xili Dai,Ziyang Wu,Mingyang Li,Brent Yi,Yi Ma

This work proposes a minimal computational model for learning structured memories of multiple object classes in an incremental setting. Our approach is based on establishing a {\em closed-loop transcription} between the classes and a corresponding set of subspaces, known as a linear discriminative representation, in a low-dimensional feature space. Our method is simpler than existing approaches for incremental learning, and more efficient in terms of model size, storage, and computation: it requires only a single, fixed-capacity autoencoding network with a feature space that is used for both discriminative and generative purposes. Network parameters are optimized simultaneously without architectural manipulations, by solving a constrained minimax game between the encoding and decoding maps over a single rate reduction-based objective. Experimental results show that our method can effectively alleviate catastrophic forgetting, achieving significantly better performance than prior work of generative replay on MNIST, CIFAR-10, and ImageNet-50, despite requiring fewer resources.

Curved Data Representations in Deep Learning

Ilya Kaufman,Omri Azencot

The phenomenal success of deep neural networks inspire many to understand the inner mechanisms of these models. To this end, several works have been studying geometric properties such as the intrinsic dimension of latent data representations produced by the layers of the network. In this paper, we investigate the curvature of data manifolds, i.e., the deviation of the manifold from being flat in its principal directions. We find that state-of-the-art trained convolutional neural networks have a characteristic curvature profile along layers: an initial increase, followed by a long phase of a plateau, and tailed by another increase. In contrast, untrained networks exhibit qualitatively and quantitatively different curvature profiles. We also show that the curvature gap between the last two layers is strongly correlated with the performance of the network. Further, we find that the intrinsic dimension of latent data along the network layers is not necessarily indicative of curvature. Finally, we evaluate the effect of common regularizers such as weight decay and mixup on curvature, and we find that mixup-based methods flatten intermediate layers, whereas the final layers still feature high curvatures. Our results indicate that relatively flat manifolds which transform to highly-curved manifolds toward the last layers generalize well to unseen data.

When Data Geometry Meets Deep Function: Generalizing Offline Reinforcement Learning

Jianxiong Li,Xianyuan Zhan,Haoran Xu,Xiangyu Zhu,Jingjing Liu,Ya-Qin Zhang
In offline reinforcement learning (RL), one detrimental issue to policy learning is the error accumulation of deep \textit{Q} function in out-of-distribution (OOD) areas. Unfortunately, existing offline RL methods are often over-conservative, inevitably hurting generalization performance outside data distribution. In our study, one interesting observation is that deep \textit{Q} functions approximate well inside the convex hull of training data. Inspired by this, we propose a new method, \textit{DOGE (Distance-sensitive Offline RL with better GEneralization)}. DOGE marries dataset geometry with deep function approximators in offline RL, and enables exploitation in generalizable OOD areas rather than strictly constraining policy within data distribution. Specifically, DOGE trains a state-conditioned distance function that can be readily plugged into standard actor-critic methods as a policy constraint. Simple yet elegant, our algorithm enjoys better generalization compared to state-of-the-art methods on D4RL benchmarks. Theoretical analysis demonstrates the superiority of our approach to existing methods that are solely based on data distribution or support constraints.
****

Self-supervised debiasing using low rank regularization
Geon Yeong Park,Chanyong Jung,Jong Chul Ye,Sang Wan Lee
Spurious correlations can cause strong biases in deep neural networks, impairing generalization ability. While most of existing debiasing methods require full supervisions on either spurious attributes or target labels, training a debiased model from a limited amount of both annotations is still an open issue. To overcome such limitations, we first examined an interesting phenomenon by the spectral analysis of latent representations: spuriously correlated, easy-to-learn attributes make neural networks inductively biased towards encoding lower effective rank representations. We also show that a rank regularization can amplify this bias in a way that encourages highly correlated features. Motivated by these observations, we propose a self-supervised debiasing framework that is potentially compatible with unlabeled samples. We first pretrain a biased encoder in a self-supervised manner with the rank regularization, serving as a semantic bottleneck to enforce the encoder to learn the spuriously correlated attributes. This biased encoder is then used to discover and upweight bias-conflicting samples in a downstream task, serving as a boosting to effectively debias the main model. Remarkably, the proposed debiasing framework significantly improves the generalization performance of self-supervised learning baselines and, in some cases, even outperforms state-of-the-art supervised debiasing approaches.

Wasserstein Gradient Flows for Optimizing GMM-based Policies
Hanna Ziesche,Leonel Rozo
Robots often rely on a repertoire of previously-learned motion policies for performing tasks of diverse complexities.
When facing unseen task conditions or when new task requirements arise, robots must adapt their motion policies accordingly.
In this context, policy optimization is the de facto paradigm to adapt robot policies as a function of task-specific objectives.
Most commonly-used motion policies carry particular structures that are often overlooked in policy optimization algorithms.
We instead propose to leverage the structure of probabilistic policies by casting the policy optimization as an optimal transport problem.
Specifically, we focus on robot motion policies that build on Gaussian mixture models (GMMs) and formulate the policy optimization as a Wassertein gradient flow over the GMMs space.
This naturally allows us to constrain the policy updates via the L^2-Wasserstein distance between GMMs to enhance the stability of the policy optimization process.
Furthermore, we leverage the geometry of the Bures-Wasserstein manifold to optimize the Gaussian distributions of the GMM policy via Riemannian optimization.
We evaluate our approach over a set of common robotic settings: Reaching motions, collision-avoidance behaviors and multi-goal tasks.

Our results show that our method outperforms common policy optimization baselines in terms of task success rate and low-variance solutions.
****

Neural Unbalanced Optimal Transport via Cycle-Consistent Semi-Couplings
Frederike Lübeck,Charlotte Bunne,Gabriele Gut,Jacobo Sarabia del Castillo,Lucas Pelkmans,David Alvarez-Melis
Comparing unpaired samples of a distribution or population taken at different points in time is a fundamental task in many application domains where measuring populations is destructive and cannot be done repeatedly on the same sample, such as in single-cell biology. Optimal transport (OT) can solve this challenge by learning an optimal coupling of samples across distributions from unpaired data. However, the usual formulation of OT assumes conservation of mass, which is violated in unbalanced scenarios in which the population size changes (e.g., cell proliferation or death) between measurements. In this work, we introduce NubOT, a neural unbalanced OT formulation that relies on the formalism of semi-couplings to account for creation and destruction of mass. To estimate such semi-couplings and generalize out-of-sample, we derive an efficient parameterization based on neural optimal transport maps and propose a novel algorithmic scheme through a cycle-consistent training procedure. We apply our method to the challenging task of forecasting heterogeneous responses of multiple cancer cell lines to various drugs, where we observe that by accurately modeling cell proliferation and death, our method yields notable improvements over previous neural optimal transport methods.

Budgeted Training for Vision Transformer
zhuofan xia,Xuran Pan,Xuan Jin,Yuan He,Hui Xue',Shiji Song,Gao Huang
The superior performances of Vision Transformers often come with higher training costs. Compared to their CNN counterpart, Transformer models are hungry for large-scale data and their training schedules are usually prolonged. This sets great restrictions on training Transformers with limited resources, where a proper trade-off between training cost and model performance is longed. In this paper, we address the problem by proposing a framework that enables the training process under \textit{any training budget} from the perspective of model structure, while achieving competitive model performances. Specifically, based on the observation that Transformer exhibits different levels of model redundancies at different training stages, we propose to dynamically control the activation rate of the model structure along the training process and meet the demand on the training budget by adjusting the duration on each level of model complexity. Extensive experiments demonstrate that our framework is applicable to various Vision Transformers, and achieves competitive performances on a wide range of training budgets.

Knowledge-in-Context: Towards Knowledgeable Semi-Parametric Language Models
Xiaoman Pan,Wenlin Yao,Hongming Zhang,Dian Yu,Dong Yu,Jianshu Chen
Fully-parametric language models generally require a huge number of model parameters to store the necessary knowledge for solving multiple natural language tasks in zero/few-shot settings. In addition, it is hard to adapt to the evolving world knowledge without the costly model re-training. In this paper, we develop a novel semi-parametric language model architecture, Knowledge-in-Context (KiC), which empowers a parametric text-to-text language model with a knowledge-rich external memory. Specifically, the external memory contains six different types of knowledge: entity, dictionary, commonsense, event, script, and causality knowledge. For each input instance, the KiC model adaptively selects a knowledge type and retrieves the most helpful pieces of knowledge. The input instance along with its knowledge augmentation is fed into a text-to-text model (e.g., T5) to generate the output answer, where both the input and the output are in natural language forms after prompting. Interestingly, we find that KiC can be identified as a special mixture-of-experts (MoE) model, where the knowledge selector plays the role of a router that is used to determine the sequence-to-expert assignment in MoE. This key observation inspires us to develop a novel algorithm for trainin

g KiC with an instance-adaptive knowledge selector. As a knowledge-rich semi-parametric language model, KiC only needs a much smaller parametric part to achieve superior zero-shot performance on unseen tasks. By evaluating on 40+ different tasks, we show that KiC-Large with 770M parameters easily outperforms large language models that are 4-39x larger. In addition, KiC also exhibits emergent abilities at a much smaller model scale compared to the fully-parametric models.

Understanding and Mitigating Robust Overfitting through the Lens of Feature Dynamics

Yifei Wang,Liangchen Li,Yisen Wang,Jiansheng Yang,Zhouchen Lin

Adversarial Training (AT) has become arguably the state-of-the-art algorithm for extracting robust features. However, researchers recently notice that AT suffers from severe robust overfitting problems, particularly after the learning rate (LR) decay, while the existing static view of feature robustness fails to explain this phenomenon. In this paper, we propose a new dynamic feature robustness framework which takes the dynamic interplay between the model trainer and the attacker into consideration. By tracing temporal and dataset-specific feature robustness, we develop a new understanding of robust overfitting from the dynamics of non-robust features, and empirically verify it on real-world datasets. Built upon this understanding, we explore three techniques to restore the balance between the model trainer and the attacker, and show that they could effectively alleviate robust overfitting and attain state-of-the-art robustness on benchmark datasets. Notably, different from previous studies, our interpretation highlights the necessity of considering the min-max nature of AT for robust overfitting.

Augmentative Topology Agents For Open-Ended Learning

Muhammad Umair Nasir,Michael Beukman,Steven James,Christopher Wesley Cleghorn

In this work, we tackle the problem of Open-Ended Learning by a method that simultaneously evolves agents and increasingly challenging environments. Unlike previous open-ended approaches that optimize agents using a fixed neural network topology, we hypothesize that generalization can be improved by allowing agents' controllers to become more complex as they encounter more difficult environments. Our method, Augmentative Topology EPOET (ATEP), extends the Enhanced Paired Open-Ended Trailblazer (EPOET) algorithm by allowing agents to evolve their own neural network structures over time, adding complexity and capacity as necessary. Empirical results demonstrate that ATEP results in general agents capable of solving more environments than a fixed-topology baseline. We also investigate mechanisms for transferring agents between environments and find that a species-based approach further improves the performance and generalization of agents.

Learning to Boost Resilience of Complex Networks via Neural Edge Rewiring

Shanchao Yang,MA KAILI,Tianshu Yu,Baoxiang Wang,Hongyuan Zha

The resilience of complex networks, a critical structural characteristic in network science, measures the network's ability to withstand noise corruption and structural changes. Improving resilience typically resorts to minimal modifications of the network structure via degree-preserving edge rewiring-based methods. Despite their effectiveness, existing methods are learning-free, sharing the limitation of transduction: a learned edge rewiring strategy from one graph cannot be generalized to another. Such a limitation cannot be trivially addressed by existing graph neural networks (GNNs)-based approaches since there is no rich initial node features for GNNs to learn meaningful representations. However, neural edge rewiring relies on GNNs for obtaining meaningful representations from pure graph topologies to select edges. We found existing GNNs degenerate remarkably with only pure topologies on the resilience task, leading to the undesired infinite action backtracking. In this work, inspired by persistent homology, we specifically design a variant of GNN called FireGNN for learning inductive edge rewiring strategies. Based on meaningful representations from FireGNN, we develop the first end-to-end inductive method, ResiNet, to discover $\textbf{resi}$lient $\textbf{net}$work topologies while balancing network utility. ResiNet reformulates n etwork resilience optimization as a Markov decision process equipped with edge rewiring action space and learns to select correct edges successively. Extensive experiments demonstrate that ResiNet achieves a near-optimal resilience gain on various graphs while balancing the utility and outperforms existing approaches by a large margin.

Deep Transformer Q-Networks for Partially Observable Reinforcement Learning
Kevin Esslinger,Robert Platt,Christopher Amato

Real-world reinforcement learning tasks often involve some form of partial observability where the observations only give a partial or noisy view of the true state of the world. Such tasks typically require some form of memory, where the agent has access to multiple past observations, in order to perform well. One popular way to incorporate memory is by using a recurrent neural network to access the agent's history. However, recurrent neural networks in reinforcement learning are often fragile and difficult to train, susceptible to catastrophic forgetting and sometimes fail completely as a result. In this work, we propose Deep Transformer Q-Networks (DTQN), a novel architecture utilizing transformers and self-attention to encode an agent's history. DTQN is designed modularly, and we compare results against several modifications to our base model. Our experiments demonstrate the transformer can solve partially observable tasks faster and more stably than previous recurrent approaches.

Mind's Eye: Grounded Language Model Reasoning through Simulation
Ruibo Liu,Jason Wei,Shixiang Shane Gu,Te-Yen Wu,Soroush Vosoughi,Claire Cui,Denny Zhou,Andrew M. Dai

Successful and effective communication between humans and AI relies on a shared experience of the world. By training solely on written text, current language models (LMs) miss the grounded experience of humans in the real-world---their failure to relate language to the physical world causes knowledge to be misrepresented and obvious mistakes in their reasoning. We present Mind's Eye, a paradigm to ground language model reasoning in the physical world. Given a physical reasoning question, we use a computational physics engine (DeepMind's MuJoCo) to simulate the possible outcomes, and then use the simulation results as part of the input, which enables language models to perform reasoning. Experiments on 39 tasks in a physics alignment benchmark demonstrate that Mind's Eye can improve reasoning ability by a large margin (27.9% zero-shot, and 46.0% few-shot absolute accuracy improvement on average). Smaller language models armed with Mind's Eye can obtain similar performance to models that are 100x larger. Finally, we confirm the robustness of Mind's Eye through ablation studies.

Visual Expertise and the Log-Polar Transform Explain Image Inversion Effects
Martha Gahl,Shubham Kulkarni,Nikhil Pathak,Alex Russell,Garrison W. Cottrell

Visual expertise can be defined as the ability to discriminate among subordinate-level objects in homogeneous classes, such as identities of faces within the class "face". Despite being able to discriminate many faces, subjects perform poorly at recognizing even familiar faces once inverted. This face-inversion effect is in contrast to subjects’ performance identifying inverted objects for which their experience is at a basic level, which results in less impairment. Experimental results have suggested that when identifying mono-oriented objects, such as cars, car novices' performance is between that of faces and other objects. We build an anatomically-inspired neurocomputational model to explore this effect. Our model includes a foveated retina and the log-polar mapping from the visual field to V1. This transformation causes changes in scale to appear as horizontal translations, leading to scale equivariance. Rotation is similarly equivariant, leading to vertical translations. When fed into a standard convolutional network, this provides rotation and scale invariance. It may be surprising that a rotation-invariant network shows any inversion effect at all. This is because there is a crucial topological difference between scale and rotation: Rotational invariance is discontinuous, with V1 ranging from 90 degrees (vertically up) to 270 degrees (vertically down). Hence when a face is inverted, the configural informati

on in the face is disrupted while feature information is relatively unaffected. We show that the inversion effect arises as a result of visual expertise, where configural information becomes relevant as more identities are learned at the subordinate level. Our model matches the classic result: faces suffer more from inversion than mono-oriented objects, which are more disrupted than non-mono-oriented objects when objects are only familiar at a basic level.

Cross-Protein Wasserstein Transformer for Protein-Protein Interactions
Gongping Xu,Tong Zhang,Wenting Zhao,Zhen Cui,Jian Yang
Previous studies reveal intimate relationships between the structure and function of proteins. Motivated by this, for protein-protein interactions (PPIs), we hypothesize that cross-protein structural correspondence, including both global correlation and local co-occurrence, poses a great influence. Accordingly, a novel deep learning framework named Cross-Protein Wasserstein Transformer (CPWT) is proposed to predict PPI sites through fine-grained cross-graph structural modeling. Considering the irregular architecture of acid sequences, for a pair of proteins, graphs are constructed to describe them. Then, a core Cross-Graph Transformer (CGT) module of two branches (e.g. ligand and receptor branches) is proposed for cross-protein structural modeling. Specifically, in this module, Wasserstein affinity across graphs is calculated through cross-graph query (i.e. ligand (query) - receptor (key) or the converse), based on which the multi-head attention is derived to adaptively mine fine-grained cues of PPI sites. By stacking CGT modules, the two branches in CGT are co-evolved in a deep architecture during forward inference, hence being powerful and advantageous in cross-protein structural representation and fine-grained learning. We verify the effectiveness of our CPWT framework by conducting comprehensive experiments on multiple PPI datasets, and further visualize the learned fine-grained saliencies for intuitive understanding.

What Do Self-Supervised Vision Transformers Learn?
Namuk Park,Wonjae Kim,Byeongho Heo,Taekyung Kim,Sangdoo Yun
We present a comparative study on how and why contrastive learning (CL) and masked image modeling (MIM) differ in their representations and in their performance of downstream tasks. In particular, we demonstrate that self-supervised Vision Transformers (ViTs) have the following properties: (1) CL trains self-attentions to capture longer-range global patterns than MIM, such as the shape of an object, especially in the later layers of the ViT architecture. This CL property helps ViTs linearly separate images in their representation spaces. However, it also makes the self-attentions collapse into homogeneity for all query tokens and heads. Such homogeneity of self-attention reduces the diversity of representations, worsening scalability and dense prediction performance. (2) CL utilizes the low-frequency signals of the representations, but MIM utilizes high-frequencies. Since low- and high-frequency information respectively represent shapes and textures, CL is more shape-oriented and MIM more texture-oriented. (3) CL plays a crucial role in the later layers, while MIM mainly focuses on the early layers. Upon these analyses, we find that CL and MIM can complement each other and observe that even the simplest harmonization can help leverage the advantages of both methods. The code is available at https://github.com/naver-ai/cl-vs-mim.

Confident Sinkhorn Allocation for Pseudo-Labeling
Vu Nguyen,Sachin Farfade,Anton van den Hengel
Semi-supervised learning is a critical tool in reducing machine learning’s dependence on labeled data. It has been successfully applied to structure data, such as image and language data, by exploiting the inherent spatial and semantic structure therein with pretrained models or data augmentation. Some of these methods are no longer applicable for the data where domain structures are not available because the pretrained models or data augmentation can not be used.

Due to simplicity, existing pseudo-labeling (PL) methods can be widely used with out any domain assumption, but are vulnerable to noise samples and to greedy assignments given a predefined threshold which is typically unknown. This paper addresses this problem by proposing a Confident Sinkhorn Allocation (CSA), which assigns labels to only samples with high confidence scores and learns the best label allocation via optimal transport. CSA outperforms the current state-of-the-art in this practically important area of semi-supervised learning.

****

Adversarial Robustness based on Randomized Smoothing in Quantum Machine Learning

Aditya Sahdev,Mehul Kumar

We present an end-to-end Quantum Machine Learning algorithm that encodes a classical input into a Quantum Computing state and provides certified radius for a base classifier, with robustness guarantees based on randomized smoothing - current state-of-the-art defense against adversarial attacks. Classically, the number of samples, also the number of queries to the classifier, scale with $O(1/\epsilon^2)$ where ϵ is the desired error bound in expected value of the probability measure ρ defined over the randomized smoothing neighborhood. Our algorithm is designed to solve the same problem for a Quantum Computing classifier. We prove that number of queries to the classifier scale as $O(1/\epsilon)$ for the same confidence and error bound. We also present the unitary circuit corresponding to the quantum randomized smoothing algorithm, as well as the state preparation methods and circuits for smoothing distributions used to defend against common adversaries - modeled using l_0, l_1, l_2 norms, and other metrics. The results of comparison between the classical and simulation of the quantum algorithm are also discussed.

Multi-Vector Retrieval as Sparse Alignment

Yujie Qian,Jinhyuk Lee,Karthik Duddu,Zhuyun Dai,Tao Lei,Siddhartha Brahma,Iftekhar Naim,Vincent Y Zhao

Multi-vector retrieval models improve over single-vector dual encoders on many information retrieval tasks. In this paper, we cast the multi-vector retrieval problem as sparse alignment between query and document tokens. We propose ALIGNER, a novel multi-vector retrieval model that learns sparsified pairwise alignments between query and document tokens (e.g. `dog' vs. `puppy') and per-token unary saliences reflecting their relative importance for retrieval. We show that controlling the sparsity of pairwise token alignments often brings significant performance gains. While most factoid questions focusing on a specific part of a document require a smaller number of alignments, others requiring a broader understanding of a document favor a larger number of alignments. Unary saliences, on the other hand, decide whether a token ever needs to be aligned with others for retrieval (e.g. `kind' from `what kind of currency is used in new zealand'). With sparsified unary saliences, we are able to prune a large number of query and document token vectors and improve the efficiency of multi-vector retrieval. We learn the sparse unary saliences with entropy-regularized linear programming, which outperforms other methods to achieve sparsity. In a zero-shot setting, ALIGNER scores 51.1 nDCG@10, achieving a new retriever-only state-of-the-art on 13 tasks in the BEIR benchmark. In addition, adapting pairwise alignments with a few examples (<= 8) further improves the performance up to 15.7 points nDCG@10 for argument retrieval tasks. The unary saliences of ALIGNER helps us to keep only 20% of the document token representations with minimal performance loss. We further show that our model often produces interpretable alignments and significantly improves its performance when initialized from larger language models.

Sampled Transformer for Point Sets

Shidi Li,Christian Walder,Alexander Soen,Lexing Xie,miaomiao Liu

The sparse transformer can reduce the computational complexity of the self-attention layers to $O(n)$, whilst still being a universal approximator of continuous sequence-to-sequence functions. However, this permutation variant operation is not appropriate for direct application to sets. In this paper, we proposed an $O(n)$ complexity sampled transformer that can process point set elements directly without any additional inductive bias. Our sampled transformer introduces random element sampling, which randomly splits point sets into subsets, followed by applying a shared Hamiltonian self-attention mechanism to each subset. The overall attention mechanism can be viewed as a Hamiltonian cycle in the complete attention graph, and the permutation of point set elements is equivalent to randomly sampling Hamiltonian cycles. This mechanism implements a Monte Carlo simulation of the $O(n^2)$ dense attention connections. We show that it is a universal approximator for continuous set-to-set functions. Experimental results for classification and few-shot learning on point-clouds show comparable or better accuracy with significantly reduced computational complexity compared to the dense transformer or alternative sparse attention schemes.

****

Population-size-Aware Policy Optimization for Mean-Field Games

Pengdeng Li,Xinrun Wang,Shuxin Li,Hau Chan,Bo An

In this work, we attempt to bridge the two fields of finite-agent and infinite-agent games, by studying how the optimal policies of agents evolve with the number of agents (population size) in mean-field games, an agent-centric perspective in contrast to the existing works focusing typically on the convergence of the empirical distribution of the population. To this end, the premise is to obtain the optimal policies of a set of finite-agent games with different population sizes. However, either deriving the closed-form solution for each game is theoretically intractable, training a distinct policy for each game is computationally intensive, or directly applying the policy trained in a game to other games is sub-optimal. We address these challenges through the \textbf{P}opulation-size-\textbf{A}ware \textbf{P}olicy \textbf{O}ptimization (PAPO). Our contributions are three-fold. First, to efficiently generate efficient policies for games with different population sizes, we propose PAPO, which unifies two natural options (augmentation and hypernetwork) and achieves significantly better performance. PAPO consists of three components: i) the population-size encoding which transforms the original value of population size to an equivalent encoding to avoid training collapse, ii) a hypernetwork to generate a distinct policy for each game conditioned on the population size, and iii) the population size as an additional input to the generated policy. Next, we construct a multi-task-based training procedure to efficiently train the neural networks of PAPO by sampling data from multiple games with different population sizes. Finally, extensive experiments on multiple environments show the significant superiority of PAPO over baselines, and the analysis of the evolution of the generated policies further deepens our understanding of the two fields of finite-agent and infinite-agent games.

PartAfford: Part-level Affordance Discovery

Chao Xu,Yixin Chen,He Wang,Song-Chun Zhu,Yixin Zhu,Siyuan Huang

Understanding what objects could furnish for humans—learning object affordance—is the crux of bridging perception and action. In the vision community, prior work has primarily focused on learning object affordance with dense (e.g., at a per-pixel level) supervision. In stark contrast, we humans learn the object affordance without dense labels. As such, the fundamental question to devise a computational model is: What is the natural way to learn the object affordance from geometry with humanlike sparse supervision? In this work, we present the new task of part-level affordance discovery (PartAfford): Given only the affordance labels for each object, the machine is tasked to (i) decompose 3D shapes into parts and (ii) discover how each part of the object corresponds to a certain affordance category. We propose a novel learning framework that discovers part-level representations by leveraging only the affordance set supervision and geometric primitive regularization without dense supervision. To learn and evaluate PartAfford, we construct a part-level, cross-category 3D object affordance dataset, annotated with 24 affordance categories shared among >25, 000 objects. We demonstrate through extensive experiments that our method enables both the abstraction of 3D objects and part-level affordance discovery, with generalizability to difficult and cross-category examples. Further ablations reveal the contribution of each component.

On The Relative Error of Random Fourier Features for Preserving Kernel Distance

Kuan Cheng,Shaofeng H.-C. Jiang,Luojian Wei,Zhide Wei

The method of random Fourier features (RFF), proposed in a seminal paper by Rahimi and Recht (NIPS'07), is a powerful technique to find approximate low-dimensional representations of points in (high-dimensional) kernel space, for shift-invariant kernels. While RFF has been analyzed under various notions of error guarantee, the ability to preserve the kernel distance with \emph{relative} error is less understood. We show that for a significant range of kernels, including the well-known Laplacian kernels, RFF cannot approximate the kernel distance with small relative error using low dimensions. We complement this by showing as long as the shift-invariant kernel is analytic, RFF with $\mathrm{poly}(\epsilon^{-1} \log n)$ dimensions achieves ϵ-relative error for pairwise kernel distance of n points, and the dimension bound is improved to $\mathrm{poly}(\epsilon^{-1}\log k)$ for the specific application of kernel k-means. Finally, going beyond RFF, we make the first step towards data-oblivious dimension-reduction for general shift-invariant kernels, and we obtain a similar $\mathrm{poly}(\epsilon^{-1} \log n)$ dimension bound for Laplacian kernels. We also validate the dimension-error tradeoff of our methods on simulated datasets, and they demonstrate superior performance compared with other popular methods including random-projection and Nystr\"{o}m methods.

****

UTC-IE: A Unified Token-pair Classification Architecture for Information Extraction

Hang Yan,Yu Sun,Xiaonan Li,Yunhua Zhou,Xuanjing Huang,Xipeng Qiu

Information Extraction (IE) spans several tasks with different output structures, such as named entity recognition, relation extraction and event extraction. Previously, those tasks were solved with different models because of diverse task output structures. Through re-examining IE tasks, we find that all of them can be interpreted as extracting spans and span relations. We propose using the start and end token of a span to pinpoint the span in texts, and using the start-to-start and end-to-end token pairs of two spans to determine the relation. Hence, we can unify all IE tasks under the same token-pair classification formulation. Based on the reformulation, we propose a \textbf{U}nified \textbf{T}oken-pair \textbf{C}lassification architecture for \textbf{I}nformation \textbf{E}xtraction (\textbf{UTC-IE}), where we introduce Plusformer on top of the token-pair feature matrix. Specifically, it models axis-aware interaction with plus-shaped self-attention and local interaction with Convolutional Neural Network over token pairs. Experiments show that our approach outperforms task-specific and unified models on all tasks in 10 datasets, and achieves better or comparable results on 2 joint IE datasets. Moreover, UTC-IE speeds up over state-of-the-art models on IE tasks significantly in most datasets, which verifies the effectiveness of our architecture.

Linear Convergence of Decentralized FedAvg for Non-Convex Objectives: The Interpolation Regime

Shruti P Maralappanavar,Prashant Khanduri,Bharath B N

In the age of Bigdata, Federated Learning (FL) provides machine learning (ML) practitioners with an indispensable tool for solving large-scale learning problems. FL is a distributed optimization paradigm where multiple nodes each having access to a local dataset collaborate (with or without a server) to solve a joint problem. Federated Averaging (FedAvg) although the algorithm of choice for many FL applications is not very well understood especially in the interpolation regime, a common phenomenon observed in modern overparameterized neural networks. In this work, we address this challenge and perform a thorough theoretical performance analysis of FedAvg in the interpolation regime for training of overparameterized neural networks. Specifically, we analyze the performance of FedAvg in two settings: (i) {\em[Server]}: When the network has access to a server that coordinates the information sharing among nodes, and (ii) {\em[Decentralized]:} The serverless setting, where the local nodes communicate over an undirected graph. We consider a class of non-convex functions satisfying the Polyak-Lojasiewicz (PL) condition, a condition that is satisfied by overparameterized neural networks. For the first time, we establish that FedAvg under both {\em Server} and {\em Decentralized} settings achieve linear convergence rates of $\mathcal{O}(T^{3/2} \log (1/{\epsilon}))$ and $\mathcal{O}({T^2} \log ({1}/{\epsilon}))$, respectively, where ϵ is the desired solution accuracy, and T is the number of local updates at each node. In contrast to the standard FedAvg analysis, our work does not require bounded heterogeneity, variance, and gradient assumptions. Instead, we show that sample-wise (and local) smoothness of the local loss functions suffice to capture the effect of heterogeneity in FL training. We use a novel application of induction to prove the linear convergence in the {\em Decentralized} setting, which can be of independent interest. Finally, we conduct experiments on multiple real datasets to corroborate our theoretical findings.

Rethinking Missing Modality Learning: From a Decoding View
Tao Jin,Zhou Zhao

Conventional pipeline of multimodal learning consists of three stages, including encoding, fusion, and decoding. Most existing methods under missing modality condition focus on the first stage and aim to learn the modality invariant representation or reconstruct missing features. However, these methods rely on strong assumptions (i.e., all the pre-defined modalities are available for each input sample during training and the number of modalities is fixed). To solve this problem, we propose a simple yet effective method called Interaction Augmented Prototype Decomposition (IPD) for a more general setting, where the number of modalities is arbitrary and there are various incomplete modality conditions happening in both training and inference phases, even there are unseen testing conditions. Different from the previous methods, we improve the decoding stage. Concretely, IPD jointly learns the common and modality-specific task prototypes. Considering that the number of missing modality conditions scales exponentially with the number of modalities ${\bf O}({\text 2^n})$ and different conditions may have implicit interaction, the low-rank partial prototype decomposition with enough theoretical analysis is employed for modality-specific components to reduce the complexity. The decomposition also can promote unseen generalization with the modality factors of existing conditions. To simulate the low-rank setup, we further constrain the explicit interaction of specific modality conditions by employing disentangled contrastive constraints. Extensive results on the newly-created benchmarks of multiple tasks illustrate the effectiveness of our proposed model.

UNDERSTANDING PURE CLIP GUIDANCE FOR VOXEL GRID NERF MODELS
Han-Hung Lee,Angel X Chang

We explore the task of text to 3D object generation using CLIP. Specifically, we use CLIP for guidance without access to any datasets, a setting we refer to as pure CLIP guidance. While prior work has adopted this setting, there is no systematic study of mechanics for preventing adversarial generations within CLIP. We illustrate how different image-based augmentations prevent the adversarial generation problem, and how the generated results are impacted. We test different CLIP model architectures and show that ensembling different models for guidance can prevent adversarial generations within bigger models and generate sharper results. Furthermore, we implement an implicit voxel grid model to show how neural networks provide an additional layer of regularization, resulting in better geometrical structure and coherency of generated objects. Compared to prior work, we achieve more coherent results with higher memory efficiency and faster training speeds.

Task-Agnostic Online Meta-Learning in Non-stationary Environments
Daouda Sow,Sen Lin,Yingbin Liang,Junshan Zhang

Online meta-learning has recently emerged as a marriage between batch meta-learning and online learning, for achieving the capability of quick adaptation on new tasks in a lifelong manner. However, most existing approaches focus on the restrictive setting where the distribution of the online tasks remains fixed with kn own task boundaries. In this work we relax these assumptions and propose a novel algorithm for task-agnostic online meta-learning in non-stationary environments. More specifically, we first propose two simple but effective detection mechanisms of task switches and distribution shift based on empirical observations, which serve as a key building block for more elegant online model updates in our algorithm: the task switch detection mechanism allows reusing of the best model available for the current task at hand, and the distribution shift detection mechanism differentiates the meta model update so as to preserve the knowledge for in-distribution tasks and quickly learn the new knowledge for out-of-distribution tasks.

Motivated by the recent advance in online learning, our online meta model updates are based only on the current data, which eliminates the need of storing previous data as required in most existing methods. This crucial choice is also well supported by our theoretical analysis of dynamic regret in online meta-learning, where a sublinear regret can be achieved by updating the meta model at each round using the current data only. Empirical studies on three different benchmarks clearly demonstrate the significant advantage of our algorithm over related baseline approaches.

Meta-Weighted Language Model Tuning for Augmentation-Enhanced Few-Shot Learning

Yu Meng,Martin Michalski,Jiaxin Huang,Yu Zhang,Tarek Abdelzaher,Jiawei Han

Recent studies have revealed the intriguing few-shot learning ability of pretrained language models (PLMs): They can quickly adapt to a new task when fine-tuned on a small amount of labeled data formulated as prompts, without requiring abundant task-specific annotations. Despite their promising performance, most existing few-shot approaches that only learn from the small training set still underperform fully supervised training by nontrivial margins. In this work, we study few-shot learning with PLMs from a different perspective: We first tune an autoregressive PLM on the few-shot samples and then use it as a generator to synthesize a large amount of novel training samples which augment the original training set. To encourage the generator to produce label-discriminative samples, we train it via weighted maximum likelihood where the weight of each token is automatically adjusted based on a discriminative meta-learning objective. A classification PLM can then be fine-tuned on both the few-shot and the synthetic samples with regularization for better generalization and stability. Our approach FewGen achieves an overall better result across seven classification tasks of the GLUE benchmark than existing few-shot learning methods.

Online Reinforcement Learning via Posterior Sampling of Policy

Shuqing Shi,zhiqiang xu,Fan Zhang,Zhiyou Yang,Yali Du,Hong Qu

We propose a Reward-Weighted Posterior Sampling of Policy (RWPSP) algorithm to tackle the classic trade-off problem between exploration and exploitation under finite Markov decision processes (MDPs). The Thompson sampling method so far has only considered posterior sampling over transition probabilities, which is hard to gain the globally sub-optimal rewards. RWPSP runs posterior sampling over stationary policy distributions instead of transition probabilities, and meanwhile keeps transition probabilities updated. Particularly, we leverage both relevant count functions and reward-weighting to online update the policy posterior, aiming to balance between local and long-term policy distributions for a globally near-optimal game value. Theoretically, we establish a bound of $\tilde{\mathcal{O}}(\Gamma\sqrt{T}/S^{2})$\footnote{The symbol $\tilde{\mathcal{O}}$ hides logarithmic factors.} on the total regret in time horizon T with $\Gamma/S^{2} < D\sqrt{SA}$ satisfied in general, where S and A represents the sizes of state and action spaces, respectively, D the diameter. This matches the best regret bound thus far for MDPs. Experimental results corroborate our theoretical results and show the advantage of our algorithm over the state of the art in terms of efficiency.

****

DeBERTaV3: Improving DeBERTa using ELECTRA-Style Pre-Training with Gradient-Disentangled Embedding Sharing

Pengcheng He,Jianfeng Gao,Weizhu Chen

This paper presents a new pre-trained language model, NewModel, which improves the original DeBERTa model by replacing mask language modeling (MLM) with replaced token detection (RTD), a more sample-efficient pre-training task. Our analysis shows that vanilla embedding sharing in ELECTRA hurts training efficiency and model performance. This is because the training losses of the discriminator and the generator pull token embeddings in different directions, creating the “tug-of-war” dynamics. We thus propose a new gradient-disentangled embedding sharing method that avoids the tug-of-war dynamics, improving both training efficiency and the quality of the pre-trained model. We have pre-trained NewModel using the same settings as DeBERTa to demonstrate its exceptional performance on a wide range of downstream natural language understanding (NLU) tasks. Taking the GLUE benchmark with eight tasks as an example, the NewModel Large model achieves a 91.37% average score, which is 1.37% over DeBERTa and 1.91% over ELECTRA, setting a new state-of-the-art (SOTA) among the models with a similar structure. Furthermore, we have pre-trained a multi-lingual model mNew-Model and observed a larger improvement over strong baselines compared to English models. For example, the mNewModel Base achieves a 79.8% zero-shot cross-lingual accuracy on XNLI and a 3.6% improvement over XLM-R Base, creating a new SOTA on this benchmark. We will make our model and code publicly available.

Weakly Supervised Neuro-Symbolic Image Manipulation via Multi-Hop Complex Instructions

Harman Singh,Poorva Garg,Mohit Gupta,Kevin Shah,Arnab Kumar Mondal,Dinesh Khandelwal,Parag Singla,Dinesh Garg

We are interested in image manipulation via natural language text – a task that is extremely useful for multiple AI applications but requires complex reasoning over multi-modal spaces. Recent work on neuro-symbolic approaches (Mao et al., 2019) (NSCL) has been quite effective for solving VQA as they offer better modularity, interpretability, and generalizability. We extend NSCL for the image manipulation task and propose a solution referred to as NeuroSIM. Previous work either requires supervised training data in the form of manipulated images or can only deal with very simple reasoning instructions over single object scenes. In contrast, NeuroSIM can perform complex multi-hop reasoning over multi-object scenes and only requires weak supervision in the form of annotated data for VQA. NeuroSIM parses an instruction into a symbolic program, based on a Domain Specific Language (DSL) comprising of object attributes and manipulation operations, that guides the manipulation. We design neural modules for manipulation, as well as novel loss functions that are capable of testing the correctness of manipulated object and scene graph representations via query networks trained merely on VQA data. An image decoder is trained to render the final image from the manipulated scene graph. Extensive experiments demonstrate that NeuroSIM, without using target images as supervision, is highly competitive with SOTA baselines that make use of supervised data for manipulation.

Graph Neural Networks for Aerodynamic Flow Reconstruction from Sparse Sensing

Gregory Duthé,Imad Abdallah,Sarah Barber,Eleni Chatzi

Sensing the fluid flow around an arbitrary geometry entails extrapolating from the physical quantities perceived at its surface in order to reconstruct the features of the surrounding fluid. This is a challenging inverse problem, yet one that if solved could have a significant impact on many engineering applications. The exploitation of such an inverse logic has gained interest in recent years with the advent of widely available cheap but capable MEMS-based sensors. When combined with novel data-driven methods, these sensors may allow for flow reconstruction around immersed structures, benefiting applications such as unmanned airborne/underwater vehicle path planning or control and structural health monitoring of wind turbine blades. In this work, we train deep reversible Graph Neural Networks (GNNs) to perform flow sensing (flow reconstruction) around two-dimensional aerodynamic shapes: airfoils. Motivated by recent work, which has shown that GNNs can be powerful alternatives to mesh-based forward physics simulators, we i mplement a Message-Passing Neural Network to simultaneously reconstruct both the pressure and velocity fields surrounding simulated airfoils based on their surface pressure distributions, whilst additionally gathering useful farfield properties in the form of context vectors. We generate a unique dataset of Computational Fluid Dynamics simulations by simulating random, yet meaningful combinations of input boundary conditions and airfoil shapes. We show that despite the challenges associated with reconstructing the flow around arbitrary airfoil geometries in high Reynolds turbulent inflow conditions, our framework is able to generalize well to unseen cases.

Learning Binary Networks on Long-Tailed Distributions

Jihun Kim,Dahyun Kim,Hyung Rok Jung,TaeIL Oh,Jonghyun Choi

In deploying deep models to real world scenarios, there are a number of issues including computational resource constraints and long-tailed data distributions. For the first time in the literature, we address the combined challenge of learning long-tailed distributions under the extreme resource constraints of using binary networks as backbones. Specifically, we propose a framework of calibrating off-the-shelf pretrained full precision weights that are learned on $\textit{non-long-tailed}$ distributions when training binary networks on long-tailed datasets. In the framework, we additionally propose a novel adversarial balancing and a multi-resolution learning method for better generalization to diverse semantic domains and input resolutions. We conduct extensive empirical evaluations on 15 datasets including newly derived long-tailed datasets from existing balanced datasets, which is the largest benchmark in the literature. Our empirical studies show that our proposed method outperforms prior arts by large margins, $\textit{e.g.}$, at least $+14.33\%$ on average.

Backdoor Mitigation by Correcting Activation Distribution Alteration

Xi Li,Zhen Xiang,George Kesidis,Bo Li,David J. Miller

Backdoor (Trojan) attacks are an important type of adversarial exploit against deep neural networks (DNNs), wherein a test instance is (mis)classified to the attacker's target class whenever a backdoor trigger is present. In this paper, we reveal and analyze an important property of backdoor attacks: a successful attack causes an alteration in the distribution of internal layer activations for backdoor-trigger instances, compared to that for clean instances. Even more importantly, we find that instances with the backdoor trigger will be correctly classified to their original source classes if this distribution alteration is reversed. Based on our observations, we propose an efficient and effective method that achieves post-training backdoor mitigation by correcting the distribution alteration using reverse-engineered triggers. Notably, our method does not change any trainable parameters of the DNN, but achieves generally better mitigation performance than existing methods that do require intensive DNN parameter tuning. It also efficiently detects test instances with the trigger, which may help to catch adversarial entities.

Local Distance Preserving Auto-encoders using Continuous k-Nearest Neighbours Graphs

Nutan Chen,Patrick van der Smagt,Botond Cseke

Auto-encoder models that preserve similarities in the data are a popular tool in representation learning. In this paper we introduce several auto-encoder models that preserve local distances when mapping from the data space to the latent space. We use a local distance-preserving loss that is based on the continuous k-nearest neighbours graph which is known to capture topological features at all scales simultaneously. To improve training performance, we formulate learning as a constraint optimisation problem with local distance preservation as the main objective and reconstruction accuracy as a constraint. We generalise this approach to hierarchical variational auto-encoders thus learning generative models with geometrically consistent latent and data spaces. Our method provides state-of-the-art or comparable performance across several standard datasets and evaluation metrics.

****

Clustering for directed graphs using parametrized random walk diffusion kernels

Harry Sevi,Matthieu Jonckheere,Argyris Kalogeratos

Clustering based on the random walk operator has been proven effective for undirected graphs, but its generalization to directed graphs (digraphs) is much more challenging. Although the random walk operator is well-defined for digraphs, in most cases such graphs are not strongly connected, and hence the associated random walks are not irreducible, which is a crucial property for clustering that exists naturally in the undirected setting. To remedy this, the usual workaround is to either naively symmetrize the adjacency matrix or to replace the natural random walk operator by the teleporting random walk operator, but this can lead to the loss of valuable information carried by edge directionality. In this paper, we introduce a new clustering framework, the Parametrized Random Walk Diffusion Kernel Clustering (P-RWDKC), which is suitable for handling both directed and undirected graphs. Our framework is based on the diffusion geometry and the generalized spectral clustering framework. Accordingly, we propose an algorithm that automatically reveals the cluster structure at a given scale, by considering the random walk dynamics associated with a parametrized kernel operator, and by estimating its critical diffusion time. Experiments on K-NN graphs constructed from real-world datasets and real-world graphs show that our clustering approach performs well in all tested cases, and outperforms existing approaches in most of them.

Poisoning Generative Models to Promote Catastrophic Forgetting

Siteng Kang,Zhan Shi,Xinhua Zhang

Generative models have grown into the workhorse of many state-of-the-art machine learning methods. However, their vulnerability under poisoning attacks has been largely understudied. In this work, we investigate this issue in the context of continual learning, where generative replayers are utilized to tackle catastrophic forgetting. By developing a novel customization of dirty-label input-aware backdoor to the online setting, our attacker manages to stealthily promote forgetting while retaining high accuracy at the current task and sustaining strong defenders. Our approach taps into an intriguing property of generative models, namely that they cannot well capture input-dependent triggers. Experiments on four standard datasets corroborate the poisoner’s effectiveness.

Squeeze Training for Adversarial Robustness

Qizhang Li,Yiwen Guo,Wangmeng Zuo,Hao Chen

The vulnerability of deep neural networks (DNNs) to adversarial examples has attracted great attention in the machine learning community. The problem is related to non-flatness and non-smoothness of normally obtained loss landscapes. Training augmented with adversarial examples (a.k.a., adversarial training) is considered as an effective remedy. In this paper, we highlight that some collaborative examples, nearly perceptually indistinguishable from both adversarial and benign examples yet show extremely lower prediction loss, can be utilized to enhance adversarial training. A novel method is therefore proposed to achieve new state-of-the-arts in adversarial robustness. Code: https://github.com/qizhangli/ST-AT.

Knowledge Unlearning for Mitigating Privacy Risks in Language Models

Joel Jang,Dongkeun Yoon,Sohee Yang,Sungmin Cha,Moontae Lee,Lajanugen Logeswaran,
Minjoon Seo

Pretrained Language Models (LMs) memorize a vast amount of knowledge during initial pretraining, including information that may violate the privacy of personal lives and identities. Previous work addressing privacy issues for language models has mostly focused on data preprocessing and differential privacy methods, both requiring re-training the underlying LM. We propose knowledge unlearning as an alternative method to reduce privacy risks for LMs post hoc. We show that simply applying the unlikelihood training objective to target token sequences is effective at forgetting them with little to no degradation of general language model ing performances; it sometimes even substantially improves the underlying LM with just a few iterations. We also find that sequential unlearning is better than trying to unlearn all the data at once and that unlearning is highly dependent on which kind of data (domain) is forgotten. By showing comparisons with a previous data preprocessing method known to mitigate privacy risks for LMs, we show that unlearning can give a stronger empirical privacy guarantee in scenarios where the data vulnerable to extraction attacks are known a priori while being orders of magnitude more computationally efficient. We release the code and dataset needed to replicate our results at http://www.omitted.link/.

Revisiting the Activation Function for Federated Image Classification
Jaewoo Shin,Taehyeon Kim,Se-Young Yun

Federated learning (FL) has become one of the most popular distributed machine learning paradigms; these paradigms enable training on a large corpus of decentralized data that resides on devices. The recent evolution in FL research is mainly credited to the refinements in training procedures by developing the optimization methods. However, there has been little verification of other technical improvements, especially improvements to the activation functions (e.g., ReLU), that are widely used in the conventional centralized approach (i.e., standard data-centric optimization). In this work, we verify the effectiveness of activation functions in various federated settings. We empirically observe that off-the-shelf activation functions that are used in centralized settings exhibit a totally different performance trend than do federated settings. The experimental results demonstrate that HardTanh achieves the best accuracy when severe data heterogeneity or low participation rate is present. We provide a thorough analysis to investigate why the representation powers of activation functions are changed in a federated setting by measuring the similarities in terms of weight parameters and representations. Lastly, we deliver guidelines for selecting activation functions in both a cross-silo setting (i.e., a number of clients <= 20) and a cross-device setting (i.e., a number of clients >= 100). We believe that our work provides benchmark data and intriguing insights for designing models FL models.

Open-domain Visual Entity Linking
Hexiang Hu,Yi Luan,Urvashi Khandelwal,Mandar Joshi,Kenton Lee,Kristina Toutanova,Ming-Wei Chang

We introduce the task of Open-domain Visual Entity Linking (OVEN), targeting a wide range of entities including animals, plants, buildings, locations and much more. Given an image (e.g., an image of an aircraft), a text query (`What is the model?' or `What is the airline?'), and a multi-modal knowledge base (e.g., Wikipedia), the goal is to link to an entity (Boeing-777 or EVA Air) out of all entities in the knowledge base. We build a benchmark dataset (OVEN-wiki), by repurposing 14 existing image classification, image retrieval, and visual QA datasets. We link all existing labels to Wikipedia entities when possible, using a state-of-the-art entity linking system and human annotators, creating a diverse and unified label space. OVEN is a rich and challenging task, which requires models to recognize and link visual content to both a small set of seen entities as well as a much larger set of unseen entities (e.g., unseen aircraft models). OVEN also requires models to generalize to previously unseen intents that may require more fine-grained reasoning (`Who manufactured the aircraft in the back?'). We build strong baselines based on state-of-the-art pre-trained models and find that current pre-trained models struggle to address the challenges posed by OVEN. We hope OVEN will inspire next-generation pre-training techniques and pave the way to future knowledge-intensive vision tasks.

****

Robustify Transformers with Robust Kernel Density Estimation
Xing Han,Tongzheng Ren,Tan Minh Nguyen,Khai Nguyen,Joydeep Ghosh,Nhat Ho

Recent advances in Transformer architecture have empowered its empirical success in various tasks across different domains. However, existing works mainly focus on improving the standard accuracy and computational cost, without considering the robustness of contaminated samples. Existing work (Nguyen et al, 2022, Fouri erFormer) has shown that the self-attention mechanism, which is the center of the Transformer architecture, can be viewed as a non-parametric estimator based on the well-known kernel density estimation (KDE). This motivates us to leverage the robust kernel density estimation (RKDE) in the self-attention mechanism, to alleviate the issue of the contamination of data by down-weighting the weight of bad samples in the estimation process. The modified self-attention mechanism can be incorporated into different Transformer variants. Empirical results on language modeling and image classification tasks demonstrate the effectiveness of this approach.

****

Pushing the Accuracy-Group Robustness Frontier with Introspective Self-play

Jeremiah Zhe Liu,Krishnamurthy Dj Dvijotham,Jihyeon Lee,Quan Yuan,Balaji Lakshminarayanan,Deepak Ramachandran

Standard empirical risk minimization (ERM) training can produce deep neural network (DNN) models that are accurate on average but under-perform in under-represented population subgroups, especially when there are imbalanced group distributions in the long-tailed training data. Therefore, approaches that improve the accuracy - group robustness trade-off frontier of a DNN model (i.e. improving worst-group accuracy without sacrificing average accuracy, or vice versa) is of crucial importance. Uncertainty-based active learning (AL) can potentially improve the frontier by preferentially sampling underrepresented subgroups to create a more balanced training dataset. However, the quality of uncertainty estimates from modern DNNs tend to degrade in the presence of spurious correlations and dataset bias, compromising the effectiveness of AL for sampling tail groups. In this work, we propose Introspective Self-play (ISP), a simple approach to improve the uncertainty estimation of a deep neural network under dataset bias, by adding an auxiliary introspection task requiring a model to predict the bias for each data point in addition to the label. We show that ISP provably improves the bias-awareness of the model representation and the resulting uncertainty estimates. On two real-world tabular and language tasks,ISP serves as a simple “plug-in” for AL model training, consistently improving both the tail-group sampling rate and the final accuracy-fairness trade-off frontier of popular AL methods.

****

Learning to Predict Parameter for Unseen Data

Shiye Wang,Kaituo Feng,Changsheng Li,Ye Yuan,Guoren Wang

Typical deep learning models depend heavily on large amounts of training data and resort to an iterative optimization algorithm (e.g., SGD or Adam) for learning network parameters, which makes the training process very time- and resource-intensive. In this paper, we propose a new training paradigm and formulate network parameter training into a prediction task: given a network architecture, we observe there exists correlations between datasets and their corresponding optimal network parameters, and explore if we can learn a hyper-mapping between them to capture the relations, such that we can directly predict the parameters of the network for a new dataset never seen during the training phase. To do this, we put forward a new hypernetwork with the purpose of building a mapping between datasets and their corresponding network parameters, and then predict parameters for unseen data with only a single forward propagation of the hypernetwork. At its heart, our model benefits from a series of GRU sharing weights to capture the dependencies of parameters among different layers in the network. Extensive experimental studies are performed and experimental results validate our proposed method achieves surprisingly good efficacy. For instance, it takes 119 GPU seconds to train ResNet-18 using Adam from scratch and obtain a top-1 accuracy of 74.56%, while our method costs only 0.5 GPU seconds to predict the network parameters of ResNet-18 achieving comparable performance (73.33%), more than 200 times faster than the traditional training paradigm.

****

UNREAL: Unlabeled Nodes Retrieval and Labeling for Heavily-imbalanced Node Classification

Liang Yan,Shengzhong Zhang,Bisheng Li,min zhou,Zengfeng Huang

Extremely skewed label distributions are common in real-world node classificatio

n tasks. If not dealt with appropriately, it significantly hurts the performance of GNNs on minority classes. Due to the practical importance, there have been a series of recent researches devoted to this challenge. Existing over-sampling techniques smooth the label distribution by generating ''fake'' minority nodes and synthesize their features and local topology, which largely ignore the rich information of unlabeled nodes on graphs. Recent methods based on loss function modification re-weight different samples or change classification margins, which achieve good performance. However, representative methods need label information to estimate the distance of each node to its class center, which is unavailable on unlabeled nodes. In this paper, we propose UNREAL, which is an iterative over-sampling method. The first key difference is that we only add unlabeled nodes instead of synthetic nodes, which eliminates the challenge of feature and neighborhood generation. To select which unlabeled nodes to add, we propose geometric ranking, which ranks unlabeled nodes based on unsupervised learning results in the node embedding space. Finally, we identify the issue of geometric imbalance in the embedding space and provide a simple metric to filter out geometrically imbalanced nodes. Extensive experiments on real-world benchmark datasets are conducted, and the empirical results show that our method significantly outperforms current state-of-the-art methods consistent on different datasets with different imbalance ratios.
****

On Nullspace of Vision Transformers and What Does it Tell Us?

Aditya Singh,Haohan Wang

Nullspace of a linear mapping is the subspace which is mapped to the zero vector. For a linear map, adding an element of the nullspace to its input has no effect on the output of the mapping. We position this work as an exposition towards answering one simple question, ``Does a vision transformer have a non-trivial nullspace?" If TRUE, this would imply that adding elements from this non-trivial nullspace to an input will have no effect on the output of the network. This finding can eventually lead us closer to understanding the generalization properties of vision transformers. In this paper, we first demonstrate that provably a non-trivial nullspace exists for a particular class of vision transformers. This proof is drawn by simply computing the nullspace of the patch embedding matrices. We extend this idea to the non-linear layers of the vision transformer and show that it is possible to learn a non-linear counterpart to the nullspace via simple optimisations for any vision transformer. Subsequently, we perform studies to understand robustness properties of ViTs under nullspace noise. Under robustness, we investigate prediction stability, and (network and interpretation) fooling properties of the noise. Lastly, we provide image watermarking as an application of nullspace noise.
****

Max-Margin Works while Large Margin Fails: Generalization without Uniform Convergence

Margalit Glasgow,Colin Wei,Mary Wootters,Tengyu Ma

A major challenge in modern machine learning is theoretically understanding the generalization properties of overparameterized models. Many existing tools rely on uniform convergence (UC), a property that, when it holds, guarantees that the test loss will be close to the training loss, uniformly over a class of candidate models. Nagarajan and Kolter (2019) show that in certain simple linear and neural-network settings, any uniform convergence bound will be vacuous, leaving open the question of how to prove generalization in settings where UC fails. Our main contribution is proving novel generalization bounds in two such settings, one linear, and one non-linear. We study the linear classification setting of Nagarajan and Kolter (2019), and a quadratic ground truth function learned via a two-layer neural network in the non-linear regime. We prove a new type of margin bound showing that above a certain signal-to-noise threshold, any near-max-margin classifier will achieve almost no test loss in these two settings. Our results show that near-max-margin is important: while any model that achieves at least a $(1 - \epsilon)$-fraction of the max-margin generalizes well, a classifier achieving half of the max-margin may fail terribly. Our analysis provides insight on

why memorization can coexist with generalization: we show that in this challenging regime where generalization occurs but UC fails, near-max-margin classifiers simultaneously contain some generalizable components and some overfitting components that memorize the data. The presence of the overfitting components is enough to preclude UC, but the near-extremal margin guarantees that sufficient generalizable components are present.
****

The batch size can affect inference results
Yunkyung Park,Kyungsoo Kim,Deok-kyu Jang

When performing matrix multiplication using GPUs, the cuBLAS library is commonly used for computational efficiency. Because of the cuBLAS’ heuristics, a vast, deep neural network model with GPUs may produce different test results owing to the batch sizes in both the training and inference stages. In this paper, we show that the batch size affects the inference results of deep neural network models. Our test models were the well-known bidirectional encoder representations from transformers (BERT) and generative pre-trained transformer (GPT) natural language processing (NLP) models, and the super-resolution generative adversarial network (SRGAN) image generation model in FP32 and TF32. In the TF32 setting, the evaluation loss in BERT using the general language understanding evaluation (GLUE) data sometimes varied for different batch sizes. The GPT generated sentences depending on batch size, and we show the logit's mean square error by increasing the token length. The SRGAN model produced different images from batch to batch. However, these phenomena were not observed under the FP32 setting. Therefore, the batch size must be carefully managed in large-sized deep neural networks under the TF32 setting.
****

Asymptotic Instance-Optimal Algorithms for Interactive Decision Making
Kefan Dong,Tengyu Ma

Past research on interactive decision making problems (bandits, reinforcement learning, etc.) mostly focuses on the minimax regret that measures the algorithm's performance on the hardest instance. However, an ideal algorithm should adapt to the complexity of a particular problem instance and incur smaller regrets on easy instances than worst-case instances. In this paper, we design the first asymptotic instance-optimal algorithm for general interactive decision making problems with finite number of decisions under mild conditions. On every instance f, our algorithm outperforms all consistent algorithms (those achieving non-trivial regrets on all instances), and has asymptotic regret $\mathcal{C}(f) \ln n$, where $\mathcal{C}(f)$ is an exact characterization of the complexity of f. The key step of the algorithm involves hypothesis testing with active data collection. It computes the most economical decisions with which the algorithm collects observations to test whether an estimated instance is indeed correct; thus, the complexity $\mathcal{C}(f)$ is the minimum cost to test the instance f against other instances. Our results, instantiated on concrete problems, recover the classical gap-dependent bounds for multi-armed bandits and prior works on linear bandits, and improve upon the previous best instance-dependent upper bound for reinforcement learning.
****

GRAPHSENSOR: A Graph Attention Network for Time-Series Sensor Data
jianchao lu,Yuzhe Tian,Quan Z. Sheng,Xi Zheng

Our work focuses on the exploration of the internal relationships of signals in an individual sensor. In particular, we address the problem of not being able to evaluate such inter-sensor relationships due to missing rich and explicit feature representation. To solve this problem, we propose GRAPHSENSOR, a graph attention network, with a shared-weight convolution feature encoder to generate the signal segments and learn the internal relationships between them. Furthermore, we enrich the representation of the features by utilizing a multi-head approach when creating the internal relationship graph. Compared with traditional multi-head approaches, we propose a more efficient convolution-based multi-head mechanism, which only requires 56% of model parameters compared with the best multi-head baseline as demonstrated in the experiments. Moreover, GRAPHSENSOR is capable of

achieving the state-of-the-art performance in the electroencephalography dataset and improving the accuracy by 13.8% compared to the best baseline in an inertial measurement unit (IMU) dataset.

ProsodyBERT: Self-Supervised Prosody Representation for Style-Controllable TTS
Yushi Hu,Chunlei Zhang,Jiatong Shi,Jiachen Lian,Mari Ostendorf,Dong Yu
We propose ProsodyBERT, a self-supervised approach to learning prosody representations from raw audio. Different from most previous works, which use information bottlenecks to disentangle prosody features from speech content and speaker information, we perform an offline clustering of speaker-normalized prosody-related features (energy, pitch, their dynamics, etc.) and use the cluster labels as targets for HuBERT-like masked unit prediction. A span boundary loss is also introduced to capture long-range prosodic information. We demonstrate the effectiveness of ProsodyBERT on a multi-speaker style-controllable text-to-speech (TTS) system. Experiments show that the TTS system trained with ProsodyBERT features can generate natural and expressive speech samples, surpassing the model supervised by energy and pitch on subjective human evaluation. Also, the style and expressiveness of synthesized audio can be controlled by manipulating the prosody features. In addition, We achieve new state-of-the-art results on the IEMOCAP emotion recognition task by combining our prosody features with HuBERT features, showing that ProsodyBERT is complementary to popular pretrained speech self-supervised models.

FedDebias: Reducing the Local Learning Bias Improves Federated Learning on Heterogeneous Data
Yongxin Guo,Xiaoying Tang,Tao Lin
Federated Learning (FL) is a machine learning paradigm that learns from data kept locally to safeguard the privacy of clients, whereas local SGD is typically employed on the clients' devices to improve communication efficiency. However, such a scheme is currently constrained by the slow and unstable convergence induced by clients' heterogeneous data.
In this work, we identify three under-explored phenomena of the biased local learning that may explain these challenges caused by local updates in supervised FL.
As a remedy, we propose FedDebias, a novel unified algorithm that reduces the local learning bias on features and classifiers to tackle these challenges.
FedDebias consists of two components:
The first component alleviates the bias in the local classifiers by balancing the output distribution of models.
The second component learns client invariant features that are close to global features but considerably distinct from those learned from other input distributions.
In a series of experiments, we show that FedDebias consistently outperforms other SOTA FL and domain generalization (DG) baselines, in which both two components have individual performance gains.

CRISP: Curriculum inducing Primitive Informed Subgoal Prediction for Hierarchical Reinforcement Learning
Utsav Singh,Vinay P Namboodiri
Hierarchical reinforcement learning is a promising approach that uses temporal abstraction to solve complex long horizon problems. However, simultaneously learning a hierarchy of policies is unstable as it is challenging to train higher-level policy when the lower-level primitive is non-stationary. In this paper, we propose to generate a curriculum of achievable subgoals for evolving lower-level primitives using reinforcement learning and imitation learning. The lower level primitive periodically performs data relabeling on a handful of expert demonstrations using our primitive informed parsing method. We derive expressions to bound the sub-optimality of our method and develop a practical algorithm for hierarchical reinforcement learning. Since our approach uses a handful of expert demonstrations, it is suitable for most real world robotic control tasks. Experimental

results on complex maze navigation and robotic manipulation environments show that inducing hierarchical curriculum learning significantly improves sample efficiency, and results in better learning of goal conditioned policies in complex temporally extended tasks.

Near-Optimal Deployment Efficiency in Reward-Free Reinforcement Learning with Linear Function Approximation

Dan Qiao,Yu-Xiang Wang

We study the problem of deployment efficient reinforcement learning (RL) with linear function approximation under the \emph{reward-free} exploration setting. This is a well-motivated problem because deploying new policies is costly in real-life RL applications. Under the linear MDP setting with feature dimension d and planning horizon H, we propose a new algorithm that collects at most $\widetilde{O}(\frac{d^2H^5}{\epsilon^2})$ trajectories within H deployments to identify ϵ-optimal policy for any (possibly data-dependent) choice of reward functions. To the best of our knowledge, our approach is the first to achieve optimal deployment complexity and optimal d dependence in sample complexity at the same time, even if the reward is known ahead of time. Our novel techniques include an exploration-preserving policy discretization and a generalized G-optimal experiment design, which could be of independent interest. Lastly, we analyze the related problem of regret minimization in low-adaptive RL and provide information-theoretic lower bounds for switching cost and batch complexity.

****

Provably efficient multi-task Reinforcement Learning in large state spaces

Baihe Huang,Jason D. Lee,Zhaoran Wang,Zhuoran Yang

We study multi-task Reinforcement Learning where shared knowledge among different environments is distilled to enable scalable generalization to a variety of problem instances. In the context of general function approximation, Markov Decision Process (MDP) with low Bilinear rank encapsulates a wide range of structural conditions that permit polynomial sample complexity in large state spaces, where the Bellman errors are related to bilinear forms of features with low intrinsic dimensions. To achieve multi-task learning in MDPs, we propose online representation learning algorithms to capture the shared features in the different task-specific bilinear forms. We show that in the presence of low-rank structures in the features of the bilinear forms, the algorithms benefit from sample complexity improvements compared to single-task learning. Therefore, we achieve the first sample efficient multi-task reinforcement learning algorithm with general function approximation.

An Equal-Size Hard EM Algorithm for Diverse Dialogue Generation

Yuqiao Wen,Yongchang Hao,Yanshuai Cao,Lili Mou

Open-domain dialogue systems aim to interact with humans through natural language texts in an open-ended fashion. Despite the recent success of super large dialogue systems such as ChatGPT, using medium-to-small-sized dialogue systems remains the common practice as they are more lightweight and accessible; however, generating diverse dialogue responses is challenging, especially with smaller models. In this work, we propose an Equal-size Hard Expectation--Maximization (EqHard-EM) algorithm to train a multi-decoder model for diverse dialogue generation. Our algorithm assigns a sample to a decoder in a hard manner and additionally imposes an equal-assignment constraint to ensure that all decoders are well-trained. We provide detailed theoretical analysis to justify our approach. Further, experiments on two large-scale open-domain dialogue datasets verify that our EqHard-EM algorithm generates high-quality diverse responses.

NeuralEQ: Neural-Network-Based Equalizer for High-Speed Wireline Communication

Hanseok Kim,Jae Hyung Ju,Hyun Seok Choi,Hyeri Roh,Woo-Seok Choi

Rapid growth of ML applications demand high-performance computing systems to perform massive data processing. In such systems, I/O bandwidth must be scaled up to prevent any performance degradation due to the limited data transfer rates. To meet this demand, recently wireline communication started adopting PAM4 signali ng and DSP-based equalizers. However, multi-level signaling and conventional equalizing techniques degrade the bit-error-rate (BER) performance significantly. To mitigate this problem, this paper proposes a novel neural network architecture that mimics the forward-backward algorithm estimating the posterior probabilities in Hidden Markov Models. The proposed neural network overcomes the existing equalizer performance such as feed-forward equalizers or decision-feedback equalizers, while reducing the complexity of the forward-backward algorithm.

Which is Better for Learning with Noisy Labels: The Semi-supervised Method or Modeling Label Noise?

Yu Yao,Mingming Gong,Yuxuan Du,Jun Yu,Bo Han,Kun Zhang,Tongliang Liu

In real life, accurately annotating large-scale datasets is sometimes difficult. Datasets used for training deep learning models are likely to contain label noise. To make use of the dataset containing label noise, two typical methods have been proposed. One is to employ the semi-supervised method by exploiting labeled \textit{confident examples} and unlabeled \textit{non-confident examples}. The other one is to \textit{model label noise} and design \textit{statistically consistent} classifiers. A natural question remains unsolved: which one should be used for a specific real-world application? In this paper, we answer the question from the perspective of \textit{causal data generative process}. Specifically, the semi-supervised method depends heavily on the data generation process while the modeling label noise method is independent of the generation process. For example, for a given dataset, if it has a causal generative structure that the features cause the label, the semi-supervised method would not be helpful. When the causal structure is unknown, we provide an intuitive method to discover the causal structure for a given dataset containing label noise.

The hidden uniform cluster prior in self-supervised learning

Mido Assran,Randall Balestriero,Quentin Duval,Florian Bordes,Ishan Misra,Piotr Bojanowski,Pascal Vincent,Michael Rabbat,Nicolas Ballas

A successful paradigm in representation learning is to perform self-supervised pretraining using tasks based on mini-batch statistics; (e.g., SimCLR, VICReg, SwAV, MSN). We show that in the formulation of all these methods is an overlooked prior to learn features that enable uniform clustering of the data. While this prior has led to remarkably semantic representations when pretraining on class-balanced data, such as ImageNet, we demonstrate that it can hamper performance when pretraining on class-imbalanced data. By moving away from conventional uniformity priors and instead preferring power-law distributed feature clusters, we show that one can improve the quality of the learned representations on real-world class-imbalanced datasets. To demonstrate this, we develop an extension of the Masked Siamese Networks (MSN) method to support the use of arbitrary features priors.

****

Revisiting Over-smoothing in Graph Neural Networks

Pantelis Elinas,Edwin V. Bonilla

Shallow graph neural networks (GNNs) are state-of-the-art models for relational data. However, it is known that deep GNNs suffer from over-smoothing where, as the number of layers increases, node representations become nearly indistinguishable and model performance on the downstream task degrades significantly. Despite multiple approaches being proposed to address this problem, it is unclear when any of these methods (or their combination) works best and how they perform when evaluated under exactly the same experimental setting. In this paper, we systematically and carefully evaluate different methods for alleviating over-smoothing in GNNs. Furthermore, inspired by standard deeply supervised nets, we propose a general architecture that helps alleviate over-smoothing based on the idea of layer-wise supervision. We term this architecture deeply supervised GNNs (or DSGNNs for short). Our experiments show that deeper GNNs can indeed provide better performance when trained on a combination of different approaches and that DSGNNs are robust under various conditions and can provide the best performance in missing-feature scenarios.

Mosaic Representation Learning for Self-supervised Visual Pre-training

Zhaoqing Wang,Ziyu Chen,Yaqian Li,Yandong Guo,Jun Yu,Mingming Gong,Tongliang Liu

Self-supervised learning has achieved significant success in learning visual representations without the need for manual annotation. To obtain generalizable representations, a meticulously designed data augmentation strategy is one of the most crucial parts. Recently, multi-crop strategies utilizing a set of small crops as positive samples have been shown to learn spatially structured features. However, it overlooks the diverse contextual backgrounds, which reduces the variance of the input views and degenerates the performance. To address this problem, we propose a mosaic representation learning framework (MosRep), consisting of a new data augmentation strategy that enriches the backgrounds of each small crop and improves the quality of visual representations. Specifically, we randomly sample numbers of small crops from different input images and compose them into a mosaic view, which is equivalent to introducing different background information for each small crop. Additionally, we further jitter the mosaic view to prevent memorizing the spatial locations of each crop. Along with optimization, our MosRep gradually extracts more discriminative features. Extensive experimental results demonstrate that our method improves the performance far greater than the multi-crop strategy on a series of downstream tasks, e.g., +7.4% and +4.9% than the multi-crop strategy on ImageNet-1K with 1% label and 10% label, respectively. Code is available at https://github.com/DerrickWang005/MosRep.git.

FluidLab: A Differentiable Environment for Benchmarking Complex Fluid Manipulation

Zhou Xian,Bo Zhu,Zhenjia Xu,Hsiao-Yu Tung,Antonio Torralba,Katerina Fragkiadaki,Chuang Gan

Humans manipulate various kinds of fluids in their everyday life: creating latte art, scooping floating objects from water, rolling an ice cream cone, etc. Using robots to augment or replace human labors in these daily settings remain as a challenging task due to the multifaceted complexities of fluids. Previous research in robotic fluid manipulation mostly consider fluids governed by an ideal, Newtonian model in simple task settings (e.g., pouring water into a container). However, the vast majority of real-world fluid systems manifest their complexities in terms of the fluid’s complex material behaviors (e.g., elastoplastic deformation) and multi-component interactions (e.g. coffee and frothed milk when making latte art), both of which were well beyond the scope of the current literature. To evaluate robot learning algorithms on understanding and interacting with such complex fluid systems, a comprehensive virtual platform with versatile simulation capabilities and well-established tasks is needed. In this work, we introduce FluidLab, a simulation environment with a diverse set of manipulation tasks involving complex fluid dynamics. These tasks address interactions between solid and fluid as well as among multiple fluids. At the heart of our platform is a fully differentiable physics simulator, FluidEngine, providing GPU-accelerated simulations and gradient calculations for various material types and their couplings, extending the scope of the existing differentiable simulation engines. We identify several challenges for fluid manipulation learning by evaluating a set of reinforcement learning and trajectory optimization methods on our platform. To address these challenges, we propose several domain-specific optimization schemes coupled with differentiable physics, which are empirically shown to be effective in tackling optimization problems featured by fluid system’s non-convex and non-smooth properties. Furthermore, we demonstrate reasonable sim-to-real transfer by deploying optimized trajectories in real-world settings. FluidLab is publicly available at: https://fluidlab2023.github.io.

Route, Interpret, Repeat: Blurring the Line Between Posthoc Explainability and Interpretable Models

Shantanu Ghosh,Ke Yu,Forough Arabshahi,kayhan Batmanghelich

The current approach to ML model design is either to choose a flexible Blackbox model and explain it post hoc or to start with an interpretable model. Blackbox models are flexible but difficult to explain, whereas interpretable models are designed to be explainable. However, developing interpretable models necessitates extensive ML knowledge, and the resulting models tend to be less flexible, offering potentially subpar performance compared to their Blackbox equivalents. This paper aims to blur the distinction between a post hoc explanation of a BlackBox and constructing interpretable models. We propose beginning with a flexible BlackBox model and gradually carving out a mixture of interpretable models and a residual network. Our design identifies a subset of samples and routes them through the interpretable models. The remaining samples are routed through a flexible residual network. We adopt First Order Logic (FOL) as the interpretable model's backbone, which provides basic reasoning on the concept retrieved from the BlackBox model. On the residual network, we repeat the method until the proportion of data explained by the residual network falls below a desired threshold.

Our approach offers several advantages. First, the mixture of interpretable and flexible residual networks results in almost no compromise in performance. Second, the rout, interpret, and repeat approach yields a highly flexible interpretable model. Our extensive experiment demonstrates the performance of the model on various datasets. We show that by editing the FOL model, we can fix the shortcut learned by the original BlackBox model. Finally, our method provides a framework for a hybrid symbolic-connectionist network that is simple to train and adaptable to many applications.

On Regularization for Explaining Graph Neural Networks: An Information Theory Perspective

Junfeng Fang,Wei Liu,An Zhang,Xiang Wang,Xiangnan He,Kun Wang,Tat-Seng Chua

This work studies the explainability of graph neural networks (GNNs), which is important for the credibility of GNNs in practical usage. Existing work mostly follows the two-phase paradigm to interpret a prediction: feature attribution and selection. However, another important component --- regularization, which is crucial to facilitate the above paradigm --- has been seldom studied. In this work, we explore the role of regularization in GNNs explainability from the perspective of information theory. Our main findings are: 1) regularization is essentially pursuing the balance between two phases, 2) its optimal coefficient is proportional to the sparsity of explanations, 3) existing methods imply an implicit regularization effect of stochastic mechanism, and 4) its contradictory effects on two phases are responsible for the out-of-distribution (OOD) issue in post-hoc explainability. Based on these findings, we propose two common optimization methods, which can bolster the performance of the current explanation methods via sparsity-adaptive and OOD-resistant regularization schemes. Extensive empirical studies validate our findings and proposed methods. Code is available at https://anonymous.4open.science/r/Rethink_Reg-07F0.

The Dark Side of Invariance: Revisiting the Role of Augmentations in Contrastive Learning

Alex Tamkin,Margalit Glasgow,Xiluo He,Noah Goodman

What role do augmentations play in contrastive learning? Recent work suggests that good augmentations are label-preserving with respect to a specific downstream task. We complicate this picture by showing that label-destroying augmentations are often crucial in the foundation model setting, where the goal is to learn diverse, general-purpose representations for multiple downstream tasks. We perform contrastive learning experiments on a range of image and audio datasets with multiple downstream tasks (e.g. for digits superimposed on photographs, predicting the class of one vs. the other). We find that Viewmaker Networks, a recently proposed model for learning augmentations for contrastive learning, produce label-destroying augmentations that stochastically destroy features needed for different downstream tasks. These augmentations are interpretable (e.g. altering shapes, digits, or letters added to images) and surprisingly often result in better performance compared to expert-designed augmentations, despite not preserving lab el information. To support our empirical results, we theoretically analyze a simple contrastive learning setting with a linear model. In this setting, label-destroying augmentations are crucial for preventing one set of features from suppressing the learning of features useful for another downstream task. Our results highlight the need for analyzing the interaction between multiple downstream tasks when trying to explain the success of foundation models

Hierarchical Gaussian Mixture based Task Generative Model for Robust Meta-Learning

Yizhou Zhang,Jingchao Ni,Wei Cheng,Zhengzhang Chen,Liang Tong,Haifeng Chen

Meta-learning enables quick adaptation of machine learning models to new tasks with limited data. While tasks could come from varying distributions in reality, most of the existing meta-learning methods consider both training and testing tasks as from the same uni-component distribution, overlooking two critical needs of a practical solution: (1) the various sources of tasks may compose a multi-component mixture distribution, and (2) novel tasks may come from a distribution that is unseen during meta-training. In this paper, we demonstrate these two challenges can be solved jointly by modeling the density of task instances. We develop a meta-training framework underlain by a novel Hierarchical Gaussian Mixture based Task Generative Model (HTGM). HTGM extends the widely used empirical process of sampling tasks to a theoretical model, which learns task embeddings, fits mixture distribution of tasks, and enables density-based scoring of novel tasks. The framework is agnostic to the encoder and scales well with large backbone networks. The model parameters are learned end-to-end by maximum likelihood estimation via an Expectation-Maximization algorithm. Extensive experiments on benchmark datasets indicate the effectiveness of our method for both sample classification and novel task detection.

Game-Theoretic Understanding of Misclassification

Kosuke Sumiyasu,Kazuhiko Kawamoto,Kera Hiroshi

This paper analyzes various types of image misclassification from a game-theoretic view. Particularly, we consider the misclassification of clean, adversarial, and corrupted images and characterize it through the distribution of multi-order interactions. We discover that the distribution of multi-order interactions varies across the types of misclassification. For example, misclassified adversarial images have a higher strength of high-order interactions than correctly classified clean images, which indicates that adversarial perturbations create spurious features that arise from complex cooperation between pixels. By contrast, misclassified corrupted images have a lower strength of low-order interactions than correctly classified clean images, which indicates that corruptions break the local cooperation between pixels. We also provide the first analysis of Vision Transformers using interactions. We found that Vision Transformers show a different tendency in the distribution of interactions from that in CNNs, and this implies that they exploit the features that CNNs do not use for the prediction. Our study demonstrates that the recent game-theoretic analysis of deep learning models can be broadened to analyze various malfunctions of deep learning models including Vision Transformers by using the distribution, order, and sign of interactions.

****

The Final Ascent: When Bigger Models Generalize Worse on Noisy-Labeled Data

Yihao Xue,Kyle Whitecross,Baharan Mirzasoleiman

Increasing the size of overparameterized neural networks has been shown to improve their generalization performance. However, real-world datasets often contain a significant fraction of noisy labels, which can drastically harm the performance of the models trained on them. In this work, we study how neural networks' test loss changes with model size when the training set contains noisy labels. We show that under a sufficiently large noise-to-sample size ratio, generalization error eventually increases with model size. First, we provide a theoretical analysis on random feature regression and show that this phenomenon occurs as the variance of the generalization loss experiences a second ascent under large noise-to-sample size ratio. Then, we present extensive empirical evidence confirming that our theoretical results hold for neural networks. Furthermore, we empirically observe that the adverse effect of network size is more pronounced when robust training methods are employed to learn from noisy-labeled data. Our results have important practical implications: First, larger models should be employed with extra care, particularly when trained on smaller dataset or using robust learning methods. Second, a large sample size can alleviate the effect of noisy labels and allow larger models to achieve a superior performance even under noise.

****

Long-Tailed Partial Label Learning via Dynamic Rebalancing

Feng Hong,Jiangchao Yao,Zhihan Zhou,Ya Zhang,Yanfeng Wang

Real-world data usually couples the label ambiguity and heavy imbalance, challenging the algorithmic robustness of partial label learning (PLL) and long-tailed learning (LT). The straightforward combination of LT and PLL, i.e., LT-PLL, suffers from a fundamental dilemma: LT methods build upon a given class distribution that is unavailable in PLL, and the performance of PLL is severely influenced in long-tailed context. We show that even with the auxiliary of an oracle class prior, the state-of-the-art methods underperform due to an adverse fact that the constant rebalancing in LT is harsh to the label disambiguation in PLL. To overcome this challenge, we thus propose a dynamic rebalancing method, termed as RECORDS, without assuming any prior knowledge about the class distribution. Based on a parametric decomposition of the biased output, our method constructs a dynamic adjustment that is benign to the label disambiguation process and theoretically converges to the oracle class prior. Extensive experiments on three benchmark datasets demonstrate the significant gain of RECORDS compared with a range of baselines. The code is publicly available.

Task Ambiguity in Humans and Language Models

Alex Tamkin,Kunal Handa,Avash Shrestha,Noah Goodman

Language models have recently achieved strong performance across a wide range of NLP benchmarks. However, real world tasks are often poorly specified, and agents must deduce the intended behavior from a combination of context, instructions, and examples. We investigate how both humans and models behave in the face of such task ambiguity by proposing AmbiBench, a new benchmark of six ambiguously-specified classification tasks. We evaluate humans and models on AmbiBench by seeing how well they identify the intended task using 1) instructions with varying degrees of ambiguity, and 2) different numbers of labeled examples. We find that the combination of model scaling (to 175B parameters) and reinforcement learning from human feedback (RLHF) enables models to approach or exceed the accuracy of human participants across tasks, but that either one of these alone is not sufficient. In addition, we show how to dramatically improve the accuracy of language models trained without RLHF by finetuning on a small number of ambiguous in-context examples, providing a promising direction for teaching models to generalize well in the face of ambiguity.

****

Equivariant Disentangled Transformation for Domain Generalization under Combination Shift

Yivan Zhang,Jindong Wang,Xing Xie,Masashi Sugiyama

Machine learning systems may encounter unexpected problems when the data distribution changes in the deployment environment. A major reason is that certain combinations of domains and labels are not observed during training but appear in the test environment. Although various invariance-based algorithms can be applied, we find that the performance gain is often marginal. To formally analyze this issue, we provide a unique algebraic formulation of the combination shift problem based on the concepts of homomorphism, equivariance, and a refined definition of disentanglement. The algebraic requirements naturally derive a simple yet effective method, referred to as equivariant disentangled transformation (EDT), which augments the data based on the algebraic structures of labels and makes the transformation satisfy the equivariance and disentanglement requirements. Experimental results demonstrate that invariance may be insufficient, and it is importan

t to exploit the equivariance structure in the combination shift problem.
****

Best Possible Q-Learning

Jiechuan Jiang,Zongqing Lu

Fully decentralized learning, where the global information, i.e., the actions of other agents, is inaccessible, is a fundamental challenge in multi-agent reinforcement learning. However, the convergence and optimality of most decentralized algorithms are not theoretically guaranteed, since the transition probabilities are non-stationary as all agents are updating policies simultaneously. To tackle this challenge, we propose \textit{best possible operator}, a novel decentralized operator, and prove that the policies of agents will converge to the optimal joint policy if each agent independently updates its individual state-action value by the operator. Further, to make the update more efficient and practical, we simplify the operator and prove that the convergence and optimality still hold with the simplified one. By instantiating the simplified operator, the derived fully decentralized algorithm, best possible Q-learning (BQL), does not suffer from non-stationarity. Empirically, we show that BQL achieves remarkable improvement over baselines in a variety of cooperative multi-agent tasks.

Winning Both the Accuracy of Floating Point Activation and the Simplicity of Integer Arithmetic

Yulhwa Kim,Jaeyong Jang,Jehun Lee,Jihoon Park,Jeonghoon Kim,Byeongwook Kim,Baeseong park,Se Jung Kwon,Dongsoo Lee,jae-joon kim

Even though floating point (FP) numbers have been adopted as a de facto standard data format for deep learning computing, the complexity of FP arithmetic impedes a broader deployment of Deep Neural Networks (DNNs). Recent works such as quantization have attempted to replace the FP matrix multiplication (MatMul) of DNNs with simple integer MatMul by transforming the datatypes of both weights and activations into integers. Unfortunately, unlike weight values that are static, it is challenging to represent dynamic activations with integers. In this paper, to simultaneously achieve the accuracy of FP activation and the simplicity of integer arithmetic, we present a method for replacing FP arithmetic with integer one without changing FP activations in the storage format while weights are quantized. The proposed method pre-aligns the significands of FP activations just ahead of the MatMul on-the-fly so that the aligned significands (integers) can be used for the computation. Inspired by an observation that conventional FP arithmetic does not produce precise results due to rounding, we demonstrate that our proposed integer arithmetic-based scheme can produce the same level of errors as that of the FP arithmetic in case DNNs use FP activations and quantized weights. Experimental results show that the hardware based on the proposed scheme shows significant improvement over FP arithmetic-based designs in terms of energy efficiency and throughput-per-area while maintaining a similar level of accuracy.

Preference Transformer: Modeling Human Preferences using Transformers for RL

Changyeon Kim,Jongjin Park,Jinwoo Shin,Honglak Lee,Pieter Abbeel,Kimin Lee

Preference-based reinforcement learning (RL) provides a framework to train agents using human preferences between two behaviors. However, preference-based RL has been challenging to scale since it requires a large amount of human feedback to learn a reward function aligned with human intent. In this paper, we present Preference Transformer, a neural architecture that models human preferences using transformers. Unlike prior approaches assuming human judgment is based on the Markovian rewards which contribute to the decision equally, we introduce a new preference model based on the weighted sum of non-Markovian rewards. We then design the proposed preference model using a transformer architecture that stacks causal and bidirectional self-attention layers. We demonstrate that Preference Transformer can solve a variety of control tasks using real human preferences, while prior approaches fail to work. We also show that Preference Transformer can induce a well-specified reward and attend to critical events in the trajectory by automatically capturing the temporal dependencies in human decision-making. Code is available on the project website: https://sites.google.com/view/preference-tr ansformer.

Flow Matching for Generative Modeling

Yaron Lipman,Ricky T. Q. Chen,Heli Ben-Hamu,Maximilian Nickel,Matthew Le

We introduce a new paradigm for generative modeling built on Continuous Normalizing Flows (CNFs), allowing us to train CNFs at unprecedented scale. Specifically, we present the notion of Flow Matching (FM), a simulation-free approach for training CNFs based on regressing vector fields of fixed conditional probability paths. Flow Matching is compatible with a general family of Gaussian probability paths for transforming between noise and data samples---which subsumes existing diffusion paths as specific instances. Interestingly, we find that employing FM with diffusion paths results in a more robust and stable alternative for training diffusion models. Furthermore, Flow Matching opens the door to training CNFs with other, non-diffusion probability paths. An instance of particular interest is using Optimal Transport (OT) displacement interpolation to define the conditional probability paths. These paths are more efficient than diffusion paths, provide faster training and sampling, and result in better generalization. Training CNFs using Flow Matching on ImageNet leads to consistently better performance than alternative diffusion-based methods in terms of both likelihood and sample quality, and allows fast and reliable sample generation using off-the-shelf numerical ODE solvers.

Graph-informed Neural Point Process With Monotonic Nets

Zhimeng Pan,Zheng Wang,Shandian Zhe

Multi-class event data is ubiquitous in real-world applications. The recent neural temporal point processes have used monotonic nets to model the cumulative conditional intensity to avoid an intractable integration in the likelihood. While successful, they are restricted to single-type events and easily sink into poor learning results. To address these limitations and exploit valuable structural information within event participants, we develop a Graph-Informed Neural Point Process (GINPP) that can freely handle multiple event types, greatly improve learning efficiency with the monotonic net, and effectively integrate the graph information to facilitate training. First, we find the bottleneck of the previous model arises from the standard soft-plus transformation over the output of the monotonic net, which greatly enlarges the prediction variations of the monotonic net and increases the training challenge. We propose a shift-scale version that can significantly reduce the variation and promote learning efficiency. Second, we use a conditional mark distribution to model multiple event types, without the need for explicitly estimating the intensity for each type. The latter can be much more challenging. Third, we use random walks to collect the neighborhood of each event participant and use an attention mechanism to update the hidden state of each participant according to the observed events of both the participant itself and its neighborhood. In this way, we can effectively leverage the graph knowledge, and scale up to large graphs. We have shown the advantage of our approach in both ablation studies and real-world applications.

****

Targeted Hyperparameter Optimization with Lexicographic Preferences Over Multiple Objectives

Shaokun Zhang,Feiran Jia,Chi Wang,Qingyun Wu

Motivated by various practical applications, we propose a novel and general formulation of targeted multi-objective hyperparameter optimization. Our formulation allows a clear specification of an automatable optimization goal using lexicographic preference over multiple objectives. We then propose a randomized directed search method named LexiFlow to solve this problem. We demonstrate the strong empirical performance of the proposed algorithm in multiple hyperparameter optimization tasks.

Learning to Decouple Complex System for Sequential Data

Zihan Zhou,Minxin Ao,Tianshu Yu

A complex system with cluttered observations may be a coupled mixture of multipl e simple sub-systems corresponding to \emph{latent entities}. Such sub-systems may hold distinct dynamics in the continuous-time domain, therein complicated interactions between sub-systems also evolve over time. This setting is fairly common in the real world, but has been less considered. In this paper, we propose a sequential learning approach under this setting by decoupling a complex system for handling irregularly sampled and cluttered sequential observations. Such decoupling brings about not only subsystems describing the dynamics of each latent entity, but also a meta-system capturing the interaction between entities over time. Specifically, we argue that the meta-system of interactions is governed by a smoothed version of \emph{projected differential equations}. Experimental results on synthetic and real-world datasets show the advantages of our approach when facing complex and cluttered sequential data compared to the state-of-the-art.

****

Restoration based Generative Models

Jaemoo Choi,Yesom Park,Myungjoo Kang

Denoising generative models (DGMs) have recently attracted increasing attention by showing impressive synthesis quality. DGMs are built on a diffusion process that pushes data to the noise distribution and the models learn to denoise. In this paper, we establish the interpretation of DGMs in terms of image restoration (IR). Integrating IR literature allows us to use an alternative objective and diverse forward processes, not confining to the diffusion process. By imposing prior knowledge on the loss function grounded on MAP estimation, we eliminate the need for the expensive sampling of DGMs. Also, we propose a multi-scale training, which alleviates the latent inefficiency of DGMs, by taking advantage of the flexibility of the forward process. Our model improves the quality and efficiency of both training and inference, achieving state-of-the-art performance when the number of forward steps is limited. Furthermore, we show the applicability of our model to inverse problems. We believe that our framework paves the way for designing a new type of flexible general generative model.

How hard are computer vision datasets? Calibrating dataset difficulty to viewing time

David Mayo,Jesse Cummings,Xinyu Lin,Dan Gutfreund,Boris Katz,Andrei Barbu

Humans outperform object recognizers despite the fact that models perform well on current datasets. Numerous attempts have been made to create more challenging datasets by scaling them up from the web, exploring distribution shift, or adding controls for biases. The difficulty of each image in each dataset is not independently evaluated, nor is the concept of dataset difficulty as a whole well-posed. We develop a new dataset difficulty metric based on how long humans must view an image in order to classify a target object. Images whose objects can be recognized in 17ms are considered to be easier than those which require seconds of viewing time. Using 133,588 judgments on two major datasets, ImageNet and ObjectNet, we determine the distribution of image difficulties in those datasets, which we find varies wildly, but significantly undersamples hard images. Rather than hoping that distribution shift or other approaches will lead to hard datasets, we should measure the difficulty of datasets and seek to explicitly fill out the class of difficult examples. Analyzing model performance guided by image difficulty reveals that models tend to have lower performance and a larger generalization gap on harder images. Encouragingly for the biological validity of current architectures, much of the variance in human difficulty can be accounted for given an object recognizer by computing a combination of prediction depth, c-score, and adversarial robustness. We release a dataset of such judgments as a complementary metric to raw performance and a network’s ability to explain neural recordings. Such experiments with humans allow us to create a metric for progress in object recognition datasets, which we find are skewed toward easy examples, to test the biological validity of models in a novel way, and to develop tools for shaping datasets as they are being gathered to focus them on filling out the missing class of hard examples from today’s datasets. Dataset and analysis code can be found at https://github.com/image-flash/image-flash-2022.

Self-Supervised Logit Adjustment

Zhihan Zhou,Jiangchao Yao,Feng Hong,Yanfeng Wang,Bo Han,Ya Zhang

Self-supervised learning (SSL) has achieved tremendous success on various well curated datasets in computer vision and natural language processing. Nevertheless, it is hard for existing works to capture transferable and robust features, when facing the long-tailed distribution in the real-world scenarios. The attribution is that plain SSL methods to pursue sample-level uniformity easily leads to the distorted embedding space, where head classes with the huge sample number dominate the feature regime and tail classes passively collapse. To tackle this problem, we propose a novel Self-Supervised Logit Adjustment (S^2LA) method to achieve the category-level uniformity from a geometric perspective. Specially, we measure the geometric statistics of the embedding space to construct the calibration, and jointly learn a surrogate label allocation to constrain the space expansion of head classes and avoid the passive collapse of tail classes. Our proposal does not alter the setting of SSL and can be easily integrated into existing works in an end-to-end and low-cost manner. Extensive results on a range of benchmark datasets show the effectiveness of S^2LA with high tolerance to the distribution skewness.

Proportional Amplitude Spectrum Training Augmentation for Synthetic-to-Real Domain Generalization

Prithvijit Chattopadhyay,Kartik Sarangmath,Vivek Vijaykumar,Judy Hoffman

Synthetic data offers the promise of cheap and bountiful training data for settings where lots of labeled real-world data for some task is unavailable. However, models trained on synthetic data significantly underperform on real-world data. In this paper, we propose Proportional Amplitude Spectrum Training Augmentation (PASTA), a simple and effective augmentation strategy to improve out-of-the-box synthetic-to-real (syn-to-real) generalization performance. PASTA involves perturbing the amplitude spectrums of the synthetic images in the Fourier domain to generate augmented views. We design PASTA to perturb the amplitude spectrums in a structured manner such that high-frequency components are perturbed relatively more than the low-frequency ones. For the tasks of semantic segmentation (GTAV→Real), object detection (Sim10K→Real), and object recognition (VisDAC Syn→Real), across a total of 5 syn-to-real shifts, we find that PASTA either outperforms or is consistently competitive with more complex state-of-the-art methods while being complementary to other generalization approaches.

More Centralized Training, Still Decentralized Execution: Multi-Agent Conditional Policy Factorization

Jiangxing Wang,Deheng Ye,Zongqing Lu

In cooperative multi-agent reinforcement learning (MARL), combining value decomposition with actor-critic enables agents to learn stochastic policies, which are more suitable for the partially observable environment. Given the goal of learning local policies that enable decentralized execution, agents are commonly assumed to be independent of each other, even in centralized training. However, such an assumption may prohibit agents from learning the optimal joint policy. To address this problem, we explicitly take the dependency among agents into centralized training. Although this leads to the optimal joint policy, it may not be factorized for decentralized execution. Nevertheless, we theoretically show that from such a joint policy, we can always derive another joint policy that achieves the same optimality but can be factorized for decentralized execution. To this end, we propose multi-agent conditional policy factorization (MACPF), which takes more centralized training but still enables decentralized execution. We empirically verify MACPF in various cooperative MARL tasks and demonstrate that MACPF achieves better performance or faster convergence than baselines. Our code is available at https://github.com/PKU-RL/FOP-DMAC-MACPF.

GAPS: Few-Shot Incremental Semantic Segmentation via Guided Copy-Paste Synthesis

Ri-Zhao Qiu,Peiyi Chen,Wangzhe Sun,Yu-Xiong Wang,Kris Hauser

Few-shot incremental segmentation is the task of updating a segmentation model, as novel classes are introduced online overtime with a small number of training images. Although incremental segmentation methods exist in the literature, they tend to fall short in the few-shot regime and when given partially-annotated training images, where only the novel class is segmented. This paper proposes a data synthesizer, Guided copy-And-Paste Synthesis (GAPS), that improves the performance of few-shot incremental segmentation in a model-agnostic fashion. Despite the great success of copy-paste synthesis in the conventional offline visual recognition, we demonstrate substantially degraded performance of its naive extension in our online scenario, due to newly encountered challenges. To this end, GAPS (i) addresses the partial-annotation problem by leveraging copy-paste to generate fully-labeled data for training, (ii) helps augment the few images of novel objects by introducing a guided sampling process, and (iii) mitigates catastrophic forgetting by employing a diverse memory-replay buffer. Compared to existing state-of-the-art methods, GAPS dramatically boosts the novel IoU of baseline methods on established few-shot incremental segmentation benchmarks by up to 80%. More notably, GAPS maintains good performance in even more impoverished annotation settings, where only single instances of novel objects are annotated.

Edgeformers: Graph-Empowered Transformers for Representation Learning on Textual-Edge Networks

Bowen Jin,Yu Zhang,Yu Meng,Jiawei Han

Edges in many real-world social/information networks are associated with rich text information (e.g., user-user communications or user-product reviews). However, mainstream network representation learning models focus on propagating and aggregating node attributes, lacking specific designs to utilize text semantics on edges. While there exist edge-aware graph neural networks, they directly initialize edge attributes as a feature vector, which cannot fully capture the contextualized text semantics of edges. In this paper, we propose Edgeformers, a framework built upon graph-enhanced Transformers, to perform edge and node representation learning by modeling texts on edges in a contextualized way. Specifically, in edge representation learning, we inject network information into each Transformer layer when encoding edge texts; in node representation learning, we aggregate edge representations through an attention mechanism within each node’s ego-graph. On five public datasets from three different domains, Edgeformers consistently outperform state-of-the-art baselines in edge classification and link prediction, demonstrating the efficacy in learning edge and node representations, respectively.

How Distinguishable Are Vocoder Models? Analyzing Vocoder Fingerprints for Fake Audio

Chu Yuan Zhang,Jiangyan Yi,Jianhua Tao,Tao Wang,Xinrui Yan,Chenglong Wang

In recent years, vocoders powered by deep neural networks (DNNs) have found much success in the task of generating raw waveforms from acoustic features, as the audio generated becomes increasingly realistic. This development however raises a few challenges, especially in the field of forensics, where the attribution of audio to real or generated sources is vital. To our knowledge, our investigation constitutes the first efforts to answer the question on the existence of vocoder fingerprints and to analyze them. In this paper, we present our discoveries in identifying the sources of generated audio waveforms. Our experiments conducted on the multi-speaker LibriTTS dataset show that (1) vocoder models do leave model-specific fingerprints on the audio they generate, and (2) minor differences in vocoder training can result in sufficiently different fingerprints in generated audio as to allow for distinguishing between the two. We believe that these differences are strong evidence that there exist vocoder-specific fingerprints that can be exploited for source identification purposes.

Any-scale Balanced Samplers for Discrete Space

Haoran Sun,Bo Dai,Charles Sutton,Dale Schuurmans,Hanjun Dai

The locally balanced informed proposal has proved to be highly effective for sampling from discrete spaces. However, its success relies on the "local'' factor, which ensures that whenever the proposal distribution is restricted to be near the current state, the locally balanced weight functions are asymptotically optimal and the gradient approximations are accurate. In seeking a more efficient sampling algorithm, many recent works have considered increasing the scale of the proposal distributions, but this causes the "local'' factor to no longer hold. Instead, we propose any-scale balanced samplers to repair the gap in non-local proposals. In particular, we substitute the locally balanced function with an any-scale balanced function that can self-adjust to achieve better efficiency for proposal distributions at any scale. We also use quadratic approximations to capture curvature of the target distribution and reduce the error in the gradient approximation, while employing a Gaussian integral trick with a special estimated diagonal to efficiently sample from the quadratic proposal distribution. On various synthetic and real distributions, the proposed sampler substantially outperforms existing approaches.

BinSGDM: Extreme One-Bit Quantization for Communication Efficient Large-Scale Distributed Training

Hanyang Peng,Shuang Qin,Yue Yu,Jin Wang,Hui Wang,Ge Li

To alleviate the communication bottleneck of large-scale distributed training, a rich body of prior communication-compression optimizers have been proposed. These methods focus mainly on high compression ratio to expect acceleration. However, some recent works pointed out, when running with distributed training frameworks (\emph{e.g.}, \emph{DistributedDataParallel} in pytorch), these methods may provide no acceleration over the off-the-shelve uncompressed SGD/Adam in the typical settings, due to heavy compression/decompression computation or incompatibility with efficient communication primitives or the requirement of uncompressed warmup at the early stage. For these reasons, we propose a novel extreme one-bit quantization optimizer, dubbed \emph{BinSGDM}. The quantization of \emph{BinSGDM} is computed easily and lightly, and it does not need to resort to uncompressed optimizers for warmup. We also theoretically prove that it can promise the same convergence speed as the original Adam. Moreover, we specially present a hierarchical communication scheme to further lower the communication volume. Extensive experiments are conducted on 8 to 64 GPUs (1 to 8 nodes) for distributed training with \emph{DistributedDataParallel}, and the experimental results demonstrates that \emph{BinSGDM} with the communication scheme can achieve up to {$\bm{2.47 \times}$} speedup for training ResNet-50 and $\bm{6.26\times}$ speedup for training BERT-Base, compared to the full-precision optimizers.

Equivariant Shape-Conditioned Generation of 3D Molecules for Ligand-Based Drug Design

Keir Adams,Connor W. Coley

Shape-based virtual screening is widely used in ligand-based drug design to search chemical libraries for molecules with similar 3D shapes yet novel 2D graph structures compared to known ligands. 3D deep generative models can potentially automate this exploration of shape-conditioned 3D chemical space; however, no existing models can reliably generate geometrically realistic drug-like molecules in conformations with a specific shape. We introduce a new multimodal 3D generative model that enables shape-conditioned 3D molecular design by equivariantly encoding molecular shape and variationally encoding chemical identity. We ensure local geometric and chemical validity of generated molecules by using autoregressive fragment-based generation with heuristic bonding geometries, allowing the model to prioritize the scoring of rotatable bonds to best align the growing conformation to the target shape. We evaluate our 3D generative model in tasks relevant to drug design including shape-conditioned generation of chemically diverse molecular structures and shape-constrained molecular property optimization, demonstrating its utility over virtual screening of enumerated libraries.

Leaves: Learning Views for Time-Series Data in Contrastive Learning

Han Yu,Huiyuan Yang,Akane Sano

Contrastive learning, a self-supervised learning method that can learn represent ations from unlabeled data, has been developed promisingly. Many methods of contrastive learning depend on data augmentation techniques, which generate different views from the original signal. However, tuning policies and hyper-parameters for more effective data augmentation methods in contrastive learning is often time and resource-consuming. Researchers have designed approaches to automatically generate new views for some input signals, especially on the image data. But the view-learning method is not well developed for time-series data. In this work, we propose a simple but effective module for automating view generation for time-series data in contrastive learning, named learning views for time-series data (LEAVES). The proposed module learns the hyper-parameters for augmentations using adversarial training in contrastive learning. We validate the effectiveness of the proposed method using multiple time-series datasets. The experiments demonstrate that the proposed method is more effective in finding reasonable views and performs downstream tasks better than the baselines, including manually tuned augmentation-based contrastive learning methods and SOTA methods.

The Eigenlearning Framework: A Conservation Law Perspective on Kernel Ridge Regression and Wide Neural Networks

James B Simon,Madeline Dickens,Dhruva Karkada,Michael Deweese

We derive simple closed-form estimates for the test risk and other generalization metrics of kernel ridge regression (KRR). Relative to prior work, our derivations are greatly simplified and our final expressions are far more interpretable. These improvements are enabled by our identification of a sharp conservation law which limits the ability of KRR to learn any orthonormal basis of functions. Test risk and other objects of interest are expressed in a transparent, interpretable way in terms of our conserved quantity evaluated in the kernel eigenbasis. We use our improved framework to:

i) provide a theoretical explanation for the ``deep bootstrap" of Nakkiran et al (2020),

ii) prove a new result regarding the hardness of the classic parity problem,

iii) fashion a theoretical tool for the study of adversarial robustness, and

iv) draw a tight analogy between KRR and a well-studied system in statistical physics.

Imbalanced Semi-supervised Learning with Bias Adaptive Classifier

Renzhen Wang,Xixi Jia,Quanziang Wang,Yichen Wu,Deyu Meng

Pseudo-labeling has proven to be a promising semi-supervised learning (SSL) paradigm. Existing pseudo-labeling methods commonly assume that the class distributions of training data are balanced. However, such an assumption is far from realistic scenarios and thus severely limits the performance of current pseudo-labeling methods under the context of class-imbalance. To alleviate this problem, we design a bias adaptive classifier that targets the imbalanced SSL setups. The core idea is to automatically assimilate the training bias caused by class imbalance via the bias adaptive classifier, which is composed of a novel bias attractor and the original linear classifier. The bias attractor is designed as a light-weight residual network and learned through a bi-level learning framework, which enables the bias adaptive classifier to fit imbalanced training data, while the linear classifier can provide unbiased label prediction for each class. We conduct extensive experiments under various imbalanced semi-supervised setups, and the results demonstrate that our method can be applied to different pseudo-labeling models and is superior to current state-of-the-art methods.

COMNET : CORTICAL MODULES ARE POWERFUL

Ashish Kumar,Laxmidhar Behera

Existing CNN architectures may achieve efficiency in either one or two dimensions: FLOPs, depth, accuracy, representation power, latency but not in all. In this work, we present a pragmatically designed novel CNN architecture “CoMNet” which offers multi-dimensional efficiency at once such as: simple yet accurate, lower latency and FLOPs, high representation power in limited parameters, low memory consumption, negligible branching, smaller depths, and only a few design hyperpa rameters. The key to achieve the multi-dimensional efficiency is our use of biological underpinnings into CoMNet which is primarily the organization of cortical modules in the visual cortex. To realize CoMNet, a few concepts from well understood CNN designs are directly inherited such as residual learning. Our solid experimental evaluations demonstrate superiority of CoMNet over many state-of-the-art industry and academia dominant architectures such as ResNet, RepVGG etc. For instance, CoMNet supersedes ResNet-50 on ImageNet while being 50% shallower, 22% lesser parameters, 25% lower FLOPs and latency, and in 16% lesser training epochs. Code will be opensourced post the reviews.

Do We Always Need to Penalize Variance of Losses for Learning with Label Noise?

Yexiong Lin,Yu Yao,Yuxuan Du,Jun Yu,Bo Han,Mingming Gong,Tongliang Liu

Algorithms which minimize the averaged loss have been widely designed for dealing with noisy labels. Intuitively, when there is a finite training sample, penalizing the variance of losses will improve the stability and generalization of the algorithms. Interestingly, we found that the variance of losses sometimes needs to be increased for the problem of learning with noisy labels. Specifically, increasing the variance of losses would boost the memorization effect and reduce the harmfulness of incorrect labels. Regularizers can be easily designed to increase the variance of losses and be plugged in many existing algorithms. Empirically, the proposed method by increasing the variance of losses could improve the generalization ability of baselines on both synthetic and real-world datasets.

DeepGuiser: Learning to Disguise Neural Architectures for Impeding Adversarial Transfer Attacks

Yi Cai,Chenyu Wang,Xuefei Ning,Zixuan Zhou,Dimin Niu,Huazhong Yang,Yu Wang

Security is becoming increasingly critical in deep learning applications. Recent researches demonstrate that NN models are vulnerable to adversarial attacks, which can mislead them with only small input perturbations. Moreover, adversaries who know the architecture of victim models can conduct more effective attacks. Unfortunately, the architectural knowledge can usually be stolen by the adversaries by exploiting the system-level hints through many side channels, which is referred to as the neural architecture extraction attack. Conventional countermeasures for neural architecture extraction can introduce large overhead, and different hardware platforms have diverse types of side-channel leakages such that many expert efforts are needed in developing hardware-specific countermeasures. In this paper, we propose DeepGuiser, an automatic, hardware-agnostic, and retrain-free neural architecture disguising method, to disguise the neural architectures to reduce the harm of neural architecture extraction attacks. In a nutshell, given a trained model, DeepGuiser outputs a deploy model that is functionally equivalent with the trained model but with a different (i.e., disguising) architecture. DeepGuiser can minimize the harm of the follow-up adversarial transfer attacks to the deploy model, even if the disguising architecture is completely stolen by the architecture extraction attack. Experiments demonstrate that DeepGuiser can effectively disguise diverse architectures and impede the adversarial transferability by 13.87% ~ 32.59%, while only introducing 10% ~ 40% extra inference latency.

****

FACS: FAST ADAPTIVE CHANNEL SQUEEZING

Ashish Kumar,Laxmidhar Behera

Channel squeezing is one of the central operations performed in CNN bottlenecks to reduce the number of channels in a feature map. This operation is carried out by using a 1 × 1 pointwise convolution which constitutes a significant amount of computations and parameters in a given network. ResNet-50 for instance, consists of 16 such layers which form 33% of total layers and 25% (1.05B/4.12B) of total FLOPs or computations. In the light of their predominance, we propose a novel “Fast Adaptive Channel Squeezing” module which carries out the squeezing operation in a computationally efficient manner. The key benefit of FACS is that it neither alters the number of parameters nor affects the accuracy of a given network. When plugged into diverse CNNs architectures, namely ResNet, VGG, and MobileN et-v2, FACS achieves state-of-the-art performance on ImageNet and CIFAR datasets at dramatically reduced FLOPs. FACS also cuts the training time significantly, and lowers the latency which is particularly advantageous for fast inference on edge devices. The source-code will be made publicly available.

Pre-trained Language Models can be Fully Zero-Shot Learners

Xuandong Zhao,Siqi Ouyang,Zhiguo Yu,Ming Wu,Lei Li

How can we extend a pre-trained model to many language understanding tasks, without labeled or additional unlabeled data? Pre-trained language models (PLMs) have been effective for a wide range of NLP tasks. However, existing approaches either require fine-tuning on downstream labeled datasets or manually constructing proper prompts. In this paper, we propose nonparametric prompting PLM (NPPrompt) for fully zero-shot language understanding. Unlike previous methods, NPPrompt uses only pre-trained language models and does not require any labeled data or additional raw corpus for further fine-tuning, nor does it rely on humans to construct a comprehensive set of prompt label words. We evaluate NPPrompt against previous major few-shot and zero-shot learning methods on diverse NLP tasks: including text classification, text entailment, similar text retrieval, and paraphrasing. Experimental results demonstrate that our NPPrompt outperforms the previous best fully zero-shot method by big margins, with absolute gains of 12.8% in accuracy on text classification and 18.9% on the GLUE benchmark.

On Compositional Uncertainty Quantification for Seq2seq Graph Parsing

Zi Lin,Du Phan,Panupong Pasupat,Jeremiah Zhe Liu,Jingbo Shang

Recent years have witnessed the success of applying seq2seq models to graph parsing tasks, where the outputs are compositionally structured (e.g., a graph or a tree). However, these seq2seq approaches pose a challenge in quantifying the model’s compositional uncertainty on graph structures due to the gap between seq2seq output probability and structural probability on the graph. This work is the first to quantify and evaluate compositional uncertainty for seq2seq graph parsing tasks. First, we proposed a generic, probabilistically interpretable framework that allows correspondences between seq2seq output probability to structural probability on the graph. This framework serves as a powerful medium for quantifying a seq2seq model's compositional uncertainty on graph elements (i.e., nodes or edges). Second, to evaluate uncertainty quality in terms of calibration, we propose a novel metric called Compositional Expected Calibration Error (CECE) which can measure a model’s calibration behavior in predicting graph structures. By a thorough evaluation for compositional uncertainty on three different tasks across ten domains, we demonstrate that CECE is a better reflection for distributional shift compared to vanilla sequence ECE. Finally, we validate the effectiveness of compositional uncertainty considering the task of collaborative semantic parsing, where the model is allowed to send limited subgraphs for human review. The results show that the collaborative performance based on uncertain subgraph selection consistently outperforms random subgraph selection (30% average error reduction rate) and performs comparably to oracle subgraph selection (only 0.33 difference in average prediction error), indicating that compositional uncertainty is an ideal signal for model errors and can benefit various downstream tasks.

****

Generative Gradual Domain Adaptation with Optimal Transport

Yifei He,Haoxiang Wang,Han Zhao

Unsupervised domain adaptation (UDA) adapts a model from a labeled source domain to an unlabeled target domain in a one-off way. Though widely applied, UDA faces a great challenge whenever the distribution shift between the source and the target is large. Gradual domain adaptation (GDA) mitigates this limitation by using intermediate domains to gradually adapt from the source to the target domain. However, it remains an open problem on how to leverage this paradigm when the oracle intermediate domains are missing or scarce. To approach this practical challenge, we propose Generative Gradual Domain Adaptation with Optimal Transport (GOAT), an algorithmic framework that can generate intermediate domains in a data-dependent way. More concretely, we generate intermediate domains along the Wass erstein geodesic between two given consecutive domains in a feature space, and apply gradual self-training, a standard GDA algorithm, to adapt the source-trained classifier to the target along the sequence of intermediate domains. Empirically, we demonstrate that our GOAT framework can improve the performance of standard GDA when the oracle intermediate domains are scarce, significantly broadening the real-world application scenarios of GDA.

Free Lunch for Domain Adversarial Training: Environment Label Smoothing

YiFan Zhang,xue wang,Jian Liang,Zhang Zhang,Liang Wang,Rong Jin,Tieniu Tan

A fundamental challenge for machine learning models is how to generalize learned models for out-of-distribution (OOD) data. Among various approaches, exploiting invariant features by Domain Adversarial Training (DAT) received widespread attention. Despite its success, we observe training instability from DAT, mostly due to over-confident domain discriminator and environment label noise. To address this issue, we proposed Environment Label Smoothing (ELS), which encourages the discriminator to output soft probability, which thus reduces the confidence of the discriminator and alleviates the impact of noisy environment labels. We demonstrate, both experimentally and theoretically, that ELS can improve training stability, local convergence, and robustness to noisy environment labels. By incorporating ELS with DAT methods, we are able to yield state-of-art results on a wide range of domain generalization/adaptation tasks, particularly when the environment labels are highly noisy.

****

Scaling Forward Gradient With Local Losses

Mengye Ren,Simon Kornblith,Renjie Liao,Geoffrey Hinton

Forward gradient learning computes a noisy directional gradient and is a biologically plausible alternative to backprop for learning deep neural networks. The standard forward gradient algorithm suffers from the curse of dimensionality in the number of parameters. In this paper, we propose to scale forward gradient by adding a large number of local greedy loss functions. We consider block-wise, patch-wise, and channel group-wise local losses, and show that activity perturbation reduces variance compared to weight perturbation. Inspired by MLPMixer, we also propose a new architecture, LocalMixer, that is more suitable for local learning. We find local learning can work well with both supervised classification and self-supervised contrastive learning. Empirically, it can match backprop on MNIST and CIFAR-10 and significantly outperform backprop-free algorithms on ImageNet.

PAC-NeRF: Physics Augmented Continuum Neural Radiance Fields for Geometry-Agnostic System Identification

Xuan Li,Yi-Ling Qiao,Peter Yichen Chen,Krishna Murthy Jatavallabhula,Ming Lin,Chenfanfu Jiang,Chuang Gan

Existing approaches to system identification (estimating the physical parameters of an object) from videos assume known object geometries. This precludes their applicability in a vast majority of scenes where object geometries are complex or unknown. In this work, we aim to identify parameters characterizing a physical system from a set of multi-view videos without any assumption on object geometry or topology. To this end, we propose "Physics Augmented Continuum Neural Radiance Fields" (PAC-NeRF), to estimate both the unknown geometry and physical parameters of highly dynamic objects from multi-view videos. We design PAC-NeRF to only ever produce physically plausible states by enforcing the neural radiance field to follow the conservation laws of continuum mechanics. For this, we design a hybrid Eulerian-Lagrangian representation of the neural radiance field, i.e., we use the Eulerian grid representation for NeRF density and color fields, while advecting the neural radiance fields via Lagrangian particles. This hybrid Eulerian-Lagrangian representation seamlessly blends efficient neural rendering with the material point method (MPM) for robust differentiable physics simulation. We validate the effectiveness of our proposed framework on geometry and physical parameter estimation over a vast range of materials, including elastic bodies, pl

asticine, sand, Newtonian and non-Newtonian fluids, and demonstrate significant performance gain on most tasks.

Linearly Constrained Bilevel Optimization: A Smoothed Implicit Gradient Approach
Prashant Khanduri,Ioannis Tsaknakis,Yihua Zhang,Jia Liu,Sijia Liu,Jiawei Zhang,Mingyi Hong
This work develops analysis and algorithms for solving a class of bilevel optimization problems where the lower-level (LL) problems have linear constraints. Most of the existing approaches for constrained bilevel problems rely on value function based approximate reformulations, which suffer from issues such as non-convex and non-differentiable constraints. In contrast, in this work, we develop an implicit gradient-based approach, which is easy to implement, and is suitable for machine learning applications. We first provide in-depth understanding of the problem, by showing that the implicit objective for such problems is in general non-differentiable. However, if we add some small (linear) perturbation to the LL objective, the resulting problem becomes differentiable almost surely. This key observation opens the door for developing (deterministic and stochastic) gradient-based algorithms similar to the state-of-the-art ones for unconstrained bi-level problems. We show that when the implicit function is assumed to be strongly-convex, convex and non-convex, the resulting algorithms converge with guaranteed rate. Finally, we experimentally corroborate the theoretical findings and evaluate the performance of the proposed framework on numerical and adversarial learning problems. To our knowledge, this is the first time that (implicit) gradient-based methods have been developed and analyzed for the considered class of bilevel problems.

Mastering the Game of No-Press Diplomacy via Human-Regularized Reinforcement Learning and Planning
Anton Bakhtin,David J Wu,Adam Lerer,Jonathan Gray,Athul Paul Jacob,Gabriele Farina,Alexander H Miller,Noam Brown
No-press Diplomacy is a complex strategy game involving both cooperation and competition that has served as a benchmark for multi-agent AI research. While self-play reinforcement learning has resulted in numerous successes in purely adversarial games like chess, Go, and poker, self-play alone is insufficient for achieving optimal performance in domains involving cooperation with humans. We address this shortcoming by first introducing a planning algorithm we call DiL-piKL that regularizes a reward-maximizing policy toward a human imitation-learned policy. We prove that this is a no-regret learning algorithm under a modified utility function. We then show that DiL-piKL can be extended into a self-play reinforcement learning algorithm we call RL-DiL-piKL that provides a model of human play while simultaneously training an agent that responds well to this human model. We used RL-DiL-piKL to train an agent we name Diplodocus.
In a 200-game no-press Diplomacy tournament involving 62 human participants spanning skill levels from beginner to expert, two Diplodocus agents both achieved a higher average score than all other participants who played more than two games, and ranked first and third according to an Elo ratings model.

Understanding Embodied Reference with Touch-Line Transformer
Yang Li,Xiaoxue Chen,Hao Zhao,Jiangtao Gong,Guyue Zhou,Federico Rossano,Yixin Zhu
We study embodied reference understanding, the task of locating referents using embodied gestural signals and language references. Human studies have revealed that, contrary to popular belief, objects referred to or pointed to do not lie on the elbow-wrist line, but rather on the so-called virtual touch line. Nevertheless, contemporary human pose representations lack the virtual touch line. To tackle this problem, we devise the touch-line Transformer: It takes as input tokenized visual and textual features and simultaneously predicts the referent’s bounding box and a touch-line vector. Leveraging this touch-line prior, we further devise a geometric consistency loss that promotes co-linearity between referents and touch lines. Using the touch line as gestural information dramatically improv

es model performances: Experiments on the YouRefIt dataset demonstrate that our method yields a +25.0% accuracy improvement under the 0.75 IoU criterion, hence closing 63.6% of the performance difference between models and humans. Furthermore, we computationally validate prior human studies by demonstrating that computational models more accurately locate referents when employing the virtual touch line than when using the elbow-wrist line.

****

Evaluating Robustness of Cooperative MARL: A Model-based Approach
Nhan H Pham,Lam M. Nguyen,Jie Chen,Hoang Thanh Lam,Subhro Das,Tsui-Wei Weng

In recent years, a proliferation of methods were developed for cooperative multi-agent reinforcement learning (c-MARL). However, the robustness of c-MARL agents against adversarial attacks has been rarely explored. In this paper, we propose to evaluate the robustness of c-MARL agents via a model-based approach, named c-MBA. Our proposed formulation can craft much stronger adversarial state perturbations of c-MARL agents to lower total team rewards than existing model-free approaches. In addition, we propose the first victim-agent selection strategy and the first data-driven approach to define targeted failure states where each of them allows us to develop even stronger adversarial attack without the expert knowledge to the underlying environment. Our numerical experiments on two representative MARL benchmarks illustrate the advantage of our approach over other baselines: our model-based attack consistently outperforms other baselines in all tested environments.

Rethinking Symbolic Regression Datasets and Benchmarks for Scientific Discovery
Yoshitomo Matsubara,Naoya Chiba,Ryo Igarashi,Tatsunori Taniai,Yoshitaka Ushiku

This paper revisits datasets and evaluation criteria for Symbolic Regression, a task of expressing given data using mathematical equations, specifically focused on its potential for scientific discovery. Focused on a set of formulas used in the existing datasets based on Feynman Lectures on Physics, we recreate 120 datasets to discuss the performance of symbolic regression for scientific discovery (SRSD). For each of the 120 SRSD datasets, we carefully review the properties of the formula and its variables to design reasonably realistic sampling range of values so that our new SRSD datasets can be used for evaluating the potential of SRSD such as whether or not an SR method can (re)discover physical laws from such datasets. As an evaluation metric, we also propose to use normalized edit distances between a predicted equation and the ground-truth equation trees. While existing metrics are either binary or errors between the target values and an SR model's predicted values for a given input, normalized edit distances evaluate a sort of similarity between the ground-truth and predicted equation trees. We have conducted experiments on our new SRSD datasets using five state-of-the-art SR methods in SRBench and a simple baseline based on a recent Transformer architecture. The results show that we provide a more realistic performance evaluation and open up a new machine learning-based approach for scientific discovery. We provide our datasets and code as part of the supplementary material.

The Cost of Privacy in Fair Machine Learning
Songkai Xue,Yuekai Sun

A common task in fair machine learning is training ML models that preserve certain summary statistics across subpopulations defined by sensitive attributes. However, access to such sensitive attributes in training data is restricted and the learner must rely on noisy proxies for the sensitive attributes. In this paper, we study the effect of a privacy mechanism that obfuscates the sensitive attributes from the learner on the fairness of the resulting classifier. We show that the cost of privacy in fair ML is a decline in the generalizability of fairness constraints.

VARIATIONAL ADAPTIVE GRAPH TRANSFORMER FOR MULTIVARIATE TIME SERIES MODELING
Long Tian,Wenchao Chen,Bo Chen,Muyao Wang,Liang Dai,BaoLin Sun,Mingyuan Zhou

Multivariate time series (MTS) are widely collected by large-scale complex systems, such as internet services, IT infrastructures, and wearable devices. The mod eling of MTS has long been an important but challenging task. To capture complex long-range dynamics, Transformers have been utilized in MTS modeling and achieved attractive performance. However, Transformers in general do not well capture the diverse relationships between different channels within MTS and have difficulty in modeling MTS with complex distributions due to the lack of stochasticity. In this paper, we first incorporate relational modeling into Transformer to develop an adaptive Graph Transformer (G-Trans) module for MTS. Then, we further consider stochastity by introducing a powerful embedding guided probabilistic generative module for G-Trans to construct Variational adaptive Graph Transformer (VG-Trans), which is a well-defined variational generative dynamic model. VG-Trans is utilized to learn expressive representations of MTS, being an plug-and-play framework that can be applied to forecasting and anomaly detection tasks of MTS. For efficient inference, we develop an autoencoding variational inference scheme with a combined prediction and reconstruction loss. Extensive experiments on diverse datasets show the efficient of VG-Trans on MTS modeling and improving the existing methods on VG-Trans outperforms state-of-the-art methods on a variety of MTS modeling tasks.

Efficient Large-scale Transformer Training via Random and Layerwise Token Dropping

Zhewei Yao,Xiaoxia Wu,Conglong Li,Connor Holmes,Minjia Zhang,Cheng Li,Yuxiong He

Large-scale transformer models have become the de-facto architectures for various machine learning applications, e.g., CV and NLP.

However, those large models also introduce prohibitive training costs.

To mitigate this issue, we propose a novel random and layerwise token dropping method (\OURS), which skips the computation of a subset of the input tokens at all middle layers.

Particularly, \OURS achieves considerable speedups and comparable accuracy as the standard training baseline.

Compared to other token dropping methods, \OURS does not require (1) any importance score-based metrics, (2) any special token treatment (e.g., \texttt{[CLS]}), and (3) many layers in full sequence length training except the first and the last layers.

Besides, a new \layertoken learning rate schedule is proposed for pretraining problems that resolve the heavy tuning requirement for our proposed training mechanism.

Finally, we demonstrate that \OURS can be applied to broader applications, including \gpt and \bert pretraining as well as ViT and \gpt finetuning tasks.

Our results show that \OURS can save about 33.3\% theoretical compute cost and 25.6\% wall-clock training time while achieving similar zero-shot evaluations on \gptb as compared to baseline.

Demystifying black-box DNN training processes through Concept-Monitor

Mohammad Ali Khan,Tuomas Oikarinen,Tsui-Wei Weng

Despite the successes of deep neural networks (DNNs) on a broad range of tasks little has been understood of why and how they achieve such victories due to their complex architecture and their opaque black-box training processes. With the goal to unveil the mystery of DNNs, in this work, we propose a general framework called Concept-Monitor to uncover the black-box DNN training processes automatically for the first time. Our proposed Concept-Monitor enables human-interpretable visualization on the DNN training processes and thus facilitates transparency as well as deeper understanding of how DNNs function and operate along the training iterations. Using Concept-Monitor, we are able to observe and compare different training paradigms at ease, including standard training, fine-tuning, adversarial training and network pruning for Lottery Ticket Hypothesis, which brings new insights on why and how adversarial training and network pruning work and how they modify the network during training. For example, we find that the lottery ticket hypothesis discovers a mask that makes neurons interpretable at initialization, \textit{without} any finetuning, and we also found that adversarially robust models have more neurons relying on color as compared to standard models tra ined on the same dataset.

Large Language Models Can Self-improve

Jiaxin Huang,Shixiang Shane Gu,Le Hou,Yuexin Wu,Xuezhi Wang,Hongkun Yu,Jiawei Han

Large Language Models (LLMs) have achieved excellent performances in various tasks. However, fine-tuning an LLM requires extensive supervision. Human, on the other hand, may improve their reasoning abilities by self-thinking without external inputs. In this work, we demonstrate that an LLM is also capable of self-improving with only unlabeled datasets. We use a pre-trained LLM to generate “high-confidence” rationale-augmented answers for unlabeled questions using Chain-of-Thought prompting and self-consistency, and fine-tune the LLM using those self-generated solutions as target outputs. We show that our approach improves the general reasoning ability of a 540B-parameter LLM (74.4%→82.1% on GSM8K, 78.2%→83.0% on DROP, 90.0%→94.4% on OpenBookQA, and 63.4%→67.9% on ANLI-A3) and achieves state-of-the-art-level performance, without any ground truth label. We conduct ablation studies and show that finetuning on reasoning is critical for self-improvement.

Calibration Matters: Tackling Maximization Bias in Large-scale Advertising Recommendation Systems

Yewen Fan,Nian Si,Kun Zhang

Calibration is defined as the ratio of the average predicted click rate to the true click rate. The optimization of calibration is essential to many online advertising recommendation systems because it directly affects the downstream bids in ads auctions and the amount of money charged to advertisers. Despite its importance, calibration often suffers from a problem called “maximization bias”. Maximization bias refers to the phenomenon that the maximum of predicted values overestimates the true maximum. The problem is introduced because the calibration is computed on the set selected by the prediction model itself. It persists even if unbiased predictions are achieved on every datapoint and worsens when covariate shifts exist between the training and test sets. To mitigate this problem, we quantify maximization bias and propose a variance-adjusting debiasing (VAD) meta-algorithm in this paper. The algorithm is efficient, robust, and practical as it is able to mitigate maximization bias problem under covariate shifts, without incurring additional online serving costs or compromising the ranking performance. We demonstrate the effectiveness of the proposed algorithm using a state-of-the-art recommendation neural network model on a large-scale real-world dataset.

Excess risk analysis for epistemic uncertainty with application to variational inference

Futoshi Futami,Tomoharu Iwata,Naonori Ueda,Issei Sato,Masashi Sugiyama

Bayesian deep learning plays an important role especially for its ability evaluating epistemic uncertainty (EU). Due to computational complexity issues, approximation methods such as variational inference (VI) have been used in practice to obtain posterior distributions and their generalization abilities have been analyzed extensively, for example, by PAC-Bayesian theory; however, little analysis exists on EU, although many numerical experiments have been conducted on it.

In this study, we analyze the EU of supervised learning in approximate Bayesian inference by focusing on its excess risk. First, we theoretically show the novel relations between generalization error and the widely used EU measurements, such as the variance and mutual information of predictive distribution, and derive their convergence behaviors. Next, we clarify how the objective function of VI regularizes the EU. With this analysis, we propose a new objective function for VI that directly controls the prediction performance and the EU based on the PAC-Bayesian theory. Numerical experiments show that our algorithm significantly improves the EU evaluation over the existing VI methods.

Memorization-Dilation: Modeling Neural Collapse Under Noise

Duc Anh Nguyen,Ron Levie,Julian Lienen,Eyke Hüllermeier,Gitta Kutyniok

The notion of neural collapse refers to several emergent phenomena that have been empirically observed across various canonical classification problems. During the terminal phase of training a deep neural network, the feature embedding of all examples of the same class tend to collapse to a single representation, and the features of different classes tend to separate as much as possible. Neural collapse is often studied through a simplified model, called the layer-peeled model, in which the network is assumed to have ``infinite expressivity'' and can map each data point to any arbitrary representation. In this work we study a more realistic variant of the layer-peeled model, which takes the positivity of the features into account. Furthermore, we extend this model to also incorporate the limited expressivity of the network. Empirical evidence suggests that the memorization of noisy data points leads to a degradation (dilation) of the neural collapse. Using a model of the memorization-dilation (M-D) phenomenon, we show one mechanism by which different losses lead to different performances of the trained network on noisy data. Our proofs reveal why label smoothing, a modification of cross-entropy empirically observed to produce a regularization effect, leads to improved generalization in classification tasks.

****

Spacetime Representation Learning

Marc T. Law,James Lucas

Much of the data we encounter in the real world can be represented as directed graphs. In this work, we introduce a general family of representations for directed graphs through connected time-oriented Lorentz manifolds, called "spacetimes" in general relativity. Spacetimes intrinsically contain a causal structure that indicates whether or not there exists a causal or even chronological order between points of the manifold, called events. This chronological order allows us to naturally represent directed edges via imposing the correct ordering when the nodes are embedded as events in the spacetime. Previous work in machine learning only considers embeddings lying on the simplest Lorentz manifold or does not exploit the connection between Lorentzian pre-length spaces and directed graphs. We introduce a well-defined approach to map data onto a general family of spacetimes. We empirically evaluate our framework in the tasks of hierarchy extraction of undirected graphs, directed link prediction and representation of directed graphs.

Meta-Learning General-Purpose Learning Algorithms with Transformers

Louis Kirsch,James Harrison,Jascha Sohl-Dickstein,Luke Metz

Modern machine learning requires system designers to specify aspects of the learning pipeline, such as losses, architectures, and optimizers. Meta-learning, or learning-to-learn, instead aims to learn those aspects, and promises to unlock greater capabilities with less manual effort. One particularly ambitious goal of meta-learning is to train general purpose learning algorithms from scratch, using only black box models with minimal inductive bias. A general purpose learning algorithm is one which takes in training data, and produces test-set predictions across a wide range of problems, without any explicit definition of an inference model, training loss, or optimization algorithm. In this paper we show that Transformers and other black-box models can be meta-trained to act as general purpose learning algorithms, and can generalize to learn on different datasets than used during meta-training. We characterize phase transitions between algorithms that generalize, algorithms that memorize, and algorithms that fail to meta-train at all, induced by changes in model size, number of tasks used during meta-training, and meta-optimization hyper-parameters. We further show that the capabilities of meta-trained algorithms are bottlenecked by the accessible state size determining the next prediction, unlike standard models which are thought to be bottlenecked by parameter count. Finally, we propose practical interventions such as biasing the training distribution that improve the meta-training and meta-generalization of general purpose learning algorithms.

****

Learning to Extrapolate: A Transductive Approach

Aviv Netanyahu,Abhishek Gupta,Max Simchowitz,Kaiqing Zhang,Pulkit Agrawal

Machine learning systems, especially with overparameterized deep neural networks, can generalize to novel test instances drawn from the same distribution as the training data. However, they fare poorly when evaluated on \emph{out-of-support} test points. In this work, we tackle the problem of developing machine learning systems that retain the power of overparameterized function approximators while enabling extrapolation to out-of-support test points when possible. This is accomplished by noting that under certain conditions, a ``transductive'' reparameterization can convert an out-of-support extrapolation problem into a problem of within-support combinatorial generalization. We propose a simple strategy based on bilinear embeddings to enable this type of combinatorial generalization, thereby addressing the out-of-support extrapolation problem under certain conditions. We instantiate a simple, practical algorithm applicable to various supervised learning and imitation learning tasks.

Label-free Concept Bottleneck Models

Tuomas Oikarinen,Subhro Das,Lam M. Nguyen,Tsui-Wei Weng

Concept bottleneck models (CBM) are a popular way of creating more interpretable neural networks by having hidden layer neurons correspond to human-understandable concepts. However, existing CBMs and their variants have two crucial limitations: first, they need to collect labeled data for each of the predefined concepts, which is time consuming and labor intensive; second, the accuracy of a CBM is often significantly lower than that of a standard neural network, especially on more complex datasets. This poor performance creates a barrier for adopting CBMs in practical real world applications. Motivated by these challenges, we propose Label-free CBM which is a novel framework to transform any neural network into an interpretable CBM without labeled concept data, while retaining a high accuracy. Our Label-free CBM has many advantages, it is: scalable - we present the first CBM scaled to ImageNet, efficient - creating a CBM takes only a few hours even for very large datasets, and automated - training it for a new dataset requires minimal human effort. Our code is available at https://github.com/Trustworthy-ML-Lab/Label-free-CBM.

Multi-level Protein Structure Pre-training via Prompt Learning

Zeyuan Wang,Qiang Zhang,Shuang-Wei HU,Haoran Yu,Xurui Jin,Zhichen Gong,Huajun Chen

A protein can focus on different structure levels to implement its functions. Each structure has its own merit and driving forces in describing some specific characteristics, and they cannot replace each other. Most existing function prediction methods take the tertiary structure as input, unintentionally ignoring the other levels of protein structures. Considering protein sequences can determine multi-level structures, in this paper, we aim to realize the comprehensive potential of protein sequences for function prediction. Specifically, we propose a new prompt-guided multi-task pre-training and fine-tuning framework, and the resulting protein model is called PromptProtein. Through the prompt-guided multi-task pre-training, we learn multiple prompt signals to steer the model to focus on different structure levels. We also design a prompt fine-tuning module to provide downstream tasks the on-demand flexibility of utilizing respective levels of structure information. Extensive experiments on function prediction and protein engineering show that PromptProtein outperforms state-of-the-art methods by large margins.

CLIP-Dissect: Automatic Description of Neuron Representations in Deep Vision Networks

Tuomas Oikarinen,Tsui-Wei Weng

In this paper, we propose CLIP-Dissect, a new technique to automatically describe the function of individual hidden neurons inside vision networks. CLIP-Dissect leverages recent advances in multimodal vision/language models to label internal neurons with open-ended concepts without the need for any labeled data or human examples. We show that CLIP-Dissect provides more accurate descriptions than existing methods for last layer neurons where the ground-truth is available as we ll as qualitatively good descriptions for hidden layer neurons. In addition, our method is very flexible: it is model agnostic, can easily handle new concepts and can be extended to take advantage of better multimodal models in the future. Finally CLIP-Dissect is computationally efficient and can label all neurons from five layers of ResNet-50 in just 4 minutes, which is more than 10$\times$ faster than existing methods. Our code is available at https://github.com/Trustworthy-ML-Lab/CLIP-dissect.

GLM-130B: An Open Bilingual Pre-trained Model

Aohan Zeng,Xiao Liu,Zhengxiao Du,Zihan Wang,Hanyu Lai,Ming Ding,Zhuoyi Yang,Yifan Xu,Wendi Zheng,Xiao Xia,Weng Lam Tam,Zixuan Ma,Yufei Xue,Jidong Zhai,Wenguang Chen,Zhiyuan Liu,Peng Zhang,Yuxiao Dong,Jie Tang

We introduce GLM-130B, a bilingual (English and Chinese) pre-trained language model with 130 billion parameters. It is an attempt to open-source a 100B-scale model as good as GPT-3 (davinci) and unveil how models of such a scale can be successfully pre-trained. Over the course of this effort, we face numerous unexpected technical and engineering challenges, particularly on loss spikes and divergence. In this paper, we introduce the pre-training process of GLM-130B including its design choices, training strategies for both efficiency and stability, and engineering efforts. The resultant GLM-130B model offers significant outperformance over GPT-3 175B on a wide range of popular English benchmarks while the performance advantage is not observed in OPT-175B and BLOOM-176B. It also consistently and significantly outperforms ERNIE TITAN 3.0 260B—the largest Chinese language model—across related benchmarks. Finally, we leverage a unique scaling property of GLM-130B to reach INT4 quantization with almost no performance loss, making it the first among 100B-scale models and more importantly, allowing its effective inference on 4×RTX 3090 (24G) or 8×RTX 2080 Ti (11G) GPUs, the most ever affordable GPUs required for using 100B-scale models. The GLM-130B model weights are publicly accessible and its code, training logs, related toolkit, and lessons learned are open-sourced at https://github.com/THUDM/GLM-130B/.

Causal Estimation for Text Data with (Apparent) Overlap Violations

Lin Gui,Victor Veitch

Consider the problem of estimating the causal effect of some attribute of a text document; for example: what effect does writing a polite vs. rude email have on response time? To estimate a causal effect from observational data, we need to adjust for confounding aspects of the text that affect both the treatment and outcome---e.g., the topic or writing level of the text. These confounding aspects are unknown a priori, so it seems natural to adjust for the entirety of the text (e.g., using a transformer). However, causal identification and estimation procedures rely on the assumption of overlap: for all levels of the adjustment variables, there is randomness leftover so that every unit could have (not) received treatment. Since the treatment here is itself an attribute of the text, it is perfectly determined, and overlap is apparently violated. The purpose of this paper is to show how to handle causal identification and obtain robust causal estimation in the presence of apparent overlap violations. In brief, the idea is to use supervised representation learning to produce a data representation that preserves confounding information while eliminating information that is only predictive of the treatment. This representation then suffices for adjustment and satisfies overlap. Adapting results on non-parametric estimation, we show that this procedure shows robustness with respect to conditional outcome misestimation and yields a low-bias estimator that admits valid uncertainty quantification under weak conditions. Empirical results show reductions in bias and strong improvements in uncertainty quantification relative to the natural (transformer-based) baseline.

Understanding Pruning at Initialization: An Effective Node-Path Balancing Perspective

Hoang Pham,Anh Ta,Shiwei Liu,Dung D. Le,Long Tran-Thanh

Pruning at initialization (PaI) methods aim to remove weights of neural networks before training in pursuit of reducing training costs. While current PaI methods are promising and outperform random pruning, much work remains to be done to understand and improve PaI methods to achieve the performance of pruning after training. In particular, recent studies (Frankle et al., 2021; Su et al., 2020) present empirical evidence for the potential of PaI, and show intriguing properties like layerwise random shuffling connections of pruned networks preserves or even improves the performance. Our paper gives new perspectives on PaI from the geometry of subnetwork configurations. We propose to use two quantities to probe the shape of subnetworks: the numbers of effective paths and effective nodes (or channels). Using these numbers, we provide a principled framework to better understand PaI methods. Our main findings are: (i) the width of subnetworks matters in regular sparsity levels (< 99%) - this matches the competitive performance of shuffled layerwise subnetworks; (ii) node-path balancing plays a critical role in the quality of PaI subnetworks, especially in extreme sparsity regimes. These innovate an important direction to network pruning that takes into account the subnetwork topology itself. To illustrate the promise of this direction, we present a fairly naive method based on SynFlow (Tanaka et al., 2020) and conduct extensive experiments on different architectures and datasets to demonstrate its effectiveness.

****

Data Continuity Matters: Improving Sequence Modeling with Lipschitz Regularizer

Eric Qu,Xufang Luo,Dongsheng Li

Sequence modeling is a core problem in machine learning, and various neural networks have been designed to process different types of sequence data. However, few attempts have been made to understand the inherent data property of sequence data, neglecting the critical factor that may significantly affect the performance of sequence modeling. In this paper, we theoretically and empirically analyze a generic property of sequence data, i.e., continuity, and connect this property with the performance of deep models. First, we empirically observe that different kinds of models for sequence modeling prefer data with different continuity. Then, we theoretically analyze the continuity preference of different models in both time and frequency domains. To further utilize continuity to improve sequence modeling, we propose a simple yet effective Lipschitz Regularizer, that can flexibly adjust data continuity according to model preferences, and bring very little extra computational cost. Extensive experiments on various tasks demonstrate that altering data continuity via Lipschitz Regularizer can largely improve the performance of many deep models for sequence modeling.

MoDem: Accelerating Visual Model-Based Reinforcement Learning with Demonstrations

Nicklas Hansen,Yixin Lin,Hao Su,Xiaolong Wang,Vikash Kumar,Aravind Rajeswaran

Poor sample efficiency continues to be the primary challenge for deployment of deep Reinforcement Learning (RL) algorithms for real-world applications, and in particular for visuo-motor control. Model-based RL has the potential to be highly sample efficient by concurrently learning a world model and using synthetic rollouts for planning and policy improvement. However, in practice, sample-efficient learning with model-based RL is bottlenecked by the exploration challenge. In this work, we find that leveraging just a handful of demonstrations can dramatically improve the sample-efficiency of model-based RL. Simply appending demonstrations to the interaction dataset, however, does not suffice. We identify key ingredients for leveraging demonstrations in model learning -- policy pretraining, targeted exploration, and oversampling of demonstration data -- which forms the three phases of our model-based RL framework. We empirically study three complex visuo-motor control domains and find that our method is 160%-250% more successful in completing sparse reward tasks compared to prior approaches in the low data regime (100k interaction steps, 5 demonstrations). Code and videos are available at https://nicklashansen.github.io/modemrl.

Improving the Estimation of Instance-dependent Transition Matrix by using Self-supervised Learning

Yexiong Lin,Yu Yao,Zhaoqing Wang,Xu Shen,Jun Yu,Bo Han,Tongliang Liu

The transition matrix reveals the transition relationship between clean labels and noisy labels. It plays an important role in building statistically consistent classifiers. In real-world applications, the transition matrix is usually unknown and has to be estimated. It is a challenging task to accurately estimate the transition matrix, especially when it depends on the instance. Given that both instances and noisy labels are available, the major difficulty of learning the transition matrix comes from the missing of clean information. A lot of methods have been proposed to infer clean information. The self-supervised learning has demonstrated great success. These methods could even achieve comparable performance with supervised learning on some datasets but without requiring any labels during the training. It implies that these methods can efficiently infer clean labels.

Motivated by this, in this paper, we have proposed a practical method that leverages self-supervised learning to help learn the instance-dependent transition matrix. Empirically, the proposed method has achieved state-of-the-art performance on different datasets.

****

Holographic-(V)AE: an end-to-end SO(3)-Equivariant (Variational) Autoencoder in Fourier Space

Gian Marco Visani,Michael Neal Pun,Armita Nourmohammad

Group-equivariant neural networks have emerged as a data-efficient approach to solve classification and regression tasks, while respecting the relevant symmetries of the data. However, little work has been done to extend this paradigm to the unsupervised and generative domains. Here, we present Holographic-(V)AE (H-(V)AE), a fully end-to-end SO(3)-equivariant (variational) autoencoder in Fourier space, suitable for unsupervised learning and generation of data distributed around a specified origin. H-(V)AE is trained to reconstruct the spherical Fourier encoding of data, learning in the process a latent space with a maximally informative invariant embedding alongside an equivariant frame describing the orientation of the data. We extensively test the performance of H-(V)AE on diverse datasets and show that its latent space efficiently encodes the categorical features of spherical images and structural features of protein atomic environments. Our work can further be seen as a case study for equivariant modeling of a data distribution by reconstructing its Fourier encoding.

****

A general differentially private learning framework for decentralized data

Mei Li,Bo Pan,Yafei Wang,Lingchen Kong,Linglong Kong,Bei Jiang

Decentralized consensus learning has been hugely successful, which minimizes a finite sum of expected objective functions over a network of nodes. However, the local communication across neighboring nodes in the network may lead to the leakage of private information. To address this challenge, we propose a general differentially private (DP) learning framework for decentralized data that applies to many non-smooth learning problems. We show that the proposed algorithm retains the performance guarantee in terms of stability, generalization, and finite sample performance. We investigate the impact of local privacy-preserving computation on the global DP guarantee. Further, we extend the discussion by adopting a new class of noise-adding DP mechanisms based on generalized Gaussian distributions to improve the utility-privacy trade-offs. Our numerical results demonstrate the effectiveness of our algorithm and its better performance over the state-of-the-art baseline methods in various decentralized settings.

****

Wasserstein Barycenter-based Model Fusion and Linear Mode Connectivity of Neural Networks

Aditya Kumar Akash,Sixu Li,Nicolas Garcia Trillos

Based on the concepts of Wasserstein barycenter (WB) and Gromov-Wasserstein barycenter (GWB), we propose a unified mathematical framework for neural network (NN) model fusion and utilize it to reveal new insights about the linear mode connectivity of SGD solutions. In our framework, the fusion occurs in a layer-wise manner and builds on an interpretation of a node in a network as a function of the layer preceding it.

The versatility of our mathematical framework allows us to talk about model fusion and linear mode connectivity for a broad class of NNs, including fully connected NN, CNN, ResNet, RNN, and LSTM, in each case exploiting the specific structure of the network architecture. We present extensive numerical experiments to: 1) illustrate the strengths of our approach in relation to other model fusion methodologies and 2) from a certain perspective, provide new empirical evidence for recent conjectures which say that two local minima found by gradient-based methods end up lying on the same basin of the loss landscape after a proper permutation of weights is applied to one of the models.

****

Weakly-Supervised Domain Adaptation in Federated Learning

Enyi Jiang,Oluwasanmi O Koyejo

Federated domain adaptation (FDA) describes the setting where a set of source clients seek to optimize the performance of a target client. To be effective, FDA must address some of the distributional challenges of Federated learning (FL). For instance, FL systems exhibit distribution shifts across clients. Further, labeled data are not always available among the clients. To this end, we propose and compare novel approaches for FDA, combining the few labeled target samples with the source data when auxiliary labels are available to the clients. The in-distribution auxiliary information is included during local training to boost out-of-domain accuracy. Also, during fine-tuning, we devise a simple yet efficient gradient projection method to detect the valuable components from each source client model towards the target direction. The extensive experiments on medical imaging datasets show that our proposed framework significantly improves federated domain adaptation performance.

****

PD-MORL: Preference-Driven Multi-Objective Reinforcement Learning Algorithm

Toygun Basaklar,Suat Gumussoy,Umit Ogras

Multi-objective reinforcement learning (MORL) approaches have emerged to tackle many real-world problems with multiple conflicting objectives by maximizing a joint objective function weighted by a preference vector. These approaches find fixed customized policies corresponding to preference vectors specified during training. However, the design constraints and objectives typically change dynamically in real-life scenarios. Furthermore, storing a policy for each potential preference is not scalable. Hence, obtaining a set of Pareto front solutions for the entire preference space in a given domain with a single training is critical. To this end, we propose a novel MORL algorithm that trains a single universal network to cover the entire preference space scalable to continuous robotic tasks. The proposed approach, Preference-Driven MORL (PD-MORL), utilizes the preferences as guidance to update the network parameters. It also employs a novel parallelization approach to increase sample efficiency. We show that PD-MORL achieves up to 25% larger hypervolume for challenging continuous control tasks and uses an order of magnitude fewer trainable parameters compared to prior approaches.

****

When Majorities Prevent Learning: Eliminating Bias to Improve Worst-group and Out-of-distribution Generalization

Yu Yang,Gintare Karolina Dziugaite,Baharan Mirzasoleiman

Modern neural networks trained on large datasets have achieved state-of-the-art (in-distribution) generalization performance on various tasks. However, their good generalization performance has been shown to be contributed largely to overfitting spurious biases in large datasets. This is evident by the poor generalization performance of such models on minorities and out-of-distribution data. To alleviate this issue, subsampling the majority groups has been shown to be very effective. However, it is not clear how to find the subgroups (e.g. within a class) in large real-world datasets. Besides, naively subsampling the majority groups can entirely deplete some of their smaller sub-populations and drastically harm the in-distribution performance. Here, we show that tracking gradient trajectories of examples in initial epochs allows for finding large subpopulations of data points. We leverage this observation and propose an importance sampling method that is biased towards selecting smaller subpopulations, and eliminates bias in the large subpopulations. Our experiments confirm the effectiveness of our approach in eliminating spurious biases and learning higher-quality models with superior in- and out-of-distribution performance on various datasets.

Understanding the Role of Nonlinearity in Training Dynamics of Contrastive Learning

Yuandong Tian

While the empirical success of self-supervised learning (SSL) heavily relies on the usage of deep nonlinear models, existing theoretical works on SSL understanding still focus on linear ones. In this paper, we study the role of nonlinearity in the training dynamics of contrastive learning (CL) on one and two-layer nonlinear networks with homogeneous activation $h(x) = h'(x)x$. We have two major theoretical discoveries. First, the presence of nonlinearity can lead to many local optima even in 1-layer setting, each corresponding to certain patterns from the data distribution, while with linear activation, only one major pattern can be learned. This suggests that models with lots of parameters can be regarded as a \emph{brute-force} way to find these local optima induced by nonlinearity. Second, in the 2-layer case, linear activation is proven not capable of learning specialized weights into diverse patterns, demonstrating the importance of nonlinearity. In addition, for 2-layer setting, we also discover \emph{global modulation}: those local patterns discriminative from the perspective of global-level patterns are prioritized to learn, further characterizing the learning process. Simulation verifies our theoretical findings.

****

Oracle-oriented Robustness: Robust Image Model Evaluation with Pretrained Models as Surrogate Oracle

Peiyan Zhang,Sunghun Kim,Eric Xing,Haohan Wang

Machine learning has demonstrated remarkable performances over finite datasets, yet whether the scores over the fixed benchmarks can sufficiently indicate the model’s performances in the real world is still in discussion. In reality, an ideal robust model will probably behave similarly to the oracle (*e.g.*, the human users), thus a good evaluation protocol is probably to evaluate the models’ behaviors in comparison to the oracle. In this paper, we introduce a new robustness measurement that directly measures the image classification model’s performance compared with a surrogate oracle. Besides, we design a simple method that can accomplish the evaluation beyond the scope of the benchmarks. Our method extends the image datasets with new samples that are sufficiently perturbed to be distinct from the ones in the original sets, but are still bounded within the same causal structure the original test image represents, constrained by a surrogate oracle model pretrained with a large amount of samples. As a result, our new method will offer us a new way to evaluate the models’ robustness performances, free of limitations of fixed benchmarks or constrained perturbations, although scoped by the power of the oracle. In addition to the evaluation results, we also leverage our generated data to understand the behaviors of the model and our new evaluation strategies.

Certified Robustness on Structural Graph Matching

Huaqing Shao,Lanjun Wang,Yongwei Wang,Qibing Ren,Junchi Yan

The vulnerability of graph matching (GM) to adversarial attacks has received increasing attention from emerging empirical studies, while the certified robustness of GM has not been explored. Motivated by randomized smoothing, we are the first to define certified robustness on GM and design a new certification strategy called Structure-based Certified Robustness of Graph Matching (SCR-GM). Structural prior information of nodes is used to construct a joint smoothing distribution matrix with physical significance, which certifies a wider range than those obtained by previous iterative optimization methods. Furthermore, we propose a certified space that can be used to derive a strictly certified radius and two radii for evaluation. Experimental results on graph matching datasets reveal that our strategy achieves state-of-the-art ℓ_{2} certified accuracy and regions.

CodeGen: An Open Large Language Model for Code with Multi-Turn Program Synthesis

Erik Nijkamp,Bo Pang,Hiroaki Hayashi,Lifu Tu,Huan Wang,Yingbo Zhou,Silvio Savarese,Caiming Xiong

Program synthesis strives to generate a computer program as a solution to a given problem specification, expressed with input-output examples or natural language descriptions. The prevalence of large language models advances the state-of-the-art for program synthesis, though limited training resources and data impede open access to such models. To democratize this, we train and release a family of large language models up to 16.1B parameters, called CODEGEN, on natural language and programming language data, and open source the training library JAXFORMER. We show the utility of the trained model by demonstrating that it is competitive with the previous state-of-the-art on zero-shot Python code generation on HumanEval. We further investigate the multi-step paradigm for program synthesis, where a single program is factorized into multiple prompts specifying subproblems. To this end, we construct an open benchmark, Multi-Turn Programming Benchmark (MTPB), consisting of 115 diverse problem sets that are factorized into multi-turn prompts. Our analysis on MTPB shows that the same intent provided to CODEGEN in multi-turn fashion significantly improves program synthesis over that provided as a single turn. We make the training library JAXFORMER and model checkpoints available as open source contribution: https://github.com/salesforce/CodeGen.

Bayesian Optimal Experimental Design for the Survey Bandit Setting

Sang T. Truong,Willie Neiswanger,Susan Athey

The contextual bandit is a classic problem in sequential decision making under uncertainty that finds broad application to tasks in precision medicine, personalized education, and drug discovery. Here, a decision maker repeatedly receives a context, takes an action, and then observes an associated outcome, with the goal of choosing actions that achieve a minimal regret. However, in many settings, the context is not given, and the decision maker must instead collect some information to infer a context before proceeding. For example, when a doctor does not have prior information about a patient, they might ask a sequence of questions before recommending a medical treatment. In this paper, we aim to develop methods for this setting—which we refer to as the \emph{survey bandit}—where the decision maker is not given access to the context but can ask a finite sequence of questions to gain information about the context before taking an action and observing an outcome. Using insights from Bayesian optimal experimental design (BOED) and decision-theoretic information theory, we view the interaction with each user as a BOED task, where the goal is to ask a sequence of questions that elicit the most information about the optimal action for this user. Our procedure is agnostic to the choice of probabilistic model, and we demonstrate its usefulness in a few common classes of distributions. Our algorithm achieves significantly better performance on both synthetic and real data relative to existing baseline methods while remaining statistically efficient, interpretable, and computationally friendly.

Synchronized Contrastive Pruning for Efficient Self-Supervised Learning

Jian Meng,Li Yang,Deliang Fan,Jinwoo Shin,Jae-sun Seo

Various self-supervised learning (SSL) methods have demonstrated strong capability in learning visual representations from unlabeled data. However, the current state-of-the-art (SoTA) SSL methods largely rely on heavy encoders to achieve comparable performance as the supervised learning counterpart. Despite the well-learned visual representations, the large-sized encoders impede the energy efficient computation, especially for resource-constrained edge computing. Prior works have utilized the sparsity-induced asymmetry to enhance the contrastive learning of dense models, but the generality between asymmetric sparsity and self-supervised learning has not been fully discovered. Furthermore, transferring the supervised sparse learning to SSL is also largely under-explored. To address the research gap in prior works, this paper investigates the correlation between in-training sparsity and SSL. In particular, we propose a novel sparse SSL algorithm, e mbracing the benefits of contrastiveness while exploiting high sparsity during SSL training. The proposed framework is evaluated comprehensively with various granularities of sparsity, including element-wise sparsity, GPU-friendly N:M structured fine-grained sparsity, and hardware-specific structured sparsity. Extensive experiments across multiple datasets are performed, where the proposed method shows superior performance against the SoTA sparse learning algorithms with various SSL frameworks. Furthermore, the training speedup aided by the proposed method is evaluated with an actual DNN training accelerator model.

VEHICLE-INFRASTRUCTURE COOPERATIVE 3D DETECTION VIA FEATURE FLOW PREDICTION

Haibao Yu,Yingjuan Tang,Jilei Mao,Enze Xie,Jirui Yuan,Ping Luo,Zaiqing Nie

Effectively utilizing data from infrastructure could greatly improve autonomous driving safety. Vehicle-Infrastructure Cooperative 3D Object Detection (VIC3D) is an important task to localize and recognize objects surrounding the ego-vehicle by combining the sensor data from both ego-vehicle and roadside infrastructure. However, there are serious temporal asynchrony problems between vehicle and infrastructure data. To the best of our knowledge, no existing work in the literature could effectively solve the asynchrony problem with limited communication bandwidth and computational resources on vehicle-infrastructure devices. This work proposes a novel approach for VIC3D, called Feature Flow Network(FFNet), to effectively address the problem of temporal asynchrony caused by different sensor initialization and latency. Compared with previous feature fusion approaches that only use the current static feature, FFNet transmits the feature flow and generates the future features on-the-fly, aligned with the ego-vehicle timestamp. We propose a self-supervised method to train the feature flow generation model, and use the pre-trained infrastructure model to extract features from randomly assigned future frames as ground truth. Extensive experiments on the DAIR-V2X dataset (a large-scale real-world V2X dataset) show that FFNet establishes a new state of the art, surpassing SOTA methods by up to 5% mAP while with comparable transmission cost. In particularly, FFNet can even make up for almost all the performance drop caused by the temporal asynchrony in 200ms delay.

M-L2O: Towards Generalizable Learning-to-Optimize by Test-Time Fast Self-Adaptation

Junjie Yang,Xuxi Chen,Tianlong Chen,Zhangyang Wang,Yingbin Liang

Learning to Optimize (L2O) has drawn increasing attention as it often remarkably accelerates the optimization procedure of complex tasks by "overfitting" specific task type, leading to enhanced performance compared to analytical optimizers. Generally, L2O develops a parameterized optimization method (i.e., "optimizer") by learning from solving sample problems. This data-driven procedure yields L2O that can efficiently solve problems similar to those seen in training, that is, drawn from the same "task distribution". However, such learned optimizers often struggle when new test problems come with a substantially deviation from the training task distribution. This paper investigates a potential solution to this open challenge, by meta-training an L2O optimizer that can perform fast test-time self-adaptation to a out-of-distribution task, in only a few steps. We theoretically characterize the generalization of L2O, and further show that our proposed framework (termed as M-L2O) provably facilitates rapid task adaptation by locating well-adapted initial points for the optimizer weight. Empirical observations on several classic tasks like LASSO and Quadratic, demonstrate that M-L2O converges significantly faster than vanilla L2O with only 5 steps of adaptation, echoing our theoretical results. Codes are available in https://github.com/VITA-Group/M-L2O.

ReG-NAS: Graph Neural Network Architecture Search using Regression Proxy Task

Boyi Wei,Cong Hao

Neural Architecture Search (NAS) has become a focus that has been extensively researched in recent years. Innovative achievements are yielded from the area like convolutional neural networks (CNN), recurrent neural networks (RNN) and so on. However, research on NAS for graph neural networks (GNN) is still in a prelimin ary stage. Because of the special structure of graph data, some conclusions drew from CNN cannot be directly applied to GNN. At the same time, for NAS, the models' ranking stability is of great importance for it reflects the reliability of the NAS performance. Unfortunately, little research attention has been paid to it, making it a pitfall in the development of NAS research. In this paper, we proposed a novel NAS pipeline, ReG-NAS, which balances stability, reliability and time cost to search the best GNN architecture. Besides, for the first time, we systematically analyzed factors that will affect models' ranking stability in a given search space, which can be used as a guideline for subsequent studies. Our codes are available at https://anonymous.4open.science/r/ReG-NAS-4D21

Mesh-Independent Operator Learning for PDEs using Set Representations

Seungjun Lee

Operator learning, learning the mapping between infinite-dimensional function spaces, has been attracted as an alternative approach to traditional numerical methods to solve partial differential equations (PDEs). In practice, the functions of the physical systems are often observed by sparse or even irregularly distributed measurements, thus the functions are discretized and usually represented by finite structured arrays, which are given as data of input-output pairs. Through training with the arrays, the solution of the trained models should be independent of the discretization of the input function and can be queried at any point continuously. Therefore, the architectures for operator learning should be flexibly compatible with arbitrary sizes and locations of the measurements, otherwise, it can restrict the scalability when the observations have discrepancies between measurement formats. In this paper, we propose to treat the discretized functions as set-valued data and construct an attention-based model, called mesh-independent operator learner (MIOL), to provide proper treatments of input functions and query coordinates for the solution functions by detaching the dependencies on input and output meshes. Our models pre-trained with benchmark datasets of operator learning are evaluated by downstream tasks to demonstrate the generalization abilities to varying discretization formats of the system, which are natural characteristics of the continuous solution of the PDEs.

ROSCOE: A Suite of Metrics for Scoring Step-by-Step Reasoning

Olga Golovneva,Moya Peng Chen,Spencer Poff,Martin Corredor,Luke Zettlemoyer,Maryam Fazel-Zarandi,Asli Celikyilmaz

Large language models show improved downstream task performance when prompted to generate step-by-step reasoning to justify their final answers. These reasoning steps greatly improve model interpretability and verification, but objectively studying their correctness (independent of the final answer) is difficult without reliable methods for automatic evaluation. We simply do not know how often the stated reasoning steps actually support the final end task predictions. In this work, we present ROSCOE, a suite of interpretable, unsupervised automatic scores that improve and extend previous text generation evaluation metrics. To evaluate ROSCOE against baseline metrics, we design a typology of reasoning errors and collect synthetic and human evaluation scores on commonly used reasoning datasets. In contrast with existing metrics, ROSCOE can measure semantic consistency, logicality, informativeness, fluency, and factuality — among other traits — by leveraging properties of step-by-step rationales. We empirically verify the strength of our metrics on five human annotated and six programmatically perturbed diagnostics datasets - covering a diverse set of tasks that require reasoning skills and show that ROSCOE can consistently outperform baseline metrics.

Robust Multi-Agent Reinforcement Learning against Adversaries on Observation

Chenghe Wang,Yuhang Ran,Lei Yuan,Yang Yu,Zongzhang Zhang

With the broad applications of deep learning, such as image classification, it is becoming increasingly essential to tackle the vulnerability of neural networks when facing adversarial attacks, which have been widely studied recently. In the cooperative multi-agent reinforcement learning field, which has also shown potential in real-life domains, little work focuses on the problem of adversarial a ttacks. However, adversarial attacks on observations that can undermine the coordination among agents are likely to occur in actual deployment. This paper proposes a training framework that progressively generates adversarial attacks on agents' observations to help agents learn a robust cooperative policy. One attacker makes decisions on a hybrid action space that it first chooses an agent to attack and then outputs the perturbation vector. The victim policy is then trained against the attackers. Experimental results show that our generated adversarial attacks are diverse enough to improve the agents' robustness against possible disturbances.

Limitations of Piecewise Linearity for Efficient Robustness Certification
Klas Leino

Certified defenses against small-norm adversarial examples have received growing attention in recent years; though certified accuracies of state-of-the-art methods remain far below their non-robust counterparts, despite the fact that benchmark datasets have been shown to be well-separated at far larger radii than the literature generally attempts to certify. In this work, we offer insights that identify potential factors in this performance gap. Specifically, our analysis reveals that piecewise linearity imposes fundamental limitations on the tightness of leading certification techniques. These limitations are felt in practical terms as a greater need for capacity in models hoped to be certified efficiently. Moreover, this is _in addition_ to the capacity necessary to learn a robust boundary, studied in prior work. However, we argue that addressing the limitations of piecewise linearity through scaling up model capacity may give rise to potential difficulties---particularly regarding robust generalization---therefore, we conclude by suggesting that developing _smooth_ activation functions may be the way forward for advancing the performance of certified neural networks.

Forces are not Enough: Benchmark and Critical Evaluation for Machine Learning Force Fields with Molecular Simulations
Xiang Fu,Zhenghao Wu,Wujie Wang,Tian Xie,Sinan Keten,Rafael Gomez-Bombarelli,Tommi S. Jaakkola

Molecular dynamics (MD) simulation techniques are widely used for various natural science applications. Increasingly, machine learning (ML) force field (FF) models begin to replace ab-initio simulations by predicting forces directly from atomic structures. Despite significant progress in this area, such techniques are primarily benchmarked by their force/energy prediction errors, even though the practical use case would be to produce realistic MD trajectories. We aim to fill this gap by introducing a novel benchmark suite for ML MD simulation. We curate representative MD systems, including water, organic molecules, peptide, and materials, and design evaluation metrics corresponding to the scientific objectives of respective systems. We benchmark a collection of state-of-the-art (SOTA) ML FF models and illustrate, in particular, how the commonly benchmarked force accuracy is not well aligned with relevant simulation metrics. We demonstrate when and how selected SOTA methods fail, along with offering directions for further improvement. Specifically, we identify stability as a key metric for ML models to improve. Our benchmark suite comes with a comprehensive open source codebase for training and simulation with ML FFs to facilitate further work.

FlexRound: Learnable Rounding by Element-wise Division for Post-Training Quantization
Jung Hyun Lee,Jeonghoon Kim,Se Jung Kwon,Dongsoo Lee

Post-training Quantization (PTQ) has been gaining popularity for the deployment of deep neural networks on resource-limited devices since unlike quantization-aware training, neither a full training dataset nor end-to-end training is required at all. As PTQ schemes based on reconstructing each layer or block output turn out to be effective to enhance quantized model performance, recent works have developed algorithms to devise and learn a new weight-rounding scheme so as to better reconstruct each layer or block output. We notice that, however, such new rounding schemes are established on element-wise addition. In this work, we propo se a simple yet effective new rounding mechanism for PTQ, coined FlexRound, via element-wise division to learn not only a common quantization grid size but also a different scale for each pre-trained weight. Thanks to the reciprocal rule of derivatives induced by element-wise division, FlexRound is inherently able to exploit the importance of a pre-trained weight when updating its corresponding scale, and thus, flexibly quantize a pre-trained weight depending on its own importance. We empirically validate the efficacy of FlexRound on a wide range of models and tasks. To the best of our knowledge, our work is the first to carry out comprehensive experiments on image classification, natural language understanding, and natural language generation in the per-tensor uniform PTQ setting. Our code will be open-sourced soon.

Re-calibrating Feature Attributions for Model Interpretation

Peiyu Yang,NAVEED AKHTAR,Zeyi Wen,Mubarak Shah,Ajmal Saeed Mian

The ability to interpret machine learning models is critical for high-stakes applications. Due to its desirable theoretical properties, path integration is a widely used scheme for feature attribution to interpret model predictions. However, the methods implementing this scheme currently rely on absolute attribution scores to eventually provide sensible interpretations. This not only contradicts the premise that the features with larger attribution scores are more relevant to the model prediction, but also conflicts with the theoretical settings for which the desirable properties of the attributions are proven. We address this by devising a method to first compute an appropriate reference for the path integration scheme. This reference further helps in identifying valid interpolation points on a desired integration path. The reference is computed in a gradient ascending direction on the model's loss surface, while the interpolations are performed by analyzing the model gradients and variations between the reference and the input. The eventual integration is effectively performed along a non-linear path. Our scheme can be incorporated into the existing integral-based attribution methods. We also devise an effective sampling and integration procedure that enables employing our scheme with multi-reference path integration efficiently. We achieve a marked performance boost for a range of integral-based attribution methods on both local and global evaluation metrics by enhancing them with our scheme. Our extensive results also show improved sensitivity, sanity preservation and model robustness with the proposed re-calibration of the attribution techniques with our method.

Adversarial Diversity in Hanabi

Brandon Cui,Andrei Lupu,Samuel Sokota,Hengyuan Hu,David J Wu,Jakob Nicolaus Foerster

Many Dec-POMDPs admit a qualitatively diverse set of ''reasonable'' joint policies, where reasonableness is indicated by symmetry equivariance, non-sabotaging behaviour and the graceful degradation of performance when paired with ad-hoc partners. Some of the work in diversity literature is concerned with generating these policies. Unfortunately, existing methods fail to produce teams of agents that are simultaneously diverse, high performing, and reasonable. In this work, we propose a novel approach, adversarial diversity (ADVERSITY), which is designed for turn-based Dec-POMDPs with public actions. ADVERSITY relies on off-belief learning to encourage reasonableness and skill, and on ''repulsive'' fictitious transitions to encourage diversity. We use this approach to generate new agents with distinct but reasonable play styles for the card game Hanabi and open-source our agents to be used for future research on (ad-hoc) coordination.

3D UX-Net: A Large Kernel Volumetric ConvNet Modernizing Hierarchical Transformer for Medical Image Segmentation

Ho Hin Lee,Shunxing Bao,Yuankai Huo,Bennett A. Landman

The recent 3D medical ViTs (e.g., SwinUNETR) achieve the state-of-the-art performances on several 3D volumetric data benchmarks, including 3D medical image segmentation. Hierarchical transformers (e.g., Swin Transformers) reintroduced several ConvNet priors and further enhanced the practical viability of adapting volum etric segmentation in 3D medical datasets. The effectiveness of hybrid approaches is largely credited to the large receptive field for non-local self-attention and the large number of model parameters. We hypothesize that volumetric ConvNets can simulate the large receptive field behavior of these learning approaches with fewer model parameters using depth-wise convolution. In this work, we propose a lightweight volumetric ConvNet, termed 3D UX-Net, which adapts the hierarchical transformer using ConvNet modules for robust volumetric segmentation. Specifically, we revisit volumetric depth-wise convolutions with large kernel (LK) size (e.g. starting from $7\times7\times7$) to enable the larger global receptive fields, inspired by Swin Transformer. We further substitute the multi-layer perceptron (MLP) in Swin Transformer blocks with pointwise depth convolutions and enhance model performances with fewer normalization and activation layers, thus reducing the number of model parameters. 3D UX-Net competes favorably with current SOTA transformers (e.g. SwinUNETR) using three challenging public datasets on volumetric brain and abdominal imaging: 1) MICCAI Challenge 2021 FLARE, 2) MICCAI Challenge 2021 FeTA, and 3) MICCAI Challenge 2022 AMOS. 3D UX-Net consistently outperforms SwinUNETR with improvement from 0.929 to 0.938 Dice (FLARE2021) and 0.867 to 0.874 Dice (Feta2021). We further evaluate the transfer learning capability of 3D UX-Net with AMOS2022 and demonstrates another improvement of 2.27% Dice (from 0.880 to 0.900). The source code with our proposed model are available at https://github.com/MASILab/3DUX-Net.

Push and Pull: Competing Feature-Prototype Interactions Improve Semi-supervised Semantic Segmentation

Yuhang Ding,Yifan Sun,Yi Yang

This paper challenges semi-supervised segmentation with a rethink on the feature-prototype interaction in the classification head. Specifically, we view each weight vector in the classification head as the prototype of a semantic category. The basic practice in the softmax classifier is to pull a feature towards its positive prototype (i.e., the prototype of its class), as well as to push it away from its negative prototypes. In this paper, we focus on the interaction between the feature and its negative prototypes, which is always “pushing” to make them dissimilar. While the pushing-away interaction is necessary, this paper reveals a new mechanism that the contrary interaction of pulling close negative prototypes is also beneficial. We have two insights for this counter-intuitive interaction: 1) some pseudo negative prototypes might actually be positive so that the pulling interaction can help resisting the pseudo-label noises, and 2) some true negative prototypes might contain contextual information that is beneficial. Therefore, we integrate these two competing interactions into a Push-and-Pull Learning (PPL) method. On the one hand, PPL introduces the novel pulling-close interaction between features and negative prototypes with a feature-to-prototype attention. On the other hand, PPL reinforces the original pushing-away interaction with a multi-prototype contrastive learning. While PPL is very simple, experiments show that it substantially improves semi-supervised segmentation and sets a new state of the art.

Interpretability in the Wild: a Circuit for Indirect Object Identification in GPT-2 Small

Kevin Ro Wang,Alexandre Variengien,Arthur Conmy,Buck Shlegeris,Jacob Steinhardt

Research in mechanistic interpretability seeks to explain behaviors of ML models in terms of their internal components. However, most previous work either focuses on simple behaviors in small models, or describes complicated behaviors in larger models with broad strokes. In this work, we bridge this gap by presenting an explanation for how GPT-2 small performs a natural language task that requires logical reasoning: indirect object identification (IOI). Our explanation encompasses 28 attention heads grouped into 7 main classes, which we discovered using a combination of interpretability approaches including causal interventions and projections.

To our knowledge, this investigation is the largest end-to-end attempt at reverse-engineering a natural behavior "in the wild" in a language model. We evaluate

the reliability of our explanation using three quantitative criteria - faithfulness, completeness and minimality. Though these criteria support our explanation, they also point to remaining gaps in our understanding.
Our work provides evidence that a mechanistic understanding of large ML models is feasible, opening opportunities to scale our understanding to both larger models and more complex tasks.

Equivariant Descriptor Fields: SE(3)-Equivariant Energy-Based Models for End-to-End Visual Robotic Manipulation Learning
Hyunwoo Ryu,Hong-in Lee,Jeong-Hoon Lee,Jongeun Choi
End-to-end learning for visual robotic manipulation is known to suffer from sample inefficiency, requiring large numbers of demonstrations. The spatial roto-translation equivariance, or the SE(3)-equivariance can be exploited to improve the sample efficiency for learning robotic manipulation. In this paper, we present SE(3)-equivariant models for visual robotic manipulation from point clouds that can be trained fully end-to-end. By utilizing the representation theory of the Lie group, we construct novel SE(3)-equivariant energy-based models that allow highly sample efficient end-to-end learning. We show that our models can learn from scratch without prior knowledge and yet are highly sample efficient (5~10 demonstrations are enough). Furthermore, we show that our models can generalize to tasks with (i) previously unseen target object poses, (ii) previously unseen target object instances of the category, and (iii) previously unseen visual distractors. We experiment with 6-DoF robotic manipulation tasks to validate our models' sample efficiency and generalizability. Codes are available at: https://github.com/tomato1mule/edf

Anatomical Structure-Aware Image Difference Graph Learning for Difference-Aware Medical Visual Question Answering
Xinyue Hu,Lin Gu,Qingyu Chen,Liangchen Liu,Kazuma Kobayashi,Qiyuan An,Zhang Mengliang,Tatsuya Harada,Zhiyong Lu,Yingying Zhu
To contribute to automating the medical vision-language model, we propose a novel Chest-Xray Different Visual Question Answering (VQA) task. Given a pair of main and reference images, this task attempts to answer several questions on both diseases and more importantly, the differences between them. This is consistent with the radiologist's diagnosis practice that compares the current image with the reference before concluding the report. For this task, we propose a new dataset, namely MIMIC-Diff-VQA including 700,821 QA pairs on 109,872 pairs of images. Meanwhile, we also propose a novel expert knowledge-aware graph representation learning model to address this problem. We leveraged the expert knowledge such as anatomical structure prior, semantic and spatial knowledge to construct a multi-relationship graph to represent the image differences between two images for the image difference VQA task. Our dataset and code will be released upon publication. We believe this work would further push forward the medical vision language model.
****
Explaining Temporal Graph Models through an Explorer-Navigator Framework
Wenwen Xia,Mincai Lai,Caihua Shan,Yao Zhang,Xinnan Dai,Xiang Li,Dongsheng Li
While GNN explanation has recently received significant attention, existing works are consistently designed for static graphs. Due to the prevalence of temporal graphs, many temporal graph models have been proposed, but explaining their predictions remains to be explored. To bridge the gap, in this paper, we propose T-GNNExplainer for temporal graph model explanation. Specifically, we regard a temporal graph constituted by a sequence of temporal events. Given a target event, our task is to find a subset of previously occurred events that lead to the model's prediction for it. To handle this combinatorial optimization problem, T-GNNExplainer includes an explorer to find the event subsets with Monte Carlo Tree Search (MCTS) and a navigator that learns the correlations between events and helps reduce the search space. In particular, the navigator is trained in advance and then integrated with the explorer to speed up searching and achieve better results. To the best of our knowledge, T-GNNExplainer is the first explainer tailo

red for temporal graph models. We conduct extensive experiments to evaluate the performance of T-GNNExplainer. Experimental results on both real-world and synthetic datasets demonstrate that T-GNNExplainer can achieve superior performance with up to about 50% improvement in Area under Fidelity-Sparsity Curve.

Tackling Diverse Tasks via Cross-Modal Transfer Learning
Junhong Shen,Liam Li,Lucio M. Dery,Corey Staten,Mikhail Khodak,Graham Neubig,Ameet Talwalkar

Fine-tuning large-scale pretrained models has led to remarkable progress in well-studied modalities such as vision and NLP. However, similar gains have not been observed in many other tasks due to an assumed lack of relevant pretrained models for these diverse modalities. In this work, we revisit this assumption by studying the cross-modal transfer ability of large-scale pretrained models. We introduce ORCA, a general cross-modal fine-tuning workflow that enables fast and automatic exploitation of existing pretrained models for diverse tasks. ORCA achieves task-specific adaptation by learning feature embeddings that minimize an optimal transport distance metric to map the data distribution in the end-task modality to the pretraining modality. We test ORCA on 13 tasks with varying modalities and input-output types. ORCA performs the best on 10 of them and is in the top three on the others. We further quantify the importance of embedding distance for downstream performance, highlight ORCA’s utility for data-limited tasks, and demonstrate its compatibility with same-modality transfer.

Leveraged Asymmetric Loss with Disambiguation for Multi-label Recognition with One-Positive Annotations
Jingyi Cui,Tao Huang,Hanyuan Hang,Yisen Wang,James Kwok

In the problem of multi-label learning from single positive labels (SPL), we learn the potential multiple labels from one observable single positive annotation. Despite many efforts to solve this problem, an effective algorithm with sound theoretical understanding is still in need. In this paper, we propose a novel loss function for the SPL problem, called leveraged asymmetric loss with disambiguation (LASD), where we introduce a pair of leverage parameters to address the severe negative-positive imbalance. From the theoretical perspective, we analyze the SPL problem, for the first time, from the perspective of risk consistency, which links the SPL loss with losses for ordinary multi-label classification. We prove the consistency of our proposed LASD loss to the cost-sensitive Hamming loss, which provides guidance to the empirical choice of our proposed leverage parameters. In experiments, we demonstrate the effectiveness of our proposed LASD loss function over other state-of-the-art methods and empirically verify our theoretical results.

Safe Reinforcement Learning with Contrastive Risk Prediction
Hanping Zhang,Yuhong Guo

As safety violations can lead to severe consequences in real-world applications, the increasing deployment of Reinforcement Learning (RL) in safety-critical domains such as robotics has propelled the study of safe exploration for reinforcement learning (safe RL). In this work, we propose a risk preventive training method for safe RL, which learns a statistical contrastive classifier to predict the probability of a state-action pair leading to unsafe states. Based on the predicted risk probabilities, we can collect risk preventive trajectories and reshape the reward function with risk penalties to induce safe RL policies. We conduct experiments in robotic simulation environments. The results show the proposed approach has comparable performance with the state-of-the-art model-based methods and outperforms conventional model-free safe RL approaches.

****

Analysis of differentially private synthetic data: a general measurement error approach
Yangdi Jiang,Yi Liu,Xiaodong Yan,Anne-Sophie Charest,Linglong Kong,Bei Jiang

Differential private (DP) synthetic datasets have been receiving significant att ention from academia, industry, and government. However, little is known about how to perform statistical inference using DP synthetic datasets. Naive approaches that do not take into account the induced uncertainty due to DP mechanism will result in biased estimators and invalid inferences. In this paper, we present a general class of bias-corrected DP estimators with valid asymptotic confidence intervals for parameters in regression settings, by establishing the connection between additive DP mechanisms and measurement error models. Our simulation shows that when the sample covariance between DP noises and data is close to zero, our estimator is far superior to the widely used sufficient statistic perturbation algorithm, and the CIs can achieve better coverage when comparing to the naive CIs obtained from ignoring the DP mechanism.

On the Efficacy of Server-Aided Federated Learning against Partial Client Participation

Haibo Yang,Peiwen Qiu,Prashant Khanduri,Jia Liu

Although federated learning (FL) has become a prevailing distributed learning framework in recent years due to its benefits in scalability/privacy, there remain many significant challenges in FL system design. Notably, most existing works in the current FL literature assume either full client or uniformly distributed client participation. Unfortunately, this idealistic assumption rarely hold in practice. It has been frequently observed that some clients may never participate in FL training (aka partial/incomplete participation) due to a meld of system heterogeneity factors. To mitigate impacts of partial client participation, an increasingly popular approach in practical FL systems is the sever-aided federated learning (SA-FL) framework, where one equips the server with an auxiliary dataset. However, despite the fact that SA-FL has been empirically shown to be effective in addressing the partial client participation problem, there remains a lack of theoretical understanding for SA-FL. Worse yet, even the ramifications of partial worker participation is not clearly understood in conventional FL so far. These theoretical gaps motivate us to rigorously investigate SA-FL. To this end, we first reveal that conventional FL is {\em not} PAC-learnable under partial participation in the worst case, which advances our understanding of conventional FL. Then, we show that the PAC-learnability of FL with partial client participation can indeed be revived by SA-FL, which theoretically justifies the use of SA-FL for the first time. Lastly, to further make SA-FL communication-efficient, we propose the \alg (\ul{s}erver-\ul{a}ided \ul{f}ederated \ul{a}ve\ul{r}ag\ul{i}ng) algorithm that enjoys convergence guarantee and the same level of communication efficiency and privacy as state-of-the-art FL.

Soft Neighbors are Positive Supporters in Contrastive Visual Representation Learning

Chongjian GE,Jiangliu Wang,Zhan Tong,Shoufa Chen,Yibing Song,Ping Luo

Contrastive learning methods train visual encoders by comparing views (e.g., often created via a group of data augmentations on the same instance) from one instance to others. Typically, the views created from one instance are set as positive, while views from other instances are negative. This binary instance discrimination is studied extensively to improve feature representations in self-supervised learning. In this paper, we rethink the instance discrimination framework and find the binary instance labeling insufficient to measure correlations between different samples. For an intuitive example, given a random image instance, there may exist other images in a mini-batch whose content meanings are the same (i.e., belonging to the same category) or partially related (i.e., belonging to a similar category). How to treat the images that correlate similarly to the current image instance leaves an unexplored problem. We thus propose to support the current image by exploring other correlated instances (i.e., soft neighbors). We first carefully cultivate a candidate neighbor set, which will be further utilized to explore the highly-correlated instances. A cross-attention module is then introduced to predict the correlation score (denoted as positiveness) of other correlated instances with respect to the current one. The positiveness score quantitatively measures the positive support from each correlated instance, and is e ncoded into the objective for pretext training. To this end, our proposed method benefits in discriminating uncorrelated instances while absorbing correlated instances for SSL. We evaluate our soft neighbor contrastive learning method (SNCLR) on standard visual recognition benchmarks, including image classification, object detection, and instance segmentation. The state-of-the-art recognition performance shows that SNCLR is effective in improving feature representations from both ViT and CNN encoders.

****

LA-BALD: An Information-Theoretic Image Labeling Task Sampler

Yuan-Hong Liao,Sanja Fidler

Large-scale visual recognition datasets with high-quality labels enable many computer vision applications, but also come with enormous annotation costs, especially since multiple annotators are typically queried per image to obtain a more reliable label. Recent work in label aggregation consolidates human annotations by combining them with the predictions of an online-learned predictive model. In this work, we devise an image labeling task sampler that actively selects image-worker pairs to efficiently reduce the noise in the human annotations and improve the predictive model at the same time. We propose an information-theoretic task sampler, Label Aggregation BALD (LA-BALD), to maximize the information contributing to the labeled dataset via human annotations and the model. The simulated experiments on ImageNet100-sandbox show that LA-BALD reduces the number of annotations by 19% and 12% on average compared to the two types of baselines. Our analysis shows that LA-BALD provides both more accurate annotations and a better online-learned predictive model, leading to better labeling efficiency over the baselines.

Offline RL for Natural Language Generation with Implicit Language Q Learning

Charlie Victor Snell,Ilya Kostrikov,Yi Su,Sherry Yang,Sergey Levine

Large language models distill broad knowledge from text corpora. However, they can be inconsistent when it comes to completing user specified tasks. This issue can be addressed by finetuning such models via supervised learning on curated datasets, or via reinforcement learning. In this work, we propose a novel offline RL method, implicit language Q-learning (ILQL), designed for use on language models, that combines both the flexible utility maximization framework of RL algorithms with the ability of supervised learning to leverage previously collected data, as well as its simplicity and stability. Our method employs a combination of value conservatism alongside an implicit dataset support constraint in learning value functions, which are then used to guide language model generations towards maximizing user-specified utility functions. In addition to empirically validating ILQL, we present a detailed empirical analysis of situations where offline RL can be useful in natural language generation settings, demonstrating how it can be a more effective utility optimizer than prior approaches for end-to-end dialogue, and how it can effectively optimize high variance reward functions based on subjective judgement, such as whether to label a comment as toxic or not.

MoCa: Cognitive Scaffolding for Language Models in Causal and Moral Judgment Tasks

Allen Nie,Yuhui Zhang,Atharva Amdekar,Christopher J Piech,Tatsunori Hashimoto,Tobias Gerstenberg

Human commonsense understanding of the physical and social world is organized around intuitive theories. These theories support making causal and moral judgments. When something bad happened, we naturally ask: who did what, and why? A rich literature in cognitive science has studied people's causal and moral intuitions. These works have revealed a number of factors that systematically influence people's judgments, such as the presence of norms, and whether or not the protagonist in a scenario was aware of their action's potential consequences. Here, we investigate whether large language models (LLMs) make causal and moral judgments about text-based scenarios that align with those of human participants. We find that without any annotations, LLMs and human participants are not well aligned (

17\%-39\% agreement). However, LLMs can accurately annotate what relevant factors are present in a scenario with simple expert-written instructions. We demonstrate how these annotations can be used to bring LLMs in closer alignment with people (36.3\%-47.2\% agreement). These results show how insights from cognitive science can help scaffold language models to more closely match human intuitions in challenging commonsense evaluation tasks.

Anchor Sampling for Federated Learning with Partial Client Participation

Feijie Wu,Song Guo,Zhihao Qu,Shiqi He,Ziming Liu

In federated learning, the support of partial client participation offers a flexible training strategy, but it deteriorates the model training efficiency. In this paper, we propose a framework FedAMD to improve the convergence property and maintain flexibility. The core idea is anchor sampling, which disjoints the partial participants into anchor and miner groups. Each client in the anchor group aims at the local bullseye with the gradient computation using a large batch. Guided by the bullseyes, clients in the miner group steer multiple near-optimal local updates using small batches and update the global model. With the joint efforts from both groups, FedAMD is able to accelerate the training process as well as improve the model performance. Measured by ϵ-approximation and compared to the state-of-the-art first-order methods, FedAMD achieves the convergence by up to $O(1/\epsilon)$ fewer communication rounds under non-convex objectives. In specific, we achieve a linear convergence rate under PL conditions. Empirical studies on real-world datasets validate the effectiveness of FedAMD and demonstrate the superiority of our proposed algorithm: Not only does it considerably save computation and communication costs, but also the test accuracy significantly improves.

Lattice Convolutional Networks for Learning Ground States of Quantum Many-Body Systems

Cong Fu,Xuan Zhang,Huixin Zhang,Hongyi Ling,Shenglong Xu,Shuiwang Ji

Deep learning methods have been shown to be effective in representing ground-state wave functions of quantum many-body systems. Existing methods use convolutional neural networks (CNNs) for square lattices due to their image-like structures. For non-square lattices, existing method uses graph neural network (GNN) in which structure information is not precisely captured, thereby requiring additional hand-crafted sublattice encoding. In this work, we propose lattice convolutions in which a set of proposed operations are used to convert non-square lattices into grid-like augmented lattices on which regular convolution can be applied. Based on the proposed lattice convolutions, we design lattice convolutional networks (LCN) that use self-gating and attention mechanisms. Experimental results show that our method achieves performance on par or better than the GNN method on spin 1/2 J_1-J_2 Heisenberg model over the square, honeycomb, triangular, and kagome lattices while without using hand-crafted encoding.

CLIPSep: Learning Text-queried Sound Separation with Noisy Unlabeled Videos

Hao-Wen Dong,Naoya Takahashi,Yuki Mitsufuji,Julian McAuley,Taylor Berg-Kirkpatrick

Recent years have seen progress beyond domain-specific sound separation for speech or music towards universal sound separation for arbitrary sounds. Prior work on universal sound separation has investigated separating a target sound out of an audio mixture given a text query. Such text-queried sound separation systems provide a natural and scalable interface for specifying arbitrary target sounds. However, supervised text-queried sound separation systems require costly labeled audio-text pairs for training. Moreover, the audio provided in existing datasets is often recorded in a controlled environment, causing a considerable generalization gap to noisy audio in the wild. In this work, we aim to approach text-queried universal sound separation by using only unlabeled data. We propose to leverage the visual modality as a bridge to learn the desired audio-textual correspondence. The proposed CLIPSep model first encodes the input query into a query vector using the contrastive language-image pretraining (CLIP) model, and the que

ry vector is then used to condition an audio separation model to separate out the target sound. While the model is trained on image-audio pairs extracted from unlabeled videos, at test time we can instead query the model with text inputs in a zero-shot setting, thanks to the joint language-image embedding learned by the CLIP model. Further, videos in the wild often contain off-screen sounds and background noise that may hinder the model from learning the desired audio-textual correspondence. To address this problem, we further propose an approach called noise invariant training for training a query-based sound separation model on noisy data. Experimental results show that the proposed models successfully learn text-queried universal sound separation using only noisy unlabeled videos, even achieving competitive performance against a supervised model in some settings.

On the Soft-Subnetwork for Few-Shot Class Incremental Learning
Haeyong Kang,Jaehong Yoon,Sultan Rizky Hikmawan Madjid,Sung Ju Hwang,Chang D. Yoo
Inspired by Regularized Lottery Ticket Hypothesis, which states that competitive smooth (non-binary) subnetworks exist within a dense network, we propose a few-shot class-incremental learning method referred to as Soft-SubNetworks (SoftNet). Our objective is to learn a sequence of sessions incrementally, where each session only includes a few training instances per class while preserving the knowledge of the previously learned ones. SoftNet jointly learns the model weights and adaptive non-binary soft masks at a base training session in which each mask consists of the major and minor subnetwork; the former aims to minimize catastrophic forgetting during training, and the latter aims to avoid overfitting to a few samples in each new training session. We provide comprehensive empirical validations demonstrating that our SoftNet effectively tackles the few-shot incremental learning problem by surpassing the performance of state-of-the-art baselines over benchmark datasets.
****
Approximating How Single Head Attention Learns
Charlie Victor Snell,Ruiqi Zhong,Dan Klein,Jacob Steinhardt
Why do models often attend to salient words, and how does this evolve throughout training? We approximate model training as a two stage process: early on in training when the attention weights are uniform, the model learns to translate individual input word `i` to `o` if they co-occur frequently. Later, the model learns to attend to `i` while the correct output is o because it knows `i` translates to `o`. To formalize, we define a model property, Knowledge to Translate Individual Words (KTIW) (e.g. knowing that `i` translates to `o`), and claim that it drives the learning of the attention. This claim is supported by the fact that before the attention mechanism is learned, KTIW can be learned from word co-occurrence statistics, but not the other way around. Particularly, we can construct a training distribution that makes KTIW hard to learn, the learning of the attention fails, and the model cannot even learn the simple task of copying the input words to the output. Our approximation explains why models sometimes attend to salient words, and inspires a toy example where a multi-head attention model can overcome the above hard training distribution by improving learning dynamics rather than expressiveness. We end by discussing the limitation of our approximation framework and suggest future directions.
****
Efficient Attention via Control Variates
Lin Zheng,Jianbo Yuan,Chong Wang,Lingpeng Kong
Random-feature-based attention (RFA) is an efficient approximation of softmax attention with linear runtime and space complexity. However, the approximation gap between RFA and conventional softmax attention is not well studied. Built upon previous progress of RFA, we characterize this gap through the lens of control variates and show that RFA can be decomposed into a sum of multiple control variate estimators for each element in the sequence. This new framework reveals that exact softmax attention can be recovered from RFA by manipulating each control variate. Besides, it allows us to develop a more flexible form of control variates, resulting in a novel attention mechanism that significantly reduces the appro

ximation gap while maintaining linear complexity. Extensive experiments demonstrate that our model outperforms state-of-the-art efficient attention mechanisms on both vision and language tasks.

Learning to Optimize Quasi-Newton Methods

Isaac Liao,Rumen Dangovski,Jakob Nicolaus Foerster,Marin Soljacic

We introduce a novel machine learning optimizer called LODO, which online meta-learns an implicit inverse Hessian of the loss as a subroutine of quasi-Newton optimization. Our optimizer merges Learning to Optimize (L2O) techniques with quasi-Newton methods to learn neural representations of symmetric matrix vector products, which are more flexible than those in other quasi-Newton methods. Unlike other L2O methods, ours does not require any meta-training on a training task distribution, and instead learns to optimize on the fly while optimizing on the test task, adapting to the local characteristics of the loss landscape while traversing it. Theoretically, we show that our optimizer approximates the inverse Hessian in noisy loss landscapes and is capable of representing a wide range of inverse Hessians. We experimentally verify our algorithm's performance in the presence of noise, and show that simpler alternatives for representing the inverse Hessians worsen performance. Lastly, we use our optimizer to train a semi-realistic deep neural network with 95k parameters, and obtain competitive results against standard neural network optimizers.

Toxicity in Multilingual Machine Translation at Scale

Marta R. Costa-jussà,Christophe Ropers,Eric Michael Smith,Daniel Licht,Carlos Escolano,Javier Ferrando

Machine Translation systems can produce different types of errors, some of which get characterized as critical or catastrophic due to the specific negative impact they can have on users. Automatic or human evaluation metrics do not necessarily differentiate between such critical errors and more innocuous ones. In this paper we focus on one type of critical error: added toxicity. We evaluate and analyze added toxicity when translating a large evaluation dataset (HOLISTICBIAS, over 472k sentences, covering 13 demographic axes) from English into 164 languages. The toxicity automatic evaluation shows that added toxicity across languages varies from 0% to 5%. The output languages with the most added toxicity tend to be low-resource ones, and the demographic axes with the most added toxicity include sexual orientation, gender and sex, and ability. We also perform human evaluation on a subset of 8 directions, confirming the prevalence of true added toxicity.

We use a measurement of the amount of source contribution to the translation, where a low source contribution implies hallucination, to interpret what causes toxicity. We observe that the source contribution is somewhat correlated with toxicity but that 45.6% of added toxic words have a high source contribution, suggesting that much of the added toxicity may be due to mistranslations. Combining the signal of source contribution level with a measurement of translation robustness allows us to flag 22.3% of added toxicity, suggesting that added toxicity may be related to both hallucination and the stability of translations in different contexts. Given these findings, our recommendations to reduce added toxicity are to curate training data to avoid mistranslations, mitigate hallucination and check unstable translations.

An Adaptive Policy to Employ Sharpness-Aware Minimization

Weisen Jiang,Hansi Yang,Yu Zhang,James Kwok

Sharpness-aware minimization (SAM), which searches for flat minima by min-max optimization, has been shown to be useful in improving model generalization. However, since each SAM update requires computing two gradients, its computational cost and training time are both doubled compared to standard empirical risk minimization (ERM). Recent state-of-the-arts reduce the fraction of SAM updates and thus accelerate SAM by switching between SAM and ERM updates randomly or periodically. In this paper, we design an adaptive policy to employ SAM based on the loss landscape geometry. Two efficient algorithms, AE-SAM and AE-LookSAM, are proposed. We theoretically show that AE-SAM has the same convergence rate as SAM. Experimental results on various datasets and architectures demonstrate the efficiency and effectiveness of the adaptive policy.

FedMT: Federated Learning with Mixed-type Labels

Qiong Zhang,Aline Talhouk,Gang Niu,Xiaoxiao Li

In federated learning (FL), classifiers (e.g., deep networks) are trained on datasets from multiple centers without exchanging data across them, and thus improves sample efficiency. In the classical setting of FL, the same labeling criterion is usually employed across all centers being involved in training. This constraint greatly limits the applicability of FL. For example, standards used for disease diagnosis are more likely to be different across clinical centers, which mismatches the classical FL setting. In this paper, we consider an important yet under-explored setting of FL, namely FL with mixed-type labels where different labeling criteria can be employed by various centers, leading to inter-center label space differences and challenging existing FL methods designed for the classical setting. To effectively and efficiently train models with mixed-type labels, we propose a theory-guided and model-agnostic approach that can make use of the underlying correspondence between those label spaces and can be easily combined with various FL methods such as FedAvg. We present convergence analysis based on over-parameterized ReLU networks. We show that the proposed method can achieve linear convergence in label projection, and demonstrate the impact of the parameters of our new setting on the convergence rate. The proposed method is evaluated and the theoretical findings are validated on benchmark and medical datasets.

Penalizing the High-likelihood: A Novel Sampling Method for Open-ended Neural Text Generation via Inverse Probability Weighting

Xinran Zhang,Maosong Sun,Jiafeng Liu,Xiaobing Li

Traditional stochastic sampling methods for open-ended neural text generation focus on truncating the low-likelihood part of the predicted distribution. They do not directly manipulate the high-likelihood part, which leads to the likelihood trap that induces repetition and boredom. They also do not directly leverage that human does not always favor high-likelihood texts. Inspired by these, we propose a novel sampling method that rescales the high-likelihood part of the distribution with inverse probability weighting. It increases the diversity by rescaling and penalizing the high-likelihood words, and preserves the fluency by using multi-filtering truncation on the low-likelihood words. We use pre-trained language models to compare our algorithm with traditional sampling methods. Results show that our algorithm can significantly increase the diversity and novelty of generated texts without corrupting the fluency.

Optimal Conservative Offline RL with General Function Approximation via Augmented Lagrangian

Paria Rashidinejad,Hanlin Zhu,Kunhe Yang,Stuart Russell,Jiantao Jiao

Offline reinforcement learning (RL), which aims at learning good policies from historical data, has received significant attention over the past years. Much effort has focused on improving offline RL practicality by addressing the prevalent issue of partial data coverage through various forms of conservative policy learning. While the majority of algorithms do not have finite-sample guarantees, several provable conservative offline RL algorithms are designed and analyzed within the single-policy concentrability framework that handles partial coverage. Yet, in the nonlinear function approximation setting where confidence intervals are difficult to obtain, existing provable algorithms suffer from computational intractability, prohibitively strong assumptions, and suboptimal statistical rates. In this paper, we leverage the marginalized importance sampling (MIS) formulation of RL and present the first set of offline RL algorithms that are statistically optimal and practical under general function approximation and single-policy concentrability, bypassing the need for uncertainty quantification. We identify that the key to successfully solving the sample-based appr oximation of the MIS problem is ensuring that certain occupancy validity constraints are nearly satisfied. We enforce these constraints by a novel application of the augmented Lagrangian method and prove the following result: with the MIS formulation, augmented Lagrangian is enough for statistically optimal offline RL. In stark contrast to prior algorithms that induce additional conservatism through methods such as behavior regularization, our approach provably eliminates this need and reinterprets regularizers as "enforcers of occupancy validity" than "promoters of conservatism."

Bandit Learning with General Function Classes: Heteroscedastic Noise and Variance-dependent Regret Bounds

Heyang Zhao,Dongruo Zhou,Jiafan He,Quanquan Gu

We consider learning a stochastic bandit model, where the reward function belongs to a general class of uniformly bounded functions, and the additive noise can be heteroscedastic. Our model captures contextual linear bandits and generalized linear bandits as special cases. While previous works (Kirschner and Krause, 2018; Zhou et al., 2021) based on weighted ridge regression can deal with linear bandits with heteroscedastic noise, they are not directly applicable to our general model due to the curse of nonlinearity. In order to tackle this problem, we propose a \emph{multi-level learning} framework for the general bandit model. The core idea of our framework is to partition the observed data into different levels according to the variance of their respective reward and perform online learning at each level collaboratively. Under our framework, we first design an algorithm that constructs the variance-aware confidence set based on empirical risk minimization and prove a variance-dependent regret bound. For generalized linear bandits, we further propose an algorithm based on follow-the-regularized-leader (FTRL) subroutine and online-to-confidence-set conversion, which can achieve a tighter variance-dependent regret under certain conditions.

****

Injecting Image Details into CLIP's Feature Space

Zilun Zhang,Cuifeng Shen,Shen Yuan,Huixin Xiong,Xinyu Zhou

Although CLIP-like Visual Language Models provide a functional joint feature space for image and text, due to the limitation of the CILP-like model's image input size (e.g., 224), subtle details are lost in the feature representation if we input high-resolution images (e.g., 2240). In this work, we introduce an efficient framework that can produce a single feature representation for a high-resolution image that injects image details and shares the same semantic space as the original CLIP. In the framework, we train a feature fusing model based on CLIP features extracted from a carefully designed image patch method (Complete Cover) that can cover objects of any scale, weakly supervised by image-agnostic class prompted queries. We validate our framework by retrieving images from class prompted queries on the existing real-world and synthetic datasets, showing significant performance improvement on these tasks. Furthermore, to fully demonstrate our framework's detail retrieval ability, we construct a CLEVR-like synthetic dataset called CLVER-DS, which is fully annotated and has a controllable object scale.

****

Adaptive Sparse Softmax: An Effective and Efficient Softmax Variant for Text Classification

Qi Lv,Lei Geng,Ziqiang Cao,Min Cao,Sujian Li,Wenjie Li,Guohong Fu

Softmax with the cross entropy loss is the standard configuration for current neural text classification models. The gold score for a target class is supposed to be 1, but it is never reachable under the softmax schema. Such a problem makes the training process continue forever and leads to overfitting. Moreover, the “target-approach-1” training goal forces the model to continuously learn all samples, leading to a waste of time in handling some samples which have already been classified correctly with high confidence, while the test goal simply requires the target class of each sample to hold the maximum score. To solve the above weaknesses, we propose the \textbf{A}daptive \textbf{S}parse softmax (AS-Softmax) which designs a reasonable and test-matching transformation on top of softmax. F or more purposeful learning, we discard the classes with far smaller scores compared with the actual class during training. Then the model could focus on learning to distinguish the target class from its strong opponents, which is also the great challenge in test. In addition, since the training losses of easy samples will gradually drop to 0 in AS-Softmax, we develop an adaptive gradient accumulation strategy based on the masked sample ratio to speed up training. We verify proposed AS-Softmax on a variety of multi-class, multi-label and token classification tasks with class sizes ranging from 5 to 5000+. The results show that AS-Softmax consistently outperforms softmax and its variants, and the loss of AS-Softmax is remarkably correlated with classification performance in validation. Furthermore, adaptive gradient accumulation strategy can bring about 1.2× training speedup comparing with the standard softmax while maintaining classification effectiveness.

****

Stochastic Bridges as Effective Regularizers for Parameter-Efficient Tuning

Weize Chen,Xu Han,Yankai Lin,Zhiyuan Liu,Maosong Sun,Jie Zhou

Parameter-efficient tuning methods (PETs) have achieved promising results in tuning large pre-trained language models (PLMs). By formalizing frozen PLMs and additional tunable parameters as systems and controls respectively, PETs can be theoretically grounded to optimal control and further viewed as optimizing terminal cost and running cost in the optimal control literature. Despite the elegance of this theoretical grounding, in practice, existing PETs often ignore the running cost and only optimize the terminal cost, i.e., focus on optimizing the loss function of the output state, regardless of the running cost that depends on the intermediate states. Since it is non-trivial to directly model the intermediate states and design a running cost function, we propose to use latent stochastic bridges to regularize the intermediate states and serve as the running cost of PETs. As the first work to propose regularized PETs that use stochastic bridges as the regularizers (running costs) for intermediate states, we show the effectiveness and generality of this regularization across different tasks, PLMs and PETs. In view of the great potential and capacity, we believe more sophisticated regularizers can be designed for PETs and better performance can be achieved in the future.

Continuous Goal Sampling: A Simple Technique to Accelerate Automatic Curriculum Learning

Mehul Damani,Lerrel Pinto

Goal-conditioned reinforcement learning (RL) tackles the problem of training an RL agent to reach multiple goals in an environment, often with sparse rewards only administered upon reaching the goal.

In this regard, automatic curriculum learning can improve an agent's learning by sampling goals in a structured order catered to the agent's current ability.

This work presents two contributions to improve learning in goal-conditioned RL environments.

First, we present a simple, algorithm-agnostic technique to accelerate learning by continuous goal sampling, in which an agent's goals are sampled and changed multiple times within a single episode.

Such continuous goal sampling enables faster exploration of the goal space and allows curriculum methods to have a more significant impact on an agent's learning.

Second, we propose VDIFF, an automatic curriculum learning method that uses an agent's value function to create a self-paced curriculum by sampling goals on which the agent is demonstrating high learning progress.

Through results on 17 multi-goal robotic environments and navigation tasks, we show that continuous goal sampling and VDIFF work synergistically and result in performance gains over current state-of-the-art methods.

What do Vision Transformers Learn? A Visual Exploration

Amin Ghiasi,Hamid Kazemi,Steven Reich,Eitan Borgnia,Manli Shu,Micah Goldblum,Andrew Gordon Wilson,Tom Goldstein

Vision transformers (ViTs) are quickly becoming the de-facto architecture for computer vision, yet we understand very little about why they work and what they learn. While existing studies visually analyze the mechanisms of convolutional neural networks, an analogous exploration of ViTs remains challenging. In this paper, we first address the obstacles to performing visualizations on ViTs. Assisted by these solutions, we observe that neurons in ViTs trained with language model supervision (e.g., CLIP) are activated by semantic concepts rather than visual features. We also explore the underlying differences between ViTs and CNNs, and we find that transformers detect image background features, just like their convolutional counterparts, but their predictions depend far less on high-frequency information. On the other hand, both architecture types behave similarly in the way features progress from abstract patterns in early layers to concrete objects in late layers. In addition, we show that ViTs maintain spatial information in all layers except the final layer. In contrast to previous works, we show that the last layer most likely discards the spatial information and behaves as a learned global pooling operation. Finally, we conduct large-scale visualizations on a wide range of ViT variants, including DeiT, CoaT, ConViT, PiT, Swin, and Twin, to validate the effectiveness of our method.

Detecting and Mitigating Indirect Stereotypes in Word Embeddings

Erin George,Deanna Needell

Societal biases in the usage of words, including harmful stereotypes, are frequently learned by common word embedding methods. These biases manifest not only between a word and an explicit marker of its stereotype, but also between words that share related stereotypes. This latter phenomenon, sometimes called ``indirect bias,'' has resisted prior attempts at debiasing. In this paper, we propose a novel method to mitigate indirect bias in distributional word embeddings by modifying biased relationships between words before embeddings are learned. This is done by considering how the co-occurrence probability of a given pair of words changes in the presence of words marking an attribute of bias, and using this to average out the effect of a bias attribute. To evaluate this method, we perform a series of common tests and demonstrate that the semantic quality of the word embeddings is retained while measures of bias in the embeddings are reduced. In addition, we conduct novel tests for measuring indirect stereotypes by extending the Word Embedding Association Test (WEAT) with new test sets for indirect binary gender stereotypes. With these tests, we demonstrate that this method can reduce the presence of more subtle stereotypes not properly addressed by previous work.

OCIM : Object-centric Compositional Imagination for Visual Abstract Reasoning

Rim Assouel,Pau Rodriguez,Perouz Taslakian,David Vazquez,Yoshua Bengio

A long-sought property of machine learning systems is the ability to compose learned concepts in novel ways that would enable them to make sense of new situations. Such capacity for imagination -- a core aspect of human intelligence -- is not yet attained for machines. In this work, we show that object-centric inductive biases can be leveraged to derive an imagination-based learning framework that achieves compositional generalization on a series of tasks. Our method, denoted Object-centric Compositional IMagination (OCIM), decomposes visual reasoning tasks into a series of primitives applied to objects without using a domain-specific language. We show that these primitives can be recomposed to generate new imaginary tasks. By training on such imagined tasks, the model learns to reuse the previously-learned concepts to systematically generalize at test time. We test our model on a series of arithmetic tasks where the model has to infer the sequence of operations (programs) applied to a series of inputs. We find that imagination is key for the model to find the correct solution for unseen combinations of operations.

How Weakly Supervised Information helps Contrastive Learning

Jingyi Cui,Weiran Huang,Yisen Wang

Contrastive learning has shown outstanding performances in both supervised and u nsupervised learning. However, little is known about when and how weakly supervised information helps improve contrastive learning, especially from the theoretical perspective. The major challenge is that the existing theory of contrastive learning based on supervised learning frameworks failed to distinguish between supervised and unsupervised contrastive learning. Therefore, we turn to the unsupervised learning frameworks, and based on the posterior probability of labels, we translate the weakly supervised information into a similarity graph under the framework of spectral clustering. In this paper, we investigate two typical weakly supervised learning problems, noisy label learning, and semi-supervised learning, and analyze their influence on contrastive learning within a unified framework. Specifically, we analyze the effect of weakly supervised information on the augmentation graph of unsupervised contrastive learning, and consequently on its corresponding error bound. Numerical experiments are carried out to verify the theoretical findings.

A computational framework to unify representation similarity and function in biological and artificial neural networks

Xuming Ran,Jie Zhang,Ziyuan Ye,Haiyan Wu,Qi Xu,Huihui Zhou,Quanying Liu

Artificial neural network (ANN) is a versatile tool to study the neural representation in the ventral visual stream, and the knowledge in neuroscience in return inspires ANN models to improve performance in the task. However, it is still unclear how to merge these two directions into a unified framework. In this study, we propose an integrated framework called Deep Autoencoder with Neural Response (DAE-NR), which incorporates information from ANN and the visual cortex to achieve better image reconstruction performance and higher neural representation similarity between biological and artificial neurons. The same visual stimuli (i.e., natural images) are input to both the mice brain and DAE-NR. The encoder of DAE-NR jointly learns the dependencies from neural spike encoding and image reconstruction. For the neural spike encoding task, the features derived from a specific hidden layer of the encoder are transformed by a mapping function to predict the ground-truth neural response under the constraint of image reconstruction. Simultaneously, for the image reconstruction task, the latent representation obtained by the encoder is assigned to a decoder to restore the original image under the guidance of neural information. In DAE-NR, the learning process of encoder, mapping function and decoder are all implicitly constrained by these two tasks. Our experiments demonstrate that if and only if with the joint learning, DAE-NRs can improve the performance of visual image reconstruction and increase the representation similarity between biological neurons and artificial neurons. The DAE-NR offers a new perspective on the integration of computer vision and neuroscience.

Fairness and Accuracy under Domain Generalization

Thai-Hoang Pham,Xueru Zhang,Ping Zhang

As machine learning (ML) algorithms are increasingly used in high-stakes applications, concerns have arisen that they may be biased against certain social groups. Although many approaches have been proposed to make ML models fair, they typically rely on the assumption that data distributions in training and deployment are identical. Unfortunately, this is commonly violated in practice and a model that is fair during training may lead to an unexpected outcome during its deployment. Although the problem of designing robust ML models under dataset shifts has been widely studied, most existing works focus only on the transfer of accuracy. In this paper, we study the transfer of both fairness and accuracy under domain generalization where the data at test time may be sampled from never-before-seen domains. We first develop theoretical bounds on the unfairness and expected loss at deployment, and then derive sufficient conditions under which fairness and accuracy can be perfectly transferred via invariant representation learning. Guided by this, we design a learning algorithm such that fair ML models learned with training data still have high fairness and accuracy when deployment environments change. Experiments on real-world data validate the proposed algorithm.

DROP: Conservative Model-based Optimization for Offline Reinforcement Learning
Jinxin Liu,Hongyin Zhang,Zifeng Zhuang,Yachen Kang,Donglin Wang,Bin Wang,Jianye HAO

In this work, we decouple the iterative (bi-level) offline RL optimization from the offline training phase, forming a non-iterative bi-level learning paradigm that avoids the iterative error propagation over two levels. Specifically, this non-iterative paradigm allows us to conduct inner-level optimization in training (ie, employing policy/value regularization), while performing outer-level optimization in testing (ie, conducting policy inference). Naturally, such paradigm raises three core questions (that are not fully answered by prior non-iterative methods): (Q1) What information should we transfer from inner-level to outer-level? (Q2) What should we pay attention to when using the transferred information in outer-level optimization? (Q3) What are the benefits of concurrently conducting outer-level optimization during testing? Motivated by model-based optimization, we proposed DROP, which fully answered the above three questions. Particularly, in inner-level, DROP decomposes offline data into multiple subsets, and learns a score model (Q1). To keep safe exploitation to score model in outer-level, we explicitly learn a behavior embedding and introduce a conservative regularization (Q2). During testing, we show that DROP permits deployment adaptation, enabling an adaptive inference across states (Q3). Empirically, we evaluate DROP on various benchmarks, showing that DROP gains comparable or better performance compared to prior offline RL methods.

Language Models Can Teach Themselves to Program Better
Patrick Haluptzok,Matthew Bowers,Adam Tauman Kalai

Recent Language Models (LMs) achieve breakthrough performance in code generation when trained on human-authored problems, even solving some competitive-programming problems. Self-play has proven useful in games such as Go, and thus it is natural to ask whether LMs can generate their own instructive programming problems to improve their performance. We show that it is possible for an LM to synthesize programming problems and solutions, which are filtered for correctness by a Python interpreter. The LM’s performance is then seen to improve when it is fine-tuned on its own synthetic problems and verified solutions; thus the model “improves itself” using the Python interpreter. Problems are specified formally as programming puzzles [Schuster et al. , 2021], a code-based problem format where solutions can easily be verified for correctness by execution. In experiments on publicly-available LMs, test accuracy more than doubles. This work demonstrates the potential for code LMs, with an interpreter, to generate instructive problems and improve their own performance.

MVP: Multi-task Supervised Pre-training for Natural Language Generation
Tianyi Tang,Junyi Li,Xin Zhao,Ji-Rong Wen

Pre-trained language models (PLMs) have achieved remarkable success in natural language generation (NLG) tasks. Up to now, most NLG-oriented PLMs are pre-trained in an unsupervised manner using the large-scale general corpus. In the meanwhile, an increasing number of models pre-trained with labeled data (i.e., “supervised pre-training”) showcase superior performance compared to unsupervised pre-trained models. Motivated by the success of supervised pre-training, we propose Multi-task superVised Pre-training (MVP) for natural language generation. We collect a large-scale natural language generation corpus, MVPCorpus, from 77 datasets over 11 diverse NLG tasks. Then we unify these examples into a general text-to-text format to pre-train the text generation model MVP in a supervised manner. For each task, we further pre-train specific soft prompts to stimulate the model’s capacity to perform a specific task. Extensive experiments have demonstrated the effectiveness and generalizability of our MVP model in a number of NLG tasks, which achieves state-of-the-art performance on 13 out of 17 datasets.

Learning Unified Representations for Multi-Resolution Face Recognition
Hulingxiao He,Wu Yuan,Yidian Huang,Shilong Zhao,Wen Yuan,HanQing Li

In this work, we propose Branch-to-Trunk network (BTNet), a novel representation learning method for multi-resolution face recognition. It consists of a trunk network (TNet), namely a unified encoder, and multiple branch networks (BNets), namely resolution adapters. As per the input, a resolution-specific BNet is used and the output are implanted as feature maps in the feature pyramid of TNet, at a layer with the same resolution. The discriminability of tiny faces is significantly improved, as the interpolation error introduced by rescaling, especially up-sampling, is mitigated on the inputs. With branch distillation and backward-compatible training, BTNet transfers discriminative high-resolution information to multiple branches while guaranteeing representation compatibility. Our experiments demonstrate strong performance on face recognition benchmarks, both for multi-resolution face verification and face identification, with much less computation amount and parameter storage. We establish new state-of-the-art on the challenging QMUL-SurvFace 1: N face identification task.

Latent Bottlenecked Attentive Neural Processes

Leo Feng,Hossein Hajimirsadeghi,Yoshua Bengio,Mohamed Osama Ahmed

Neural Processes (NPs) are popular methods in meta-learning that can estimate predictive uncertainty on target datapoints by conditioning on a context dataset. Previous state-of-the-art method Transformer Neural Processes (TNPs) achieve strong performance but require quadratic computation with respect to the number of context datapoints, significantly limiting its scalability. Conversely, existing sub-quadratic NP variants perform significantly worse than that of TNPs. Tackling this issue, we propose Latent Bottlenecked Attentive Neural Processes (LBANPs), a new computationally efficient sub-quadratic NP variant, that has a querying computational complexity independent of the number of context datapoints. The model encodes the context dataset into a constant number of latent vectors on which self-attention is performed. When making predictions, the model retrieves higher-order information from the context dataset via multiple cross-attention mechanisms on the latent vectors. We empirically show that LBANPs achieve results competitive with the state-of-the-art on meta-regression, image completion, and contextual multi-armed bandits. We demonstrate that LBANPs can trade-off the computational cost and performance according to the number of latent vectors. Finally, we show LBANPs can scale beyond existing attention-based NP variants to larger dataset settings.

VoLTA: Vision-Language Transformer with Weakly-Supervised Local-Feature Alignment

Shraman Pramanick,Li Jing,Sayan Nag,Jiachen Zhu,Hardik J Shah,Yann LeCun,Rama Chellappa

Vision-language pre-training (VLP) has recently proven highly effective for various uni- and multi-modal downstream applications. However, most existing end-to-end VLP methods use high-resolution image-text-box data to perform well on fine-grained region-level tasks, such as object detection, segmentation, and referring expression comprehension. Unfortunately, such high-resolution images with accurate bounding box annotations are expensive to collect and use for supervision at scale. In this work, we propose VoLTA (Vision-Language Transformer with weakly-supervised local-feature Alignment), a new VLP paradigm that only utilizes image-caption data but achieves fine-grained region-level image understanding, eliminating the use of expensive box annotations. VoLTA adopts graph optimal transport-based weakly-supervised alignment on local image patches and text tokens to germinate an explicit, self-normalized, and interpretable low-level matching criterion. In addition, VoLTA pushes multi-modal fusion deep into the uni-modal backbones during pre-training and removes fusion-specific transformer layers, further reducing memory requirements. Extensive experiments on a wide range of vision- and vision-language downstream tasks demonstrate the effectiveness of VoLTA on fine-grained applications without compromising the coarse-grained downstream performance, often outperforming methods using significantly more caption and box annotations.

Represent to Control Partially Observed Systems: Representation Learning with Pr ovable Sample Efficiency

Lingxiao Wang,Qi Cai,Zhuoran Yang,Zhaoran Wang

Reinforcement learning in partially observed Markov decision processes (POMDPs) faces two challenges. (i) It often takes the full history to predict the future, which induces a sample complexity that scales exponentially with the horizon. (ii) The observation and state spaces are often continuous, which induces a sample complexity that scales exponentially with the extrinsic dimension. Addressing such challenges requires learning a minimal but sufficient representation of the observation and state histories by exploiting the structure of the POMDP.

To this end, we propose a reinforcement learning algorithm named Represent to Control (RTC), which learns the representation at two levels while optimizing the policy.~(i) For each step, RTC learns to represent the state with a low-dimensional feature, which factorizes the transition kernel. (ii) Across multiple steps, RTC learns to represent the full history with a low-dimensional embedding, which assembles the per-step feature. We integrate (i) and (ii) in a unified framework that allows a variety of estimators (including maximum likelihood estimators and generative adversarial networks). For a class of POMDPs with a low-rank structure in the transition kernel, RTC attains an $O(1/\epsilon^2)$ sample complexity that scales polynomially with the horizon and the intrinsic dimension (that is, the rank). Here ϵ is the optimality gap. To our best knowledge, RTC is the first sample-efficient algorithm that bridges representation learning and policy optimization in POMDPs with infinite observation and state spaces.

Towards Better Selective Classification

Leo Feng,Mohamed Osama Ahmed,Hossein Hajimirsadeghi,Amir H. Abdi

We tackle the problem of Selective Classification where the objective is to achieve the best performance on a predetermined ratio (coverage) of the dataset. Recent state-of-the-art selective methods come with architectural changes either via introducing a separate selection head or an extra abstention logit. In this paper, we challenge the aforementioned methods. The results suggest that the superior performance of state-of-the-art methods is owed to training a more generalizable classifier rather than their proposed selection mechanisms. We argue that the best performing selection mechanism should instead be rooted in the classifier itself. Our proposed selection strategy uses the classification scores and achieves better results by a significant margin, consistently, across all coverages and all datasets, without any added compute cost. Furthermore, inspired by semi-supervised learning, we propose an entropy-based regularizer that improves the performance of selective classification methods. Our proposed selection mechanism with the proposed entropy-based regularizer achieves new state-of-the-art results.

Offline Equilibrium Finding

Shuxin Li,Xinrun Wang,Jakub Cerny,Youzhi Zhang,Pengdeng Li,Hau Chan,Bo An

Offline reinforcement learning (Offline RL) is an emerging field that has recently begun gaining attention across various application domains due to its ability to learn behavior from earlier collected datasets. Offline RL proved very successful, paving a path to solving previously intractable real-world problems, and we aim to generalize this paradigm to a multi-agent or multiplayer-game setting. To this end, we formally introduce a problem of offline equilibrium finding (OEF) and construct multiple datasets across a wide range of games using several established methods. To solve the OEF problem, we design a model-based method that can directly apply any online equilibrium finding algorithm to the OEF setting while making minimal changes. We focus on three most prominent contemporary online equilibrium finding algorithms and adapt them to the OEF setting, creating three model-based variants: OEF-PSRO and OEF-CFR, which generalize the widely-used algorithms PSRO and Deep CFR to compute Nash equilibria (NEs), and OEF-JPSRO, which generalizes the JPSRO to calculate (Coarse) Correlated equilibria ((C)CEs). We further improve their performance by combining the behavior cloning policy with the model-based policy. Extensive experimental results demonstrate the super

iority of our approach over multiple model-based and model-free offline RL algorithms and the necessity of the model-based method for solving OEF problems. We hope that our efforts may help to accelerate research in large-scale equilibrium finding.

ASGNN: Graph Neural Networks with Adaptive Structure

Zepeng Zhang,Songtao Lu,Zengfeng Huang,Ziping Zhao

The graph neural network (GNN) has presented impressive achievements in numerous machine learning tasks. However, many existing GNN models are shown to be extremely vulnerable to adversarial attacks, which makes it essential to build robust GNN architectures. In this work, we propose a novel interpretable message passing scheme with adaptive structure (ASMP) to defend against adversarial attacks on graph structure. Layers in ASMP are derived based on optimization steps that minimize an objective function that simultaneously learns the node feature and the graph structure. ASMP is adaptive in the sense that the message passing process in different layers is able to be carried out over different graphs. Such a property allows more fine-grained handling of the noisy graph structure and hence improves the robustness. Integrating ASMP with neural networks can lead to a new family of GNNs with adaptive structure (ASGNN). Extensive experiments on semi-supervised node classification tasks demonstrate that the proposed ASGNN outperforms the state-of-the-art GNN architectures with respect to classification performance under various graph adversarial attacks.

Iteratively Learning Novel Strategies with Diversity Measured in State Distances

Wei Fu,Weihua Du,Jingwei Li,Sunli Chen,Jingzhao Zhang,Yi Wu

In complex reinforcement learning (RL) problems, policies with similar rewards may have substantially different behaviors. Yet, to not only optimize rewards but also discover as many diverse strategies as possible remains a challenging problem. A natural approach to this task is constrained population-based training (PBT), which simultaneously learns a collection of policies subject to diversity constraints. However, due to the unaffordable computation cost of PBT, we adopt an alternative approach, iterative learning (IL), which repeatedly learns a single novel policy that is sufficiently different from previous ones. We first analyze these two frameworks and prove that, for any policy pool derived by PBT, we can always use IL to obtain another policy pool of the same rewards and competitive diversity scores. In addition, we also present a novel state-based diversity measure with two tractable realizations. Such a metric can impose a stronger and much smoother diversity constraint than existing action-based metrics. Combining IL and the state-based diversity measure, we develop a powerful diversity-driven RL algorithm, State-based Intrinsic-reward Policy Optimization (SIPO), with provable convergence properties. We empirically examine our algorithm in complex multi-agent environments including StarCraft Multi-Agent Challenge and Google Research Football. SIPO is able to consistently derive strategically diverse and human-interpretable policies that cannot be discovered by existing baselines.

Learning Kernelized Contextual Bandits in a Distributed and Asynchronous Environment

Chuanhao Li,Huazheng Wang,Mengdi Wang,Hongning Wang

Despite the recent advances in communication-efficient distributed bandit learning, most existing solutions are restricted to parametric models, e.g., linear bandits and generalized linear bandits (GLB). In comparison, kernel bandits, which search for non-parametric functions in a reproducing kernel Hilbert space (RKHS), offer higher modeling capacity. But the only existing work in distributed kernel bandits adopts a synchronous communication protocol, which greatly limits its practical use (e.g., every synchronization step requires all clients to participate and wait for data exchange).

In this paper, in order to improve the robustness against delays and unavailability of clients that are common in practice, we propose the first asynchronous solution based on approximated kernel regression for distributed kernel bandit learning. A set of effective treatments are developed to ensure approximation quali ty and communication efficiency. Rigorous theoretical analysis about the regret and communication cost is provided; and extensive empirical evaluations demonstrate the effectiveness of our solution.

****

ATTRIBUTES RECONSTRUCTION IN HETEROGENEOUS NETWORKS VIA GRAPH AUGMENTATION

yixuan Liang,yuan wan

Heterogeneous Graph Neural Networks(HGNNs), as an effective tool for mining heterogeneous graphs, have achieved remarkable performance on node classification tasks. Yet, HGNNs are limited in their mining power as they require all nodes to have complete and reliable attributes. It is usually unrealistic since the attributes of many nodes in reality are inevitably missing or defective. Existing methods usually take imputation schemes to complete missing attributes, in which topology information is ignored, leading to suboptimal performance. And some graph augmentation techniques have improved the quality of attributes, while few of them are designed for heterogeneous graphs. In this work, we study the data augmentation on heterogeneous graphs, tackling the missing and defective attributes simultaneously, and propose a novel generic architecture—Attributes Reconstruction in Heterogeneous networks via Graph Augmentation(ARHGA), including random sampling, attribute augmentation and consistency training. In graph augmentation, to ensure attributes plausible and accurate, the attention mechanism is adopted to reconstruct attributes under the guidance of the topological relationship between nodes. Our proposed architecture can be easily combined with any GNN-based heterogeneous model, and improves the performance. Extensive experiments on three benchmark datasets demonstrate the superior performance of ARHGA over strate-of-the-art baselines on semi-supervised node classification.

Graph Signal Sampling for Inductive One-Bit Matrix Completion: a Closed-form Solution

Chao Chen,Haoyu Geng,Gang Zeng,Zhaobing Han,Hua Chai,Xiaokang Yang,Junchi Yan

Inductive one-bit matrix completion is motivated by modern applications such as recommender systems, where new users would appear at test stage with the ratings consisting of only ones and no zeros. We propose a unified graph signal sampling framework which enjoys the benefits of graph signal analysis and processing. The key idea is to transform each user's ratings on the items to a function (signal) on the vertices of an item-item graph, then learn structural graph properties to recover the function from its values on certain vertices --- the problem of graph signal sampling. We propose a class of regularization functionals that takes into account discrete random label noise in the graph vertex domain, then develop the GS-IMC approach which biases the reconstruction towards functions that vary little between adjacent vertices for noise reduction. Theoretical result shows that accurate reconstructions can be achieved under mild conditions. For the online setting, we develop a Bayesian extension, i.e., BGS-IMC which considers continuous random Gaussian noise in the graph Fourier domain and builds upon a prediction-correction update algorithm to obtain the unbiased and minimum-variance reconstruction. Both GS-IMC and BGS-IMC have closed-form solutions and thus are highly scalable in large data. Experiments show that our methods achieve state-of-the-art performance on public benchmarks.

DocPrompting: Generating Code by Retrieving the Docs

Shuyan Zhou,Uri Alon,Frank F. Xu,Zhengbao Jiang,Graham Neubig

Publicly available source-code libraries are continuously growing and changing. This makes it impossible for models of code
to keep current with all available APIs by simply training these models on existing code repositories. Thus, existing models inherently cannot generalize to using unseen functions and libraries, because these would never appear in the training data. In contrast, when human programmers use functions and libraries for the first time, they frequently refer to textual resources such as code manuals and documentation, to explore and understand the available functionality. Inspired by this observation, we introduce DocPrompting: a natural-language-to-code generation approach that explicitly leverages documentation by (1) retrieving the re

levant documentation pieces given an NL intent, and (2) generating code based on the NL intent and the retrieved documentation. DocPrompting is general: it can be applied to any programming language and is agnostic to the underlying neural model. We demonstrate that DocPrompting consistently improves NL-to-code models: DocPrompting improves strong base models such as CodeT5 by 2.85% in pass@1 (52% relative gain) and 4.39% in pass@10 (30% relative gain) in execution-based evaluation on the popular Python CoNaLa benchmark; on a new Bash dataset tldr, DocPrompting improves CodeT5 and GPT-Neo1.3B by up to absolute 6.9% exact match.

Comparing semantic and morphological analogy completion in word embeddings
Haopeng Xie
Word embeddings have prompted great excitement in the NLP community due to their capacity for generalization to unforeseen tasks, including semantic analogy completion. Features such as color and category relationships have been examined by previous work, but this is the first research considering the morphological relationships encoded in word embeddings. We construct several natural experiments examining analogy completion across word stems modified by affixes, and find no evidence that Word2Vec, glove, and fasttext models encode these morphological relationships. We note that a special case of this problem is part-of-speech transformation, and note that the lack of support for part-of-speech analogies is surprising in the context of other successful cases of semantic inference using word embeddings.

LipsFormer: Introducing Lipschitz Continuity to Vision Transformers
Xianbiao Qi,Jianan Wang,Yihao Chen,Yukai Shi,Lei Zhang
We present a Lipschitz continuous Transformer, called LipsFormer, to pursue training stability both theoretically and empirically for Transformer-based models. In contrast to previous practical tricks that address training instability by learning rate warmup, layer normalization, attention formulation, and weight initialization, we show that Lipschitz continuity is a more essential property to ensure training stability. In LipsFormer, we replace unstable Transformer component modules with Lipschitz continuous counterparts: CenterNorm instead of LayerNorm, spectral initialization instead of Xavier initialization, scaled cosine similarity attention instead of dot-product attention, and weighted residual shortcut. We prove that these introduced modules are Lipschitz continuous and derive an upper bound on the Lipschitz constant of LipsFormer. Our experiments show that LipsFormer allows stable training of deep Transformer architectures without the need of careful learning rate tuning such as warmup, yielding a faster convergence and better generalization. As a result, on the ImageNet 1K dataset, LipsFormer-Tiny training for 100 epochs without learning rate warmup attains a top-1 accuracy of 81.6\% which is higher than Swin Transformer-Tiny training for 300 epochs with warmup. Moreover, LipsFormer-Tiny training for 300 epochs achieves a top-1 accuracy of 83.5\% with 4.7G FLOPs and 24M parameters.

Automatic Chain of Thought Prompting in Large Language Models
Zhuosheng Zhang,Aston Zhang,Mu Li,Alex Smola
Large Language Models (LLMs) can carry out complex reasoning tasks by generating intermediate reasoning steps. These steps are triggered by what is called chain-of-thought (CoT) prompting, which comes in two flavors: one leverages a simple prompt like "Let’s think step by step" to facilitate step-by-step reasoning before answering a question (Zero-Shot-CoT). The other uses manual demonstrations, each composed of a question and a reasoning chain that leads to an answer (Manual-CoT). Unfortunately, the superior performance of the latter strategy crucially hinges on manually generating task-specific demonstrations. This makes it far less scalable and more dependent on the talent of the CoT engineer. We show that such manual efforts may be eliminated by leveraging LLMs to generate the reasoning chains on its own. Since these generated chains often come with mistakes we propose a number of mitigation strategies. Our proposed Auto-CoT method automaticaly samples diverse questions and we perform post-processing quality control to generate usable reasoning chains from Zero-Shot-CoT. On ten public benchmark reas

oning tasks, Auto-CoT performs on par with Manual-CoT without the need for human intervention. Code is available at https://github.com/amazon-research/auto-cot.

An efficient encoder-decoder architecture with top-down attention for speech separation

Kai Li,Runxuan Yang,Xiaolin Hu

Deep neural networks have shown excellent prospects in speech separation tasks. However, obtaining good results while keeping a low model complexity remains challenging in real-world applications. In this paper, we provide a bio-inspired efficient encoder-decoder architecture by mimicking the brain’s top-down attention, called TDANet, with decreased model complexity without sacrificing performance. The top-down attention in TDANet is extracted by the global attention (GA) module and the cascaded local attention (LA) layers. The GA module takes multi-scale acoustic features as input to extract global attention signal, which then modulates features of different scales by direct top-down connections. The LA layers use features of adjacent layers as input to extract the local attention signal, which is used to modulate the lateral input in a top-down manner. On three benchmark datasets, TDANet consistently achieved competitive separation performance to previous state-of-the-art (SOTA) methods with higher efficiency. Specifically, TDANet’s multiply-accumulate operations (MACs) are only 5% of Sepformer, one of the previous SOTA models, and CPU inference time is only 10% of Sepformer. In addition, a large-size version of TDANet obtained SOTA results on three datasets, with MACs still only 10% of Sepformer and the CPU inference time only 24% of Sepformer. Our study suggests that top-down attention can be a more efficient strategy for speech separation.

Treatment Effect Estimation with Collider Bias and Confounding Bias

Baohong Li,Kun Kuang,Ruoxuan Xiong,Fei Wu

To answer causal questions from observational data, it is important to consider the mechanisms that determine which data values are observed and which are missing. Prior work has considered the treatment assignment mechanism and proposed methods to remove the confounding bias from the common causes of treatment and outcome. However, there are other issues in sample selection, commonly overlooked in prior work, that can bias the treatment effect estimation, such as the issue of censored outcome as a form of collider bias. In this paper, we propose the novel Selection Controlled CounterFactual Regression (SC-CFR) to simultaneously address confounding and collider bias. Specifically, we first calculate the magnitude of the collider bias of different instances by estimating the selection model and then add a control term to remove the collider bias while learning a balanced representation to remove the confounding bias when estimating the outcome model. Our method is shown to provide unbiased treatment effect estimates from observational data with confounding and collider bias. Extensive empirical results on both synthetic and real-world datasets show that our method consistently outperforms benchmarks when both types of biases exist.

****

Adaptive Weight Decay: On The Fly Weight Decay Tuning for Improving Robustness

Amin Ghiasi,Ali Shafahi,Reza Ardekani

We introduce adaptive weight decay, which automatically tunes the hyper-parameter for weight decay during each training iteration. For classification problems, we propose changing the value of the weight-decay hyper-parameter on the fly based on the strength of updates from the classification loss (i.e., gradient of cross-entropy), and the regularization loss (i.e., ℓ_2-norm of the weights). We show that this simple modification can result in large improvements in adversarial robustness — an area which suffers from robust overfitting — without requiring extra data. Specifically, our reformulation results in 20% relative robustness improvement for CIFAR-100, and 10% relative robustness improvement on CIFAR-10 comparing to traditional weight-decay. In addition, this method has other desirable properties, such as less sensitivity to learning rate, and smaller weight norms, which the latter contributes to robustness to overfitting to label noise

, and pruning.

Machine Unlearning of Federated Clusters

Chao Pan,Jin Sima,Saurav Prakash,Vishal Rana,Olgica Milenkovic

Federated clustering (FC) is an unsupervised learning problem that arises in a number of practical applications, including personalized recommender and healthcare systems. With the adoption of recent laws ensuring the "right to be forgotten", the problem of machine unlearning for FC methods has become of significant importance. We introduce, for the first time, the problem of machine unlearning for FC, and propose an efficient unlearning mechanism for a customized secure FC framework. Our FC framework utilizes special initialization procedures that we show are well-suited for unlearning. To protect client data privacy, we develop the secure compressed multiset aggregation (SCMA) framework that addresses sparse secure federated learning (FL) problems encountered during clustering as well as more general problems. To simultaneously facilitate low communication complexity and secret sharing protocols, we integrate Reed-Solomon encoding with special evaluation points into our SCMA pipeline, and prove that the client communication cost is logarithmic in the vector dimension. Additionally, to demonstrate the benefits of our unlearning mechanism over complete retraining, we provide a theoretical analysis for the unlearning performance of our approach. Simulation results show that the new FC framework exhibits superior clustering performance compared to previously reported FC baselines when the cluster sizes are highly imbalanced. Compared to completely retraining K-means++ locally and globally for each removal request, our unlearning procedure offers an average speed-up of roughly 84x across seven datasets. Our implementation for the proposed method is available at https://github.com/thupchnsky/mufc.

A System for Morphology-Task Generalization via Unified Representation and Behavior Distillation

Hiroki Furuta,Yusuke Iwasawa,Yutaka Matsuo,Shixiang Shane Gu

The rise of generalist large-scale models in natural language and vision has made us expect that a massive data-driven approach could achieve broader generalization in other domains such as continuous control. In this work, we explore a method for learning a single policy that manipulates various forms of agents to solve various tasks by distilling a large amount of proficient behavioral data. In order to align input-output (IO) interface among multiple tasks and diverse agent morphologies while preserving essential 3D geometric relations, we introduce morphology-task graph, which treats observations, actions and goals/task in a unified graph representation. We also develop MxT-Bench for fast large-scale behavior generation, which supports procedural generation of diverse morphology-task combinations with a minimal blueprint and hardware-accelerated simulator. Through efficient representation and architecture selection on MxT-Bench, we find out that a morphology-task graph representation coupled with Transformer architecture improves the multi-task performances compared to other baselines including recent discrete tokenization, and provides better prior knowledge for zero-shot transfer or sample efficiency in downstream multi-task imitation learning. Our work suggests large diverse offline datasets, unified IO representation, and policy representation and architecture selection through supervised learning form a promising approach for studying and advancing morphology-task generalization.
****

Effective Self-Supervised Transformers For Sparse Time Series Data

Alex Labach,Aslesha Pokhrel,Seung Eun Yi,Saba Zuberi,Maksims Volkovs,Rahul G Krishnan

Electronic health records (EHRs) typically contain a wide range of time series data that is characterized by high sparsity and irregular observations. Self-supervised Transformer architectures have shown outstanding performance in a variety of structured tasks in natural language processing and computer vision. However, their use in modelling sparse irregular time series with tabular data has not been widely explored. One of the major challenges is the quadratic scaling of self-attention layers that can significantly limit the input sequence length. In t his work, we introduce TESS, Transformers for EHR data with Self Supervised learning, a self-supervised Transformer-based architecture designed to extract robust representations from EHR data. We propose an input binning scheme that aggregates the time series inputs and sparsity information into a regular sequence with fixed length, enabling the training of larger and deeper Transformers. We demonstrate that significant compression of EHR input data is possible without sacrificing useful information, likely due to the highly correlated nature of observations in small time bins. We then introduce self-supervised prediction tasks that provide rich and informative signals for model pre-training. TESS outperforms state-of-the-art deep learning models on multiple downstream tasks from the MIMIC-IV and PhysioNet-2012 EHR datasets.

****

Scalable feature selection via sparse learnable masks

Yihe Dong,Sercan O Arik

We propose a canonical approach for feature selection, sparse learnable masks (SLM). SLM integrates learnable sparse masks into end-to-end training. For the fundamental non-differentiability challenge of selecting a desired number of features, we propose duo mechanisms for automatic mask scaling to achieve the desired feature sparsity, and gradually tempering this sparsity for effective learning. In addition, SLM employs a novel objective that maximizes the mutual information between the selected features and the labels. Empirically, SLM achieves state-of-the-art results on several benchmark datasets, often by a significant margin, especially on real-world challenging datasets.

****

On the Interplay Between Misspecification and Sub-optimality Gap: From Linear Contextual Bandits to Linear MDPs

Weitong Zhang,Jiafan He,Zhiyuan Fan,Quanquan Gu

We study linear contextual bandits in the misspecified setting, where the expected reward function can be approximated by a linear function class up to a bounded misspecification level $\zeta>0$. We propose an algorithm based on a novel data selection scheme, which only selects the contextual vectors with large uncertainty for online regression. We show that, when the misspecification level ζ is dominated by $\tilde O(\Delta / \sqrt{d})$ with Δ being the minimal sub-optimality gap and d being the dimension of the contextual vectors, our algorithm enjoys the same gap-dependent regret bound $\tilde O ({d^2} /{\Delta})$ as in the well-specified setting up to logarithmic factors. Together with a lower bound adapted from Du et al. (2019); Lattimore et al.(2020), our result suggests an interplay between misspecification level and the sub-optimality gap: (1) the linear contextual bandit model is efficiently learnable when $\zeta \leq \tilde O({\Delta} / \sqrt{d})$; and (2) it is not efficiently learnable when $\zeta \geq \tilde \Omega({\Delta} / {\sqrt{d}})$. We also extend our algorithm to reinforcement learning with linear Markov decision processes (linear MDPs), and obtain a parallel result of gap-dependent regret. Experiments on both synthetic and real-world datasets corroborate our theoretical results.

HAS IT REALLY IMPROVED? KNOWLEDGE GRAPH BASED SEPARATION AND FUSION FOR RECOMMENDATION

Ying Tang,Jintian Zhang

In this paper we study the knowledge graph (KG) based recommendation systems. We first design the metric to study the relationship between different SOTA models and find that the current recommendation systems based on knowledge graph have poor ability to retain collaborative filtering signals, and higher-order connectivity would introduce noises. In addition, we explore the collaborative filtering recommendation method using GNN and design the experiment to show that the information learned between GNN models stacked with different layers is different, which provides the explanation for the unstable performance of GNN stacking different layers from a new perspective. According to the above findings, we first design the model-agnostic Cross-Layer Fusion Mechanism without any parameters to improve the performance of GNN. Experimental results on three datasets for collaborative filtering show that Cross-Layer Fusion Mechanism is effective for impro ving GNN performance. Then we design three independent signal extractors to mine the data at three different perspectives and train them separately. Finally, we use the signal fusion mechanism to fuse different signals. Experimental results on three datasets that introduce KG show that our KGSF achieves significant improvements over current SOTA KG based recommendation methods and the results are interpretable.

Counterfactual Contrastive Learning for Robust Text Classification

Xiaosong Yuan,Renchu Guan,Wanli Zuo,Yijia Zhang

Text classification has recently been promoted by large pre-trained language models (PLMs) which aim to identify target classes with knowledge transferred from sets of reading comprehension tasks. However, derivative models of PLMs still suffer from sensitive performance on different datasets, the reasons are multiple such as cross-domain and label imbalance problems, from which most models may learn the spurious correlation between texts and labels. Existing research requires people to manually add counterfactual samples to the dataset or automatically match so-called counterfactual pairs that are already in the dataset for augmentation. In this paper, we propose a novel LDA-based counterfactual contrastive learning framework and three data augmentation methods, to capture the causal information in texts, which can promote the robustness of text classification. To confirm the effectiveness of our proposed model and methods, we design and conduct several couples of experiments. Experimental results demonstrate that our model works well on five popular text classification datasets on distinct tasks, we find that training with proposed data augmentation outperforms other augmentation methods on many superior models by 1\% or above. Plus, robustness tests on different datasets also show a competitive performance, which proves the effectiveness of our model and data.

SAM as an Optimal Relaxation of Bayes

Thomas Möllenhoff,Mohammad Emtiyaz Khan

Sharpness-aware minimization (SAM) and related adversarial deep-learning methods can drastically improve generalization, but their underlying mechanisms are not yet fully understood. Here, we establish SAM as a relaxation of the Bayes objective where the expected negative-loss is replaced by the optimal convex lower bound, obtained by using the so-called Fenchel biconjugate. The connection enables a new Adam-like extension of SAM to automatically obtain reasonable uncertainty estimates, while sometimes also improving its accuracy. By connecting adversarial and Bayesian methods, our work opens a new path to robustness.

Denoising MCMC for Accelerating Diffusion-Based Generative Models

Beomsu Kim,Jong Chul Ye

Diffusion models are powerful generative models that simulate the reverse of diffusion processes using score functions to synthesize data from noise. The sampling process of diffusion models can be interpreted as solving the reverse stochastic differential equation (SDE) or the ordinary differential equation (ODE) of the diffusion process, which often requires up to thousands of discretization steps to generate a single image. This has sparked a great interest in developing efficient integration techniques for reverse-S/ODEs. Here, we propose an orthogonal approach to accelerating score-based sampling: Denoising MCMC (DMCMC). DMCMC first uses MCMC to produce samples in the product space of data and variance (or diffusion time). Then, a reverse-S/ODE integrator is used to denoise the MCMC samples. Since MCMC traverses close to the data manifold, the computation cost of producing a clean sample for DMCMC is much less than that of producing a clean sample from noise. To verify the proposed concept, we show that Denoising Langevin Gibbs (DLG), an instance of DMCMC, successfully accelerates all six reverse-S/ODE integrators considered in this work on the tasks of CIFAR10 and CelebA-HQ-256 image generation. Notably, combined with integrators of Karras et al. (2022) and pre-trained score models of Song et al. (2021b), DLG achieves state-of-the-art results. In the limited number of score function evaluation (NFE) settings on CIFAR10, we have 3.86 FID with ≈ 10 NFE and 2.63 FID with $\approx

20$ NFE. On CelebA-HQ-256, we have 6.99 FID with ≈ 160 NFE, which beats the current best record of Kim et al. (2022) among score-based models, 7.16 FID with 4000 NFE.

Learning on Large-scale Text-attributed Graphs via Variational Inference
Jianan Zhao,Meng Qu,Chaozhuo Li,Hao Yan,Qian Liu,Rui Li,Xing Xie,Jian Tang
This paper studies learning on text-attributed graphs (TAGs), where each node is associated with a text description. An ideal solution for such a problem would be integrating both the text and graph structure information with large language models and graph neural networks (GNNs). However, the problem becomes very challenging when graphs are large due to the high computational complexity brought by training large language models and GNNs together. In this paper, we propose an efficient and effective solution to learning on large text-attributed graphs by fusing graph structure and language learning with a variational Expectation-Maximization (EM) framework, called GLEM. Instead of simultaneously training large language models and GNNs on big graphs, GLEM proposes to alternatively update the two modules in the E-step and M-step. Such a procedure allows training the two modules separately while simultaneously allowing the two modules to interact and mutually enhance each other. Extensive experiments on multiple data sets demonstrate the efficiency and effectiveness of the proposed approach.

Rethinking Identity in Knowledge Graph Embedding
Jiayi Li,Jiaqi Sun,Yujiu Yang
Knowledge Graph Embedding (KGE) is a common method to complete real-world Knowledge Graphs (KGs) by learning the embeddings of entities and relations.
Beyond specific KGE models, previous work proposes a general framework based on group. A group has a special element identity that uniquely corresponds to the relation identity in KGs, which implies that identity should be represented uniquely. However, we find that this uniqueness cannot be modeled by bilinear based models, revealing the crack between the framework and models. To this end, we study the required conditions and propose a solution named Unit Ball Bilinear Model (UniBi). In addition to the theoretical superiority, UniBi is more robust and interpretable. Experiments demonstrate that UniBi models the uniqueness without the cost of performance and verify its a robustness and interpretability.

Eigen Memory Trees
Mark Rucker,Jordan T. Ash,John Langford,Paul Mineiro,Ida Momennejad
This work introduces the Eigen Memory Tree (EMT), a novel online memory model for sequential learning scenarios. EMTs store data at the leaves of a binary tree, and route new samples through the structure using the principal components of previous experiences, facilitating efficient (logarithmic) access to relevant memories. We demonstrate that EMT outperforms existing online memory approaches, and provide a hybridized EMT-parametric algorithm that enjoys drastically improved performance over purely parametric methods with nearly no downsides. Our findings are validated using 206 datasets from OpenML repository in both bounded and infinite memory budget situations.

Energy-based Predictive Representation for Reinforcement Learning
Tianjun Zhang,Tongzheng Ren,Chenjun Xiao,Wenli Xiao,Joseph E. Gonzalez,Dale Schuurmans,Bo Dai
In real world applications, it is usually necessary for a reinforcement learning algorithm to handle the partial observability beyond Markov decision processes (MDPs). Although the partially observable Markov decision process (POMDP) has been precisely motivated for this requirement, such a formulation raises significant computational and statistical hardness challenges in learning and planning. In this work, we introduce the Energy-based Predictive Representation (EPR), which leads to a unified framework for practical reinforcement learning algorithm design in both MDPs and POMDPs settings, to handle the learning, exploration, and planning in a coherent way. The proposed approach relies on the powerful neural energy-based model to extract sufficient representation, from which Q-functions

can be efficiently approximated. With such a representation, we develop an efficient approach for computing confidence, which allows optimism/pessimism in the face of uncertainty to be efficiently implemented in planning, hence managing the exploration versus exploitation tradeoff. An experimental investigation shows that the proposed algorithm can surpass state-of-the-art performance in both MDP and POMDP settings in comparison to existing baselines.

Which Invariance Should We Transfer? A Causal Minimax Learning Approach

Mingzhou Liu,Xiangyu Zheng,Xinwei Sun,Fang Fang,Yizhou Wang

A major barrier to deploy current machine learning models lies in their sensitivity to dataset shifts. To resolve this problem, most existing studies attempted to transfer stable information to unseen environments. Among these, graph-based methods causally decomposed the data generating process into stable and mutable mechanisms. By removing the effect of mutable generation, they identified a set of stable predictors. However, a key question regarding robustness remains: which subset of the whole stable information should the model transfer, in order to achieve optimal generalization ability? To answer this question, we provide a comprehensive minimax analysis that fully characterizes conditions for a subset to be optimal. Particularly in general cases, we propose to maximize over mutable mechanisms (i.e., the source of dataset shifts), which is provable to identify the worst-case risk over all environments. This ensures us to select the optimal subset with the minimal worst-case risk. To reduce computational costs, we propose to search over only equivalent classes in terms of worst-case risk, instead of over all subsets. In cases when the searching space is still large, we turn this subset selection problem into a sparse min-max optimization scheme, which enjoys the simplicity and efficiency of implementation. The utility of our methods is demonstrated on the diagnosis of Alzheimer's Disease and gene function prediction.

Exclusive Supermask Subnetwork Training for Continual Learning

Prateek Yadav,Mohit Bansal

Continual Learning (CL) methods mainly focus on avoiding catastrophic forgetting and learning representations that are transferable to new tasks. Recently, Wortsman et al. (2020) proposed a CL method, SupSup, which uses a randomly initialized, fixed base network (model) and finds a supermask for each new task that selectively keeps or removes each weight to produce a subnetwork. They prevent forgetting as the network weights are not being updated. Although there is no forgetting, the performance of supermask is sub-optimal because fixed weights restrict its representational power. Furthermore, there is no accumulation or transfer of knowledge inside the model when new tasks are learned. Hence, we propose ExSSNeT (Exclusive Supermask SubNEtwork Training), that performs exclusive and non-overlapping subnetwork weight training. This avoids conflicting updates to the shared weights by subsequent tasks to improve performance while still preventing forgetting. Furthermore, we propose a novel KNN-based Knowledge Transfer (KKT) module that dynamically initializes a new task's mask based on previous tasks for improving knowledge transfer. We demonstrate that ExSSNeT outperforms SupSup and other strong previous methods on both text classification and vision tasks while preventing forgetting. Moreover, ExSSNeT is particularly advantageous for sparse masks that activate 2-10% of the model parameters, resulting in an average improvement of 8.3% over SupSup. Additionally, ExSSNeT scales to a large number of tasks (100), and our KKT module helps to learn new tasks faster while improving the overall performance.

Dual personalization for federated recommendation on devices

Chunxu Zhang,Guodong Long,Tianyi Zhou,Zijian Zhang,Bo Yang

Federated recommendation is a new Internet service architecture that aims to provide privacy-preserving recommendation services in federated settings. Existing solutions are used to combine distributed recommendation algorithms and privacy-preserving mechanisms. Thus it inherently takes the form of heavyweight models at the server and hinders the deployment of on-device intelligent models to end-u

sers. This paper proposes a novel Personalized Federated Recommendation (PFedRec) framework to learn many user-specific lightweight models to be deployed on smart devices rather than a heavyweight model on a server. Moreover, we propose a new dual personalization mechanism to effectively learn fine-grained personalization on both users and items. The overall learning process is formulated into a unified federated optimization framework. Specifically, unlike previous methods that share exactly the same item embeddings across users in a federated system, dual personalization allows mild finetuning of item embeddings for each user to generate user-specific views for item representations which can be integrated into existing federated recommendation methods to gain improvements immediately. Experiments on multiple benchmark datasets have demonstrated the effectiveness of PFedRec and the dual personalization mechanism. Moreover, we provide visualizations and in-depth analysis of the personalization techniques in item embedding, which shed novel insights on the design of RecSys in federated settings.

Moderate Coreset: A Universal Method of Data Selection for Real-world Data-efficient Deep Learning

Xiaobo Xia,Jiale Liu,Jun Yu,Xu Shen,Bo Han,Tongliang Liu

Deep learning methods nowadays rely on massive data, resulting in substantial costs of data storage and model training. Data selection is a useful tool to alleviate such costs, where a coreset of massive data is extracted to practically perform on par with full data. Based on carefully-designed score criteria, existing methods first count the score of each data point and then select the data points whose scores lie in a certain range to construct a coreset. These methods work well in their respective preconceived scenarios but are not robust to the change of scenarios, since the optimal range of scores varies as the scenario changes. The issue limits the application of these methods, because realistic scenarios often mismatch preconceived ones, and it is inconvenient or unfeasible to tune the criteria and methods accordingly. In this paper, to address the issue, a concept of the moderate coreset is discussed. Specifically, given any score criterion of data selection, different scenarios prefer data points with scores in different intervals. As the score median is a proxy of the score distribution in statistics, the data points with scores close to the score median can be seen as a proxy of full data and generalize different scenarios, which are used to construct the moderate coreset. As a proof-of-concept, a universal method that inherits the moderate coreset and uses the distance of a data point to its class center as the score criterion, is proposed to meet complex realistic scenarios. Extensive experiments confirm the advance of our method over prior state-of-the-art methods, leading to a strong baseline for future research. The implementation is available at https://github.com/tmllab/Moderate-DS.

Effectively Clarify Confusion via Visualized Aggregation and Separation of Deep Representation

Yi Lin,Jingchi Jiang,Dongxin Chen,Zhaoyang Ma,Yi Guan,Xiguang Liu,Haiyan You,Jing Yang

Clarifying confusion is the most critical issue for improving classification performance. Confusion occurs with almost all classification models but tends to be ignored in excellent-performing models. The current mainstream research mainly focuses on solving the confusion in a specific case, such as data insufficiency and class imbalance. We believe that mining the commonalities of the same class and the gaps among different classes will effectively clarify the confusion. In this paper, we propose a novel, simple and intuitive Aggregation Separation Loss (ASLoss), as an adjunct for classification loss to clarify the confusion in some common cases. The ASLoss aggregates the representations of the same class samples as near as possible and separates the representations of different classes as far as possible.

We use two image classification tasks with three simultaneous confounding characteristics i.e. data insufficiency, class imbalance, and unclear class evidence to demonstrate ASLoss. Representation visualization, confusion comparison and detailed comparison experiments are conducted. The results show that representation s in deep spaces extracted by ASLoss are sufficiently clear and distinguishable, the confusion among different classes is significantly clarified and the optimal network using ASLoss reaches the state-of-the-art level.

Time-Transformer AAE: Connecting Temporal Convolutional Networks and Transformer for Time Series Generation

Yuansan Liu,Sudanthi Wijewickrema,Ang Li,James Bailey

Generating time series data is a challenging task due to the complex temporal properties of this type of data. Such temporal properties typically include local correlations as well as global dependencies. Most existing generative models have failed to effectively learn both the local and global properties of time series data. To address this open problem, we propose a novel time series generative model consisting of an adversarial autoencoder (AAE) and a newly designed architecture named `Time-Transformer' within the decoder. We call this generative model `Time-Transformer AAE'. The Time-Transformer first simultaneously learns local and global features in a layer-wise parallel design, combining the abilities of Temporal Convolutional Networks (TCN) and Transformer in extracting local features and global dependencies respectively. Second, a bidirectional cross attention is proposed to provide complementary guidance across the two branches and achieve proper fusion between local and global features. Experimental results demonstrate that our model can outperform existing state-of-the-art models in most cases, especially when the data contains both global and local properties. We also show our model's ability to perform a downstream task: data augmentation to support the solution of imbalanced classification problems.

A comparison of dataset distillation and active learning in text classification

Zhang Zeyu,Zhang Yuanchun

Deep learning has achieved great success over the past few years in different aspects ranging from computer vision to natural language process. However, the huge size of data in deep learning has always been a thorny problem in learning the underlying distribution and tackling various human tasks. To alleviate this problem, knowledge distillation has been proposed to simplify the model, and later dataset distillation as a new method of reducing dataset sizes has been proposed, which aims to synthesize a small number of samples that contain all the information of a very large dataset. Meanwhile, active learning is also an effective method to reduce dataset sizes by only selecting the most significant labeling samples from the original dataset. In this paper, we explore the discrepancies in the principles of dataset distillation and active learning, and evaluate two algorithms on NLP classification dataset: Stanford Sentiment Treebank. The result of the experiment is that the distilled data with the size of 0.1% of the original text data achieves approximately 88% accuracy, while the selected data achieves 52% performance of the original data.

Temporally Consistent Video Transformer for Long-Term Video Prediction

Wilson Yan,Danijar Hafner,Stephen James,Pieter Abbeel

Generating long, temporally consistent video remains an open challenge in video generation. Primarily due to computational limitations, most prior methods limit themselves to training on a small subset of frames that are then extended to generate longer videos through a sliding window fashion. Although these techniques may produce sharp videos, they have difficulty retaining long-term temporal consistency due to their limited context length. In this work, we present Temporally Consistent Video Transformer (TECO), a vector-quantized latent dynamics video prediction model that learns compressed representations to efficiently condition on long videos of hundreds of frames during both training and generation. We use a MaskGit prior for dynamics prediction which enables both sharper and faster generations compared to prior work. Our experiments show that TECO outperforms SOTA baselines in a variety of video prediction benchmarks ranging from simple mazes in DMLab, large 3D worlds in Minecraft, and complex real-world videos from Kinetics-600. In addition, to better understand the capabilities of video predict ion models in modeling temporal consistency, we introduce several challenging video prediction tasks consisting of agents randomly traversing 3D scenes of varying difficulty. This presents a challenging benchmark for video prediction in partially observable environments where a model must understand what parts of the scenes to re-create versus invent depending on its past observations or generations. An anonymized website with samples can be found at https://sites.google.com/view/iclr23-teco

Extreme Q-Learning: MaxEnt RL without Entropy

Divyansh Garg,Joey Hejna,Matthieu Geist,Stefano Ermon

Modern Deep Reinforcement Learning (RL) algorithms require estimates of the maximal Q-value, which are difficult to compute in continuous domains with an infinite number of possible actions. In this work, we introduce a new update rule for online and offline RL which directly models the maximal value using Extreme Value Theory (EVT), drawing inspiration from economics. By doing so, we avoid computing Q-values using out-of-distribution actions which is often a substantial source of error. Our key insight is to introduce an objective that directly estimates the optimal soft-value functions (LogSumExp) in the maximum entropy RL setting without needing to sample from a policy. Using EVT, we derive our \emph{Extreme Q-Learning} framework and consequently online and, for the first time, offline MaxEnt Q-learning algorithms, that do not explicitly require access to a policy or its entropy. Our method obtains consistently strong performance in the D4RL benchmark, outperforming prior works by \emph{10+ points} on the challenging Franka Kitchen tasks while offering moderate improvements over SAC and TD3 on online DM Control tasks. Visualizations and code can be found on our website.

Autoencoding Hyperbolic Representation for Adversarial Generation

Eric Qu,Dongmian Zou

With the recent advance of geometric deep learning, neural networks have been extensively used for data in non-Euclidean domains. In particular, hyperbolic neural networks have proved successful in processing hierarchical information of data. However, many hyperbolic neural networks are numerically unstable during training, which precludes using complex architectures. This crucial problem makes it difficult to build hyperbolic generative models for real and complex data. In this work, we propose a hyperbolic generative network in which we design novel architecture and layers to guarantee stable training. Our proposed network contains three parts: first, a hyperbolic autoencoder (AE) that produces hyperbolic embedding for input data; second, a hyperbolic generative adversarial network (GAN) for generating the hyperbolic latent embedding of the AE from simple noise; third, a generator that inherits the decoder from the AE and the generator from the GAN. We call this network the hyperbolic AE-GAN, or HAEGAN for short. The architecture of HAEGAN fosters expressive representation in the hyperbolic space, and the specific design of layers ensures numerical stability. Experiments show that HAEGAN is able to generate complex data with state-of-the-art structure-related performance.

CAREER: Transfer Learning for Economic Prediction of Labor Data

Keyon Vafa,Emil Palikot,Tianyu Du,Ayush Kanodia,Susan Athey,David Blei

Labor economists regularly analyze employment data by fitting predictive models to small, carefully constructed longitudinal survey datasets. Although modern machine learning methods offer promise for such problems, these survey datasets are too small to take advantage of them. In recent years large datasets of online resumes have also become available, providing data about the career trajectories of millions of individuals. However, standard econometric models cannot take advantage of their scale or incorporate them into the analysis of survey data. To this end we develop CAREER, a transformer-based model that uses transfer learning to learn representations of job sequences. CAREER is first fit to large, passively-collected resume data and then fine-tuned to smaller, better-curated datasets for economic inferences. We fit CAREER to a dataset of 24 million job sequences from resumes, and fine-tune its representations on longitudinal survey datas ets. We find that CAREER forms accurate predictions of job sequences, achieving state-of-the-art predictive performance on three widely-used economics datasets. We further find that CAREER can be used to form good predictions of other downstream variables; incorporating CAREER into a wage model provides better predictions than the econometric models currently in use.

Federated Nearest Neighbor Machine Translation

Yichao Du,Zhirui Zhang,Bingzhe Wu,Lemao Liu,Tong Xu,Enhong Chen

To protect user privacy and meet legal regulations, federated learning (FL) is attracting significant attention. Training neural machine translation (NMT) models with traditional FL algorithm (e.g., FedAvg) typically relies on multi-round model-based interactions. However, it is impractical and inefficient for machine translation tasks due to the vast communication overheads and heavy synchronization. In this paper, we propose a novel federated nearest neighbor (FedNN) machine translation framework that, instead of multi-round model-based interactions, leverages one-round memorization-based interaction to share knowledge across different clients to build low-overhead privacy-preserving systems. The whole approach equips the public NMT model trained on large-scale accessible data with a $k$-nearest-neighbor ($k$NN) classifier and integrates the external datastore constructed by private text data in all clients to form the final FL model. A two-phase datastore encryption strategy is introduced to achieve privacy-preserving during this process. Extensive experiments show that FedNN significantly reduces computational and communication costs compared with FedAvg, while maintaining promising performance in different FL settings.

Latent Variable Representation for Reinforcement Learning

Tongzheng Ren,Chenjun Xiao,Tianjun Zhang,Na Li,Zhaoran Wang,sujay sanghavi,Dale Schuurmans,Bo Dai

Deep latent variable models have achieved significant empirical successes in model-based reinforcement learning (RL) due to their expressiveness in modeling complex transition dynamics. On the other hand, it remains unclear theoretically and empirically how latent variable models may facilitate learning, planning, and exploration to improve the sample efficiency of RL. In this paper, we provide a representation view of the latent variable models for state-action value functions, which allows both tractable variational learning algorithm and effective implementation of the optimism/pessimism principle in the face of uncertainty for exploration. In particular, we propose a computationally efficient planning algorithm with UCB exploration by incorporating kernel embeddings of latent variable models. Theoretically, we establish the sample complexity of the proposed approach in the online and offline settings. Empirically, we demonstrate superior performance over current state-of-the-art algorithms across various benchmarks.

****

Look in The Mirror: Molecular Graph Contrastive Learning with Line Graph

Junran Wu,Xueyuan Chen,Bowen Shi,Jiaheng Liu,Shangzhe Li,Ke Xu

Trapped by the label scarcity in molecular property prediction and drug design, graph contrastive learning came forward. A general contrastive model consists of a view generator, view encoder, and contrastive loss, in which the view mainly controls the encoded information underlying input graphs. Leading contrastive learning works show two kinds of view generators, that is, random or learnable data corruption and domain knowledge incorporation. While effective, the two ways also lead to molecular semantics altering and limited generalization capability, respectively. Thus, a decent view that can fully retain molecular semantics and is free from profound domain knowledge is supposed to come forward. To this end, we relate molecular graph contrastive learning with the line graph and propose a novel method termed LGCL. Specifically, by contrasting the given graph with the corresponding line graph, the graph encoder can freely encode the molecular semantics without omission. While considering the information inconsistency and over-smoothing derived from the learning process because of the mismatched pace of message passing in two kinds of graphs, we present a new patch with edge attribute fusion and two local contrastive losses for performance fixing. Compared wit h state-of-the-art (SOTA) methods for view generation, superior performance on molecular property prediction suggests the effectiveness of line graphs severing as the contrasting views.

Precision Collaboration for Federated Learning

Sen Cui,Abudukelimu Wuerkaixi,Jian Liang,Weishen Pan,Jianwei Zhang,Changshui Zhang,Fei Wang

Inherent heterogeneity of local data distributions, which causes inefficient model learning and significant degradation of model performance, has been a key challenge in Federated Learning (FL). So far, plenty of efforts have focused on addressing data heterogeneity by relying on a hypothetical clustering structure or a consistent information sharing mechanism. However, because of the diversity of the real-world local data, these assumptions may be largely violated. In this work, we argue that information sharing is mostly fragmented in the federated network in reality. More specifically, the distribution overlaps are not consistent but scattered in local clients. In this work, we propose the concept ``Precision Collaboration'' which refers to learning from the informative overlaps precisely while avoiding the potential negative transfer induced by others. In particular, we propose to infer the local data manifolds and estimate the exact local data density simultaneously. The learned manifold aims to precisely identify the overlaps from other clients, and the estimated likelihood allows to generate samples from the manifold in an optimal sampling density. Experiments show that our proposed PCFL significantly overcomes baselines on benchmarks and a real-world clinical scenario.

RLSBench: A Large-Scale Empirical Study of Domain Adaptation Under Relaxed Label Shift

Saurabh Garg,Nick Erickson,James Sharpnack,Alex Smola,Sivaraman Balakrishnan,Zachary Chase Lipton

Despite the emergence of principled methods for domain adaptation under label shift (where only the class balance changes), the sensitivity of these methods to natural-seeming covariate shifts remains precariously underexplored. Meanwhile, popular deep domain adaptation heuristics, despite showing promise on benchmark datasets, tend to falter when faced with shifts in the class balance. Moreover, it's difficult to assess the state of the field owing to inconsistencies among relevant papers in evaluation criteria, datasets, and baselines. In this paper, we introduce \textsc{RLSbench}, a large-scale benchmark for such \emph{relaxed label shift} settings, consisting of 11 vision datasets spanning $>$200 distribution shift pairs with different class proportions. We evaluate 12 popular domain adaptation methods, demonstrating a more widespread susceptibility to failure under extreme shifts in the class proportions than was previously known. We develop an effective meta-algorithm, compatible with most deep domain adaptation heuristics, that consists of the following two steps: (i) \emph{pseudo-balance} the data at each epoch; and (ii) adjust the final classifier with (an estimate of) target label distribution. Furthermore, we discover that batch-norm adaption of a model trained on source with aforementioned corrections offers a strong baseline, largely missing from prior comparisons. We hope that these findings and the availability of \textsc{RLSbench} will encourage researchers to include rigorously evaluate proposed methods in relaxed label shift settings. Code is publicly available at https://github.com/ICLR2023Anon.

ROCO: A General Framework for Evaluating Robustness of Combinatorial Optimization Solvers on Graphs

Han Lu,Zenan Li,Runzhong Wang,Qibing Ren,Xijun Li,Mingxuan Yuan,Jia Zeng,Xiaokang Yang,Junchi Yan

Solving combinatorial optimization (CO) on graphs has been attracting increasing interests from the machine learning community whereby data-driven approaches were recently devised to go beyond traditional manually-designated algorithms. In this paper, we study the robustness of a combinatorial solver as a blackbox regardless it is classic or learning-based though the latter can often be more interesting to the ML community. Specifically, we develop a practically feasible robustness metric for general CO solvers. A no-worse optimal cost guarantee is developed as such the optimal solutions are not required to achieve for solvers, and we tackle the non-differentiable challenge in input instance disturbance by resorting to black-box adversarial attack methods. Extensive experiments are conducted on 14 unique combinations of solvers and CO problems, and we demonstrate that the performance of state-of-the-art solvers like Gurobi can degenerate by over 20% under the given time limit bound on the hard instances discovered by our robustness metric, raising concerns about the robustness of combinatorial optimization solvers.

Spatial reasoning as Object Graph Energy Minimization

Nikolaos Gkanatsios,Ayush Jain,Zhou Xian,Yunchu Zhang,Katerina Fragkiadaki

We propose a model that maps spatial rearrangement instructions to goal scene configurations via gradient descent on a set of relational energy functions over object 2D overhead locations, one per spatial predicate in the instruction. Energy based models over object locations are trained from a handful of examples of object arrangements annotated with the corresponding spatial predicates. Predicates can be binary (e.g., left of, right of, etc.) or multi-ary (e.g., circles, lines, etc.). A language parser maps language instructions to the corresponding set of EBMs, and a visual-language model grounds their arguments on relevant objects in the visual scene. Energy minimization on the joint set of energies iteratively updates the object locations till their final configuration. Then, low-level local policies re-locate objects to the inferred goal locations. Our framework shows many forms of strong generalization: (i)joint energy minimization handles zero-shot complex predicate compositions while each EBM is trained only from single predicate instructions, (ii) the model can execute instructions zero-shot, without a need for paired instruction-action training, (iii) instructions can mention novel objects and attributes at test time thanks to the pre-training of the visual language grounding model from large scale passive captioned datasets. We test the model in established instruction-guided manipulation benchmarks, as well as a benchmark of compositional instructions we introduce in this work. We show large improvements over state-of-the-art end-to-end language to action policies and planning in large language models, especially for long instructions and multi-ary spatial concepts.

Words are all you need? Language as an approximation for human similarity judgments

Raja Marjieh,Pol Van Rijn,Ilia Sucholutsky,Theodore Sumers,Harin Lee,Thomas L. Griffiths,Nori Jacoby

Human similarity judgments are a powerful supervision signal for machine learning applications based on techniques such as contrastive learning, information retrieval, and model alignment, but classical methods for collecting human similarity judgments are too expensive to be used at scale. Recent methods propose using pre-trained deep neural networks (DNNs) to approximate human similarity, but pre-trained DNNs may not be available for certain domains (e.g., medical images, low-resource languages) and their performance in approximating human similarity has not been extensively tested. We conducted an evaluation of 611 pre-trained models across three domains -- images, audio, video -- and found that there is a large gap in performance between human similarity judgments and pre-trained DNNs. To address this gap, we propose a new class of similarity approximation methods based on language. To collect the language data required by these new methods, we also developed and validated a novel adaptive tag collection pipeline. We find that our proposed language-based methods are significantly cheaper, in the number of human judgments, than classical methods, but still improve performance over the DNN-based methods. Finally, we also develop `stacked' methods that combine language embeddings with DNN embeddings, and find that these consistently provide the best approximations for human similarity across all three of our modalit ies. Based on the results of this comprehensive study, we provide a concise guide for researchers interested in collecting or approximating human similarity data. To accompany this guide, we also release all of the similarity and language data, a total of 206,339 human judgments, that we collected in our experiments, along with a detailed breakdown of all modeling results.

Graph Contrastive Learning with Reinforced Augmentation
Ziyang Liu,Chaokun Wang

Graph contrastive learning (GCL), designing contrastive objectives to learn embeddings from augmented graphs, has become a prevailing method for learning embeddings from graphs in an unsupervised manner. As an important procedure in GCL, graph data augmentation (GDA) directly affects the model performance on the downstream task. Currently, there are three types of GDA strategies: trial-and-error, precomputed method, and adversarial method. However, these strategies ignore the connection between the two consecutive augmentation results because GDA is regarded as an independent process. In this paper, we regard the GDA in GCL as a Markov decision process. Based on this point, we propose a reinforced method, i.e., the fourth type of GDA strategy, using a novel Graph Advantage Actor-Critic (GA2C) model for GCL. On 23 graph datasets, the experimental results verify that GA2C outperforms the SOTA GCL models on a series of downstream tasks such as graph classification, node classification, and link prediction.

****

A Novel Fast Exact Subproblem Solver for Stochastic Quasi-Newton Cubic Regularized Optimization
Jarad Forristal,Joshua Griffin,Wenwen Zhou,Seyedalireza Yektamaram

In this work we describe an Adaptive Regularization using Cubics (ARC) method for large-scale nonconvex unconstrained optimization using Limited memory Quasi-Newton (LQN) matrices. ARC methods are a relatively new family of second-order optimization strategies that utilize a cubic-regularization (CR) term in place of trust-regions or line-searches. Solving the CR subproblem exactly requires Newton's method, yet using properties of the internal structure of LQN matrices, we are able to find exact solutions to the CR subproblem in a matrix-free manner, providing very large speedups. Additionally, we expand upon previous ARC work and explicitly incorporate first-order updates into our algorithm. We provide empirical results for different LQN matrices and find our proposed method compares to or exceeds all tested optimizers with minimal tuning.

Block-Diagonal Structure Learning for Subspace Clustering
Zheng Xing,Weibing Zhao

Finding the informative subspaces of high-dimensional ordered datasets is at the core of innumerable applications in computer vision, where spectral-based subspace clustering is arguably the most commonly studied method due to its strong empirical performance. Such algorithms compute an affinity matrix to construct a self-representation for each sample utilizing other samples as a dictionary, and spectral clustering is employed to identify the clustering structure based on the affinity matrix. Since the ordered nature, the block-diagonal structure learning embedded in self-representation plays a vital role in effective subspace clustering. However, direct optimization with block-diagonal priors is challenging due to the random sparseness and connectivity nature of self-representation, and none of the existing techniques resort to the block-diagonal structure learning of self-representation alone. In this paper, we propose a technique, namely block-diagonal structure representation learning, to solve the optimal clustering of the ordered data directly instead of employing spectral clustering. The proposed algorithm can theoretically achieve the global optimal solution of the proposed discrete non-convex block-diagonal partition problem. We test the proposed clustering method on several types of segmentation databases, such as human face recognization, video scene clip partition, motion tracks, and dynamic 3-D facial expression sequences. The experiments illustrate that the proposed method outperforms state-of-the-art subspace clustering methods.

****

Offline RL of the Underlying MDP from Heterogeneous Data Sources
Chengshuai Shi,Wei Xiong,Cong Shen,Jing Yang

Most of the existing offline reinforcement learning (RL) studies assume the available dataset is sampled directly from the target environment. However, in some practical applications, the available data are often coming from several related but heterogeneous environments. A theoretical understanding of efficient learning from heterogeneous offline datasets remains lacking. In this work, we study the problem of learning a (hidden) underlying Markov decision process (MDP) based on heterogeneous offline datasets collected from multiple randomly perturbed data sources. A novel HetPEVI algorithm is proposed, which jointly considers two types of uncertainties: sample uncertainties from the finite number of data samples per data source, and source uncertainties due to a finite number of data sources. Building on HetPEVI, we further incorporate reference-advantage decompositions and Bernstein-type penalties to propose the HetPEVI-Adv algorithm. Theoretical analysis not only proves the effectiveness of both HetPEVI and HetPEVI-Adv but also demonstrates the advantage of the latter. More importantly, the results explicitly characterize the learning loss due to the finite heterogeneously realized environments compared with sampling directly from the underlying MDP. Finally, we extend the study to MDPs with linear function approximation and propose the HetPEVI-Lin algorithm that provides additional efficiency guarantees beyond the tabular case.

FreeMatch: Self-adaptive Thresholding for Semi-supervised Learning
Yidong Wang,Hao Chen,Qiang Heng,Wenxin Hou,Yue Fan,Zhen Wu,Jindong Wang,Marios Savvides,Takahiro Shinozaki,Bhiksha Raj,Bernt Schiele,Xing Xie

Semi-supervised Learning (SSL) has witnessed great success owing to the impressive performances brought by various methods based on pseudo labeling and consistency regularization. However, we argue that existing methods might fail to utilize the unlabeled data more effectively since they either use a pre-defined / fixed threshold or an ad-hoc threshold adjusting scheme, resulting in inferior performance and slow convergence. We first analyze a motivating example to obtain intuitions on the relationship between the desirable threshold and model's learning status. Based on the analysis, we hence propose FreeMatch to adjust the confidence threshold in a self-adaptive manner according to the model's learning status. We further introduce a self-adaptive class fairness regularization penalty to encourage the model for diverse predictions during the early training stage. Extensive experiments indicate the superiority of FreeMatch especially when the labeled data are extremely rare. FreeMatch achieves 5.78%, 13.59%, and 1.28% error rate reduction over the latest state-of-the-art method FlexMatch on CIFAR-10 with 1 label per class, STL-10 with 4 labels per class, and ImageNet with 100 labels per class, respectively. Moreover, FreeMatch can also boost the performance of imbalanced SSL. The codes can be found at https://github.com/microsoft/Semi-supervised-learning.

Training image classifiers using Semi-Weak Label Data
Ankit Parag Shah,Bhiksha Raj

This paper introduces a new semi-weak label learning paradigm which provides additional information in comparison to the weak label classification. We define semi-weak label data as data where we know the presence or absence of a given class and additionally we have the information about the exact count of each class as opposed to knowing the label proportions. A three-stage framework is proposed to address the problem of learning from semi-weak labels. It leverages the fact that counting information is naturally non-negative and discrete. Experiments are conducted on generated samples from CIFAR-10 and we compare our model with a fully-supervised setting baseline, a weakly-supervised setting baseline and a learning from proportion(LLP) baseline. Our framework not only outperforms both baseline models for MIL-based weakly supervised setting and learning from proportio n setting, but also gives comparable results compared to the fully supervised model. Further, we conduct thorough ablation studies to analyze across datasets and variation with batch size, losses architectural changes, bag size and regularization, thereby demonstrating robustness of our approach.

Confidence Estimation Using Unlabeled Data

Chen Li,Xiaoling Hu,Chao Chen

Overconfidence is a common issue for deep neural networks, limiting their deployment in real-world applications. To better estimate confidence, existing methods mostly focus on fully-supervised scenarios and rely on training labels. In this paper, we propose the first confidence estimation method for a semi-supervised setting, when most training labels are unavailable. We stipulate that even with limited training labels, we can still reasonably approximate the confidence of model on unlabeled samples by inspecting the prediction consistency through the training process. We use training consistency as a surrogate function and propose a consistency ranking loss for confidence estimation. On both image classification and segmentation tasks, our method achieves state-of-the-art performances in confidence estimation. Furthermore, we show the benefit of the proposed method through a downstream active learning task.

Spectral Decomposition Representation for Reinforcement Learning

Tongzheng Ren,Tianjun Zhang,Lisa Lee,Joseph E. Gonzalez,Dale Schuurmans,Bo Dai

Representation learning often plays a critical role in avoiding the curse of dimensionality in reinforcement learning. A representative class of algorithms exploits spectral decomposition of the stochastic transition dynamics to construct representations that enjoy strong theoretical properties in idealized settings. However, current spectral methods suffer from limited applicability because they are constructed for
state-only aggregation and are derived from a policy-dependent transition kernel, without considering the issue of exploration. To address these issues, we propose an alternative spectral method, Spectral Decomposition Representation (SPEDER), that extracts a state-action abstraction from the dynamics without inducing spurious dependence on the data collection policy, while also balancing the exploration-versus-exploitation trade-off during learning. A theoretical analysis establishes the sample efficiency of the proposed algorithm in both the online and offline settings. In addition, an experimental investigation demonstrates superior performance over current state-of-the-art algorithms across several RL benchmarks.

On Accelerated Perceptrons and Beyond

Guanghui Wang,Rafael Hanashiro,Etash Kumar Guha,Jacob Abernethy

The classical Perceptron algorithm of Rosenblatt can be used to find a linear threshold function to correctly classify n linearly separable data points, assuming the classes are separated by some margin $\gamma > 0$. A foundational result is that Perceptron converges after $\Omega(1/\gamma^{2})$ iterations. There have been several recent works that managed to improve this rate by a quadratic factor, to $\Omega(\sqrt{\log n}/\gamma)$, with more sophisticated algorithms. In this paper, we unify these existing results under one framework by showing that they can all be described through the lens of solving min-max problems using modern acceleration techniques, mainly through \emph{optimistic} online learning.
We then show that the proposed framework also leads to improved results for a series of problems beyond the standard Perceptron setting. Specifically, a) for the margin maximization problem, we improve the state-of-the-art result from $O(\log t/t^2)$ to $O(1/t^2)$, where t is the number of iterations; b) we provide the first result on identifying the implicit bias property of the classical Nesterov's accelerated gradient descent (NAG) algorithm, and show NAG can maximize the margin with an $O(1/t^2)$ rate; c) for the classical p-norm Perceptron problem, we provide an algorithm with $\Omega(\sqrt{(p-1)\log n}/\gamma)$ convergence rate, while existing algorithms suffer the $\Omega({(p-1)}/\gamma^2)$ convergence rate.

DITTO: Offline Imitation Learning with World Models

Branton DeMoss,Paul Duckworth,Nick Hawes,Ingmar Posner

We propose DITTO, a fully offline approach to imitation learning which addresses the problem of covariate shift without access to an oracle or any additional online interactions. By unrolling agent policies in the latent space of a learned world model and penalizing drift from expert demonstrations, we can use online reinforcement learning algorithms to learn policies which solve the imitation objective, without access to the underlying environment or reward function. Decoupling policy and world model learning lets us leverage datasets of any quality to learn latent representations which provide a natural reward signal for imitation learning, avoiding the need for complex adversarial or sparse imitation-inducing rewards. Compared to competitive baselines, our method achieves state-of-the-art performance in a variety of challenging environments from pixel observations alone.

****

BAT-Chain: Bayesian-Aware Transport Chain for Topic Hierarchies Discovery

Dongsheng Wang,He Zhao,Dan Dan Guo,Xinyang Liu,Miaoge Li,Bo Chen,Mingyuan Zhou

Topic modeling has been an important tool for text analysis. Originally, topics discovered by a model are usually assumed to be independent. However, as a semantic representation of a concept, a topic is naturally related to others, which motivates the development of learning hierarchical topic structure. Most existing Bayesian models are designed to learn hierarchical structure, but they need non-trivial posterior inference. Although the recent transport-based topic models bypass the posterior inference, none of them considers deep topic structures. In this paper, we interpret document as its word embeddings and propose a novel Bayesian-aware transport chain to discover multi-level topic structures, where each layer learns a set of topic embeddings and the document hierarchical representations are defined as a series of empirical distributions according to the topic proportions and corresponding topic embeddings. To fit such hierarchies, we develop an upward-downward optimizing strategy under the recent conditional transport theory, where document information is first transported via the upward path, and then its hierarchical representations are refined by the downward path under the Bayesian perspective. Extensive experiments on text corpora show that our approach enjoys superior modeling accuracy and interpretability. Moreover, we also conduct experiments on learning hierarchical visual topics from images, which demonstrate the adaptability and flexibility of our method.

On the Importance of Calibration in Semi-supervised Learning

Charlotte Loh,Rumen Dangovski,Shivchander Sudalairaj,Seungwook Han,Ligong Han,Leonid Karlinsky,Marin Soljacic,Akash Srivastava

State-of-the-art (SOTA) semi-supervised learning (SSL) methods have been highly successful in leveraging a mix of labeled and unlabeled data by combining techniques of consistency regularization and pseudo-labeling. During pseudo-labeling, the model's predictions on unlabeled data are used for training and thus, model calibration is important in mitigating confirmation bias. Yet, many SOTA methods are optimized for model performance, with little focus directed to improve model calibration. In this work, we empirically demonstrate that model calibration is strongly correlated with model performance and propose to improve calibration via approximate Bayesian techniques.

We introduce a family of new SSL models that optimizes for calibration and demonstrate their effectiveness across standard vision benchmarks of CIFAR-10, CIFAR-100 and ImageNet, giving up to 15.9\% improvement in test accuracy. Furthermore, we also demonstrate their effectiveness in additional realistic and challenging problems, such as class-imbalanced datasets and in photonics science.

****

SoftMatch: Addressing the Quantity-Quality Tradeoff in Semi-supervised Learning

Hao Chen,Ran Tao,Yue Fan,Yidong Wang,Jindong Wang,Bernt Schiele,Xing Xie,Bhiksha Raj,Marios Savvides

The critical challenge of Semi-Supervised Learning (SSL) is how to effectively l everage the limited labeled data and massive unlabeled data to improve the model's generalization performance. In this paper, we first revisit the popular pseudo-labeling methods via a unified sample weighting formulation and demonstrate the inherent quantity-quality trade-off problem of pseudo-labeling with thresholding, which may prohibit learning. To this end, we propose SoftMatch to overcome the trade-off by maintaining both high quantity and high quality of pseudo-labels during training, effectively exploiting the unlabeled data. We derive a truncated Gaussian function to weight samples based on their confidence, which can be viewed as a soft version of the confidence threshold. We further enhance the utilization of weakly-learned classes by proposing a uniform alignment approach. In experiments, SoftMatch shows substantial improvements across a wide variety of benchmarks, including image, text, and imbalanced classification.

Certifiably Robust Policy Learning against Adversarial Multi-Agent Communication

Yanchao Sun,Ruijie Zheng,Parisa Hassanzadeh,Yongyuan Liang,Soheil Feizi,Sumitra Ganesh,Furong Huang

Communication is important in many multi-agent reinforcement learning (MARL) problems for agents to share information and make good decisions. However, when deploying trained communicative agents in a real-world application where noise and potential attackers exist, the safety of communication-based policies becomes a severe issue that is underexplored. Specifically, if communication messages are manipulated by malicious attackers, agents relying on untrustworthy communication may take unsafe actions that lead to catastrophic consequences. Therefore, it is crucial to ensure that agents will not be misled by corrupted communication, while still benefiting from benign communication. In this work, we consider an environment with N agents, where the attacker may arbitrarily change the communication from any $C<\frac{N-1}{2}$ agents to a victim agent. For this strong threat model, we propose a certifiable defense by constructing a message-ensemble policy that aggregates multiple randomly ablated message sets. Theoretical analysis shows that this message-ensemble policy can utilize benign communication while being certifiably robust to adversarial communication, regardless of the attacking algorithm. Experiments in multiple environments verify that our defense significantly improves the robustness of trained policies against various types of attacks.

Node Importance Specific Meta Learning in Graph Neural Networks

Hao Liu,Yixin Chen,Dacheng Tao,Muhan Zhang

While current node classification methods for graphs have enabled significant progress in many applications, they rely on abundant labeled nodes for training. In many real-world datasets, nodes for some classes are always scarce, thus current algorithms are ill-equipped to handle these few-shot node classes. Some meta learning approaches for graphs have demonstrated advantages in tackling such few-shot problems, but they disregard the impact of node importance on a task. Being exclusive to graph data, the dependencies between nodes convey vital information for determining the importance of nodes in contrast to node features only, which poses unique challenges here. In this paper, we investigate the effect of node importance in node classification meta learning tasks. We first theoretically analyze the influence of distinguishing node importance on the lower bound of the model accuracy. Then, based on the theoretical conclusion, we propose a novel Node Importance Meta Learning architecture (NIML) that learns and applies the importance score of each node for meta learning. Specifically, after constructing an attention vector based on the interaction between a node and its neighbors, we train an importance predictor in a supervised manner to capture the distance between node embedding and the expectation of same-class embedding. Extensive experiments on public datasets demonstrate the state-of-the-art performance of NIML on few-shot node classification problems.

Attention-Guided Backdoor Attacks against Transformers

Weimin Lyu,Songzhu Zheng,Haibin Ling,Chao Chen

With the popularity of transformers in natural language processing (NLP) applica tions, there are growing concerns about their security. Most existing NLP attack methods focus on injecting stealthy trigger words/phrases. In this paper, we focus on the interior structure of neural networks and the Trojan mechanism. Focusing on the prominent NLP transformer models, we propose a novel Trojan Attention Loss (TAL), which enhances the Trojan behavior by directly manipulating the attention pattern. Our loss significantly improves the attack efficacy; it achieves better successful rates and with a much smaller poisoning rate (i.e., a smaller proportion of poisoned samples). It boosts attack efficacy for not only traditional dirty-label attacks, but also the more challenging clean-label attacks. TAL is also highly compatible with most existing attack methods and its flexibility enables this loss easily adapted to other backbone transformer models.

****

Disentangling the Mechanisms Behind Implicit Regularization in SGD

Zachary Novack,Simran Kaur,Tanya Marwah,Saurabh Garg,Zachary Chase Lipton

A number of competing hypotheses have been proposed to explain why small-batch Stochastic Gradient Descent (SGD) leads to improved generalization over the full-batch regime, with recent work crediting the implicit regularization of various quantities throughout training. However, to date, empirical evidence assessing the explanatory power of these hypotheses is lacking. In this paper, we conduct an extensive empirical evaluation, focusing on the ability of various theorized mechanisms to close the small-to-large batch generalization gap. Additionally, we characterize how the quantities that SGD has been claimed to (implicitly) regularize change over the course of training. By using micro-batches, i.e. disjoint smaller subsets of each mini-batch, we empirically show that explicitly penalizing the gradient norm or the Fisher Information Matrix trace, averaged over micro-batches, in the large-batch regime recovers small-batch SGD generalization, whereas Jacobian-based regularizations fail to do so. This generalization performance is shown to often be correlated with how well the regularized model’s gradient norms resemble those of small-batch SGD. We additionally show that this behavior breaks down as the micro-batch size approaches the batch size. Finally, we note that in this line of inquiry, positive experimental findings on CIFAR10 are often reversed on other datasets like CIFAR100, highlighting the need to test hypotheses on a wider collection of datasets.

****

Oracles and Followers: Stackelberg Equilibria in Deep Multi-Agent Reinforcement Learning

Matthias Gerstgrasser,David C. Parkes

Stackelberg equilibria arise naturally in a range of popular learning problems, such as in security games or indirect mechanism design, and have received in- creasing attention in the reinforcement learning literature. We present a general framework for implementing Stackelberg equilibria search as a multi-agent RL problem, allowing a wide range of algorithmic design choices. We discuss how previous approaches can be seen as specific instantiations of this framework. As a key insight, we note that the design space allows for approaches not previously seen in the literature, for instance by leveraging multitask and meta-RL techniques for follower convergence. We propose one such approach using contextual poli- cies and evaluate it experimentally on standard benchmark domains. Finally, we illustrate the effect of adopting designs outside the borders of our framework in controlled experiments.

Structural Code Representation Learning for Auto-Vectorization

Yao Xiao,Nesreen Ahmed,Mihai Capot■,Guixiang Ma,Theodore L. Willke,Shahin Nazarian,Paul Bogdan

The single instruction multiple data (SIMD) capability in modern processors is critical to improving the performance of current compute-intensive programs. SIMD allows architectures to exploit the natural data parallelism that exists in a wide-range of real applications (e.g., games, signal processing, etc) by executing a single instruction on multiple data items simultaneously. Modern compilers use vectorization techniques to exploit the SIMD capability, by detecting data parallelism in scalar source code and transforming a group of scalar instructions into vector-based instructions. In this work, we focus on one of the most common vectorization techniques called \emph{loop-based vectorization}, which targets loops and optimize their performance by grouping multiple occurrences of the same operation across loop iterations into single SIMD instructions. This is achieved by setting two key parameters: (1) the vectorization factor (VF), and (2) the interleaving factor (IF). Unfortunately, vectorizing loop computations effectively is a key challenging problem for both programmers and compilers due to the large search space. For example, manual vectorization of each loop puts a huge burden on the programmer, is more error-prone, and/or requires expert knowledge of both the software and the architecture. Alternatively, current compilers use fixed-cost models based on expert heuristics to make automatic vectorization decisions. However, these models often ignore the data dependencies, as well as the underlying computation graph. In this paper, we propose a data-driven graph-based learning framework for automatic vectorization, called \emph{autograph}, which takes an input program, extracts the loops, then learns a structured representation to automatically predict the correct VF/IF factors. Our proposed framework utilizes deep reinforcement learning to learn an optimal policy (observations to actions) from an intelligent agent in a SIMD environment, and automatically injects the predicted vectorization pragmas into the input program. We conducted an extensive evaluation on multiple benchmark datasets and comparisons with state-of-the-art baselines. Our experimental results show that the proposed framework can achieve up to 1.02x-2.26x and 1.06x-4.27x performance improvement, compared to state-of-the-art baseline and LLVM -O3 respectively.

Overthinking the Truth: Understanding how Language Models process False Demonstrations

Danny Halawi,Jean-Stanislas Denain,Jacob Steinhardt

Through few-shot learning or chain-of-thought prompting, modern language models can detect and imitate complex patterns in their prompt.
This behavior allows language models to complete challenging tasks without fine-tuning,
but can be at odds with completion quality: if the context is inaccurate or harmful, then the model
may reproduce these defects in its completions.
In this work, we show that this {harmful context-following} appears late in a model's
computation--in particular, given an inaccurate context, models perform \emph{better} after zeroing out later layers.
More concretely, at early layers models have similar performance given either accurate and inaccurate few-shot prompts, but a gap appears at later layers (e.g.~layers 10-14 for GPT-J).
This gap appears at a consistent depth across datasets, and coincides with the appearance of “induction heads” that attend to previous answers in the prompt.
We restore the performance for inaccurate contexts by ablating a subset of these heads, reducing the gap by 28\% on average across 8 datasets.
Our results suggest that studying early stages of computation could be a promising strategy to prevent misleading outputs, and that understanding and editing internal
mechanisms can help correct unwanted model behavior.

Sequential Attention for Feature Selection

Taisuke Yasuda,Mohammadhossein Bateni,Lin Chen,Matthew Fahrbach,Gang Fu,Vahab Mirrokni

Feature selection is the problem of selecting a subset of features for a machine learning model that maximizes model quality subject to a budget constraint. For neural networks, prior methods, including those based on ℓ_1 regularization, attention, and other techniques, typically select the entire feature subset in one evaluation round, ignoring the residual value of features during selection, i.e., the marginal contribution of a feature given that other features have already been selected. We propose a feature selection algorithm called Sequential

Attention that achieves state-of-the-art empirical results for neural networks. This algorithm is based on an efficient one-pass implementation of greedy forward selection and uses attention weights at each step as a proxy for feature importance. We give theoretical insights into our algorithm for linear regression by showing that an adaptation to this setting is equivalent to the classical Orthogonal Matching Pursuit (OMP) algorithm, and thus inherits all of its provable guarantees. Our theoretical and empirical analyses offer new explanations towards the effectiveness of attention and its connections to overparameterization, which may be of independent interest.

****

Trusted Aggregation (TAG): Model Filtering Backdoor Defense In Federated Learning

Joseph Lavond,Minhao Cheng,Yao Li

Federated Learning is a framework for training machine learning models from multiple local data sets without access to the data in aggregate. A shared model is jointly learned through an interactive process between server and clients that combines locally learned model gradients or weights. However, the lack of data transparency naturally raises concerns about model security. Recently, several state-of-the-art backdoor attacks have been proposed, which achieve high attack success rates while simultaneously being difficult to detect, leading to compromised federated learning models. In this paper, motivated by differences in the output layer distribution between models trained with and without the presence of backdoor attacks, we propose a defense method that can prevent backdoor attacks from influencing the model while maintaining the accuracy of the original classification task. TAG leverages a small validation data set to estimate the largest change that a benign user's local training can make to the output layer of the shared model, which can be used as a cutoff for returning user models. Experimental results on multiple data sets show that TAG defends against backdoor attacks even when 40\% of the user submissions to update the shared model are malicious.

****

What Deep Representations Should We Learn? -- A Neural Collapse Perspective

Xiao Li,Sheng Liu,Jinxin Zhou,Carlos Fernandez-Granda,Zhihui Zhu,Qing Qu

For classification problems, when sufficiently large networks are trained until convergence, an intriguing phenomenon has recently been discovered in the last-layer classifiers, and features termed neural collapse (NC): (i) the intra-class variability of the features collapses to zero, and (ii) the between-class feature means are maximally and equally separated. Despite of recent endeavors to understand why NC happens, a fundamental question remains: whether NC is a blessing or a curse for deep learning? In this work, we investigate the problem under the setting of transfer learning that we pretrain a model on a large dataset and transfer it to downstream tasks. Through various experiments, our findings on NC are two-fold: (i) when pretrain models, preventing intra-class variability collapse (to a certain extent) better preserve the structures of data, and leads to better model transferability; (ii) when fine-tuning models on downstream tasks, obtaining features with more NC on downstream data results in better test accuracy on the given task. Our findings based upon NC not only explain many widely used heuristics in model pretraining (e.g., data augmentation, projection head, self-supervised learning), but also leads to more efficient and principled transfer learning method on downstream tasks.

Improved Sample Complexity for Reward-free Reinforcement Learning under Low-rank MDPs

Yuan Cheng,Ruiquan Huang,Yingbin Liang,Jing Yang

In reward-free reinforcement learning (RL), an agent explores the environment first without any reward information, in order to achieve certain learning goals afterwards for any given reward. In this paper we focus on reward-free RL under low-rank MDP models, in which both the representation and linear weight vectors are unknown. Although various algorithms have been proposed for reward-free low-rank MDPs, the corresponding sample complexity is still far from being satisfactory. In this work, we first provide the first known sample complexity lower bound that holds for any algorithm under low-rank MDPs. This lower bound implies it is strictly harder to find a near-optimal policy under low-rank MDPs than under linear MDPs. We then propose a novel model-based algorithm, coined RAFFLE, and show it can both find an ϵ-optimal policy and achieve an ϵ-accurate system identification via reward-free exploration, with a sample complexity significantly improving the previous results. Such a sample complexity matches our lower bound in the dependence on ϵ, as well as on K {in the large d regime}, where d and K respectively denote the representation dimension and action space cardinality. Finally, we provide a planning algorithm (without further interaction with true environment) for RAFFLE to learn a near-accurate representation, which is the first known representation learning guarantee under the same setting.

****

Re-Imagen: Retrieval-Augmented Text-to-Image Generator
Wenhu Chen,Hexiang Hu,Chitwan Saharia,William W. Cohen

Research on text-to-image generation has witnessed significant progress in generating diverse and photo-realistic images, driven by diffusion and auto-regressive models trained on large-scale image-text data. Though state-of-the-art models can generate high-quality images of common entities, they often have difficulty generating images of uncommon entities, such as `Chortai (dog)' or `Picarones (food)'. To tackle this issue, we present the Retrieval-Augmented Text-to-Image Generator (Re-Imagen), a generative model that uses retrieved information to produce high-fidelity and faithful images, even for rare or unseen entities. Given a text prompt, Re-Imagen accesses an external multi-modal knowledge base to retrieve relevant (image, text) pairs, and uses them as references to generate the image. With this retrieval step, Re-Imagen is augmented with the knowledge of high-level semantics and low-level visual details of the mentioned entities, and thus improves its accuracy in generating the entities' visual appearances. We train Re-Imagen on a constructed dataset containing (image,text,retrieval) triples to teach the model to ground on both text prompt and retrieval. Furthermore, we develop a new sampling strategy to interleave the classifier-free guidance for text and retrieval condition to balance the text and retrieval alignment. Re-Imagen achieves new SoTA FID results on two image generation benchmarks, such as COCO (\ie, FID = 5.25) and WikiImage (\ie, FID = 5.82) without fine-tuning. To further evaluate the capabilities of the model, we introduce EntityDrawBench, a new benchmark that evaluates image generation for diverse entities, from frequent to rare, across multiple visual domains. Human evaluation on EntityDrawBench shows that Re-Imagen performs on par with the best prior models in photo-realism, but with significantly better real-world faithfulness, especially on less frequent entities.

****

Provably Efficient Lifelong Reinforcement Learning with Linear Representation
Sanae Amani,Lin Yang,Ching-An Cheng

We theoretically study lifelong reinforcement learning (RL) with linear representation in a regret minimization setting. The goal of the agent is to learn a multi-task policy based on a linear representation while solving a sequence of tasks that may be adaptively chosen based on the agent's past behaviors. We frame the problem as a linearly parameterized contextual Markov decision process (MDP), where each task is specified by a context and the transition dynamics is context-independent, and we introduce a new completeness-style assumption on the representation which is sufficient to ensure the optimal multi-task policy is realizable under the linear representation. Under this assumption, we propose an algorithm, called UCB Lifelong Value Distillation (UCBlvd), that provably achieves sublinear regret for any sequence of tasks while using only sublinear planning calls. Specifically, for K task episodes of horizon H, our algorithm has a regret bound $\tilde{\mathcal{O}}(\sqrt{(d^3+d^\prime d)H^4K})$ using $\mathcal{O}(dH\log(K))$ number of planning calls, where d and $d^\prime$ are the feature dimensions of the dynamics and rewards, respectively. This theoretical guarantee implies that our algorithm can enable a lifelong learning agent to learn to interna lize experiences into a multi-task policy and rapidly solve new tasks.

****

Towards Adversarially Robust Deepfake Detection: An Ensemble Approach
Ashish Hooda,Neal Mangaokar,Ryan Feng,Kassem Fawaz,Somesh Jha,Atul Prakash
Detecting deepfakes remains an open problem. Current detection methods fail against an adversary who adds imperceptible adversarial perturbations to the deepfake to evade detection. We propose Disjoint Deepfake Detection (D3), a deepfake detector designed to improve adversarial robustness beyond de facto solutions such as adversarial training. D3 uses an ensemble of models over disjoint subsets of the frequency spectrum to significantly improve robustness. Our key insight is to leverage a redundancy in the frequency domain and apply a saliency partitioning technique to disjointly distribute frequency components across multiple models. We formally prove that these disjoint ensembles lead to a reduction in the dimensionality of the input subspace where adversarial deepfakes lie. We then empirically validate the D3 method against white-box attacks and black-box attacks and find that D3 significantly outperforms existing state-of-the-art defenses applied to deepfake detection.

****

Fast Adaptation via Human Diagnosis of Task Distribution Shift
Andi Peng,Mark K Ho,Aviv Netanyahu,Julie Shah,Pulkit Agrawal
When agents fail in the world, it is important to understand why they failed. These errors could be due to underlying distribution shifts in the goals desired by the end user or to the environment layouts that impact the policy's actions. In the case of multi-task policies conditioned on goals, this problem manifests in difficulty in disambiguating between goal and policy failures: is the agent failing because it can't correctly infer what the desired goal is or because it doesn't know how to take actions toward achieving the goal? We hypothesize that successfully disentangling these two failures modes holds important implications for selecting a finetuning strategy. In this paper, we explore the feasibility of leveraging human feedback to diagnose what vs. how failures for efficient adaptation. We develop an end-to-end policy training framework that uses attention to produce a human-interpretable representation, a visual masked state, to communicate the agent's intermediate task representation. In experiments with human users in both discrete and continuous control domains, we show that our visual attention mask policy can aid participants in successfully inferring the agent's failure mode significantly better than actions alone. Leveraging this feedback, we show subsequent empirical performance gains during finetuning and discuss implications of using humans to diagnose parameter-level failures of distribution shift.

Link Prediction with Non-Contrastive Learning
William Shiao,Zhichun Guo,Tong Zhao,Evangelos E. Papalexakis,Yozen Liu,Neil Shah
Graph neural networks (GNNs) are prominent in the graph machine learning domain, owing to their strong performance across various tasks. A recent focal area is the space of graph self-supervised learning (SSL), which aims to derive useful node representations without labeled data. Notably, many state-of-the-art graph SSL methods are contrastive methods, which use a combination of positive and negative samples to learn node representations. Owing to challenges in negative sampling (slowness and model sensitivity), recent literature introduced non-contrastive methods, which instead only use positive samples. Though such methods have shown promising performance in node-level tasks, their suitability for link prediction tasks, which are concerned with predicting link existence between pairs of nodes (and have broad applicability to recommendation systems contexts) is yet unexplored. In this work, we extensively evaluate the performance of existing non-contrastive methods for link prediction in both transductive and inductive settings. While most existing non-contrastive methods perform poorly overall, we find that, surprisingly, BGRL generally performs well in transductive settings. However, it performs poorly in the more realistic inductive settings where the model has to generalize to links to/from unseen nodes. We find that non-contrastive models tend to overfit to the training graph and use this analysis to propose T

-BGRL, a novel non-contrastive framework that incorporates cheap corruptions to improve the generalization ability of the model. This simple modification strongly improves inductive performance in 5/6 of our datasets, with up to a 120% improvement in Hits@50 - all with comparable speed to other non-contrastive baselines, and up to $14\times$ faster than the best-performing contrastive baseline. Our work imparts interesting findings about non-contrastive learning for link prediction and paves the way for future researchers to further expand upon this area.

****

Distributed Differential Privacy in Multi-Armed Bandits

Sayak Ray Chowdhury,Xingyu Zhou

We consider the standard K-armed bandit problem under a distributed trust model of differential privacy (DP), which enables to guarantee privacy without a trustworthy server. Under this trust model, previous work largely focus on achieving privacy using a shuffle protocol, where a batch of users data are randomly permuted before sending to a central server. This protocol achieves (ϵ,δ) or approximate-DP guarantee by sacrificing an additive $O\!\left(\!\frac{K\log T\sqrt{\log(1/\delta)}}{\epsilon}\!\right)\!$ factor in T-step cumulative regret. In contrast, the optimal privacy cost to achieve a stronger ($\epsilon,0$) or pure-DP guarantee under the widely used central trust model is only $\Theta\!\left(\!\frac{K\log T}{\epsilon}\!\right)\!$, where, however, a trusted server is required. In this work, we aim to obtain a pure-DP guarantee under distributed trust model while sacrificing no more regret than that under central trust model. We achieve this by designing a generic bandit algorithm based on successive arm elimination, where privacy is guaranteed by corrupting rewards with an equivalent discrete Laplace noise ensured by a secure computation protocol. We also show that our algorithm, when instantiated with Skellam noise and the secure protocol, ensures \emph{R\'{e}nyi differential privacy} -- a stronger notion than approximate DP -- under distributed trust model with a privacy cost of $O\!\left(\!\frac{K\sqrt{\log T}}{\epsilon}\!\right)\!$. Finally, as a by-product of our techniques, we also recover the best-known regret bounds for bandits under central and local models while using only \emph{discrete privacy noise}, which can avoid the privacy leakage due to floating point arithmetic of continuous noise on finite computers.

Thrust: Adaptively Propels Large Language Models with External Knowledge

Xinran Zhao,Hongming Zhang,Xiaoman Pan,Wenlin Yao,Dong Yu,Jianshu Chen

Large-scale pre-trained language models (PTLM) have achieved great success in various natural language processing (NLP) tasks. Much evidence shows that PTLMs already encode rich knowledge themselves, but knowledge stored in PTLMs can be opaque and static, making external knowledge retrieval necessary. However, there are two major challenges when using external knowledge. First, knowledge indexing and retrieving on large-scale knowledge bases are time costly. Second, knowledge retrieved could be noisy and sometimes misleading. Motivated by the observation that external knowledge is not always required by PTLMs, we investigate an effective and efficient way to apply knowledge only when the knowledge is essential. Specifically, we propose instance-level adaptive propulsion of external knowledge (IAPEK), where we score each instance on whether the PTLMs need the support of external knowledge. To achieve this goal, we design a novel metric, Thrust, which leverages the distribution estimation on seen/training instances. Extensive experiments demonstrate that we can achieve significantly higher cost-efficiency through Thrust compared to the naive usage of external knowledge on 88% of the evaluated tasks with 26% average performance improvement. Such findings further shed light on the real-world practice of knowledge-enhanced LMs with a limited budget for knowledge seeking due to computation latency or costs.

Progress measures for grokking via mechanistic interpretability

Neel Nanda,Lawrence Chan,Tom Lieberum,Jess Smith,Jacob Steinhardt

Neural networks often exhibit emergent behavior in which qualitatively new capabilities that arise from scaling up the number of parameters, training data, or e ven the number of steps. One approach to understanding emergence is to find the continuous \textit{progress measures} that underlie the seemingly discontinuous qualitative changes. In this work, we argue that progress measures can be found via mechanistic interpretability---that is, by reverse engineering learned models into components and measuring the progress of each component over the course of training. As a case study, we study small transformers trained on a modular arithmetic tasks with emergent grokking behavior. We fully reverse engineer the algorithm learned by these networks, which uses discrete fourier transforms and trigonometric identities to convert addition to rotation about a circle. After confirming the algorithm via ablation, we then use our understanding of the algorithm to define progress measures that precede the grokking phase transition on this task. We see our result as demonstrating both that it is possible to fully reverse engineer trained networks, and that doing so can be invaluable to understanding their training dynamics.

On the Mysterious Optimization Geometry of Deep Neural Networks

Chedi Morchdi,Yi Zhou,Jie Ding,Bei Wang

Understanding why gradient-based algorithms are successful in practical deep learning optimization is a fundamental and long-standing problem. Most existing works promote the explanation that deep neural networks have smooth and amenable nonconvex optimization geometries. In this work, we argue that this may be an oversimplification of practical deep learning optimization by revealing a mysterious and complex optimization geometry of deep networks through extensive experiments. Specifically, we consistently observe two distinct geometric patterns in training various deep networks: a regular smooth geometry and a mysterious zigzag geometry, where gradients computed in adjacent iterations are extremely negatively correlated. Also, such a zigzag geometry exhibits a fractal structure in that it appears over a wide range of geometrical scales, implying that deep networks can be highly non-smooth in certain local parameter regions. Moreover, our results show that a substantial part of the training progress is achieved under such complex geometry. Therefore, the existing smoothness-based explanations do not fully match the practice.

Implicit regularization via Spectral Neural Networks and non-linear matrix sensing

Subhroshekhar Ghosh,Thanh Lam,Soumendu Sundar Mukherjee

The phenomenon of \textit{implicit regularization} has attracted interest in the recent years as a fundamental aspect of the remarkable generalizing ability of neural networks. In a nutshell, it entails that gradient flow dynamics in many neural nets, even without any explicit regularizer in the loss function, converges to the solution of a regularized learning problem. However, known results attempting to theoretically explain this phenomenon focus overwhelmingly on the setting of linear neural nets, and the simplicity of the linear structure is particularly crucial to existing arguments. In this paper, we explore this problem in the context of more realistic neural networks with a general class of non-linear activation functions, and rigorously demonstrate the implicit regularization phenomenon for such networks in the setting of matrix sensing problems. This is coupled with rigorous rate guarantees that ensure exponentially fast convergence of gradient descent, complemented by matching lower bounds which stipulate that the exponential rate is the best achievable. In this vein, we contribute a network architecture called Spectral Neural Networks (\textit{abbrv.} SNN) that is particularly suitable for matrix learning problems. Conceptually, this entails coordinatizing the space of matrices by their singular values and singular vectors, as opposed to by their entries, a potentially fruitful perspective for matrix learning. We demonstrate that the SNN architecture is inherently much more amenable to theoretical analysis than vanilla neural nets and confirm its effectiveness in the context of matrix sensing, supported via both mathematical guarantees and empirical investigations. We believe that the SNN architecture has the potential to be of wide applicability in a broad class of matrix learning scenarios.

Goal-Space Planning with Subgoal Models
Chunlok Lo,Gabor Mihucz,Farzane Aminmansour,Adam White,Martha White

This paper investigates a new approach to model-based reinforcement learning using background planning: mixing (approximate) dynamic programming updates and model-free updates, similar to the Dyna architecture. Background planning with learned models is often worse than model-free alternatives, such as Double DQN, even though the former uses significantly more memory and computation. The fundamental problem is that learned models can be inaccurate and often generate invalid states, especially when iterated many steps. In this paper, we avoid this limitation by constraining background planning to a set of (abstract) subgoals and learning only local, subgoal-conditioned models. This goal-space planning (GSP) approach is more computationally efficient, naturally incorporates temporal abstraction for faster long-horizon planning and avoids learning the transition dynamics entirely. We show that our GSP algorithm can learn significantly faster than a Double DQN baseline in a variety of situations.

MET : Masked Encoding for Tabular data
Kushal Alpesh Majmundar,Sachin Goyal,Praneeth Netrapalli,Prateek Jain

We propose $\textit{Masked Encoding for Tabular Data (MET)}$ for learning self-supervised representations from $\textit{tabular data}$. Tabular self-supervised learning (tabular-SSL) -- unlike structured domains like images, audio, text -- is more challenging since each tabular dataset can have a completely different structure among its features (or coordinates), which is hard to identify a priori. $\textit{MET}$ attempts to circumvent this problem by assuming the following hypothesis: the observed tabular data features come from a latent graphical model and the downstream tasks are significantly easier to solve in the latent space. Based on this hypothesis, $\textit{MET}$ uses random masking based encoders to learn a positional embedding for each coordinate, which would in turn capture the latent structure between coordinates. Through experiments on a toy dataset from a linear graphical model, we show that $\textit{MET}$ is indeed able to capture the latent graphical model. Practically, through extensive experiments on multiple benchmarks for tabular data, we demonstrate that $\textit{MET}$ significantly outperforms all the baselines. For example, on Criteo -- a large-scale click prediction dataset -- $\textit{MET}$ achieves as much as 5% improvement over the current state-of-the-art (SOTA) while purely supervised learning based approaches have been able to advance SOTA by at most 2% in the last six years. Furthermore, averaged over $\textit{nine}$ datasets, $\textit{MET}$ is around 3.9% more accurate than the next best method of Gradient-boosted decision trees -- considered as SOTA for the tabular setting.

Shortcut Learning Through the Lens of Early Training Dynamics
Nihal Murali,Aahlad Manas Puli,Ke Yu,Rajesh Ranganath,kayhan Batmanghelich

Deep Neural Networks (DNNs) are prone to learn shortcut patterns that damage the generalization of the DNN during deployment. Shortcut learning is concerning, particularly when the DNNs are applied to safety-critical domains. This paper aims to better understand shortcut learning through the lens of the learning dynamics of the internal neurons during the training process. More specifically, we make the following observations: (1) While previous works treat shortcuts as synonymous with spurious correlations, we emphasize that not all spurious correlations are shortcuts. We show that shortcuts are only those spurious features that are ``easier'' than the core features. (2) We build upon this premise and use instance difficulty methods (like Prediction Depth) to quantify ``easy'' and to identify this behavior during the training phase. (3) We empirically show that shortcut learning can be detected by observing the learning dynamics of the DNN's early layers, irrespective of the network architecture used. In other words, easy features learned by the initial layers of a DNN early during the training are potential shortcuts. We verify our claims on simulated and real medical imaging data and justify the empirical success of our hypothesis by showing the theoretical connections between Prediction Depth and information-theoretic concepts like $\mathcal{V}$-usable information. Lastly, our experiments show the insufficiency o f monitoring only accuracy plots during training (as is common in machine learning pipelines), and we highlight the need for monitoring early training dynamics using example difficulty metrics.

On $\mathcal{O}(1/K)$ Convergence and Low Sample Complexity for Single-Timescale Policy Evaluation with Nonlinear Function Approximation

Zhuqing Liu,Xin Zhang,Jia Liu,Zhengyuan Zhu,Songtao Lu

■Learning an accurate value function for a given policy is a critical step in solving reinforcement learning (RL) problems. So far, however, the convergence speed and sample complexity performances of most existing policy evaluation algorithms remain unsatisfactory, particularly with {\em non-linear} function approximation. This challenge motivates us to develop a new variance-reduced primal-dual method (VRPD) that is able to achieve a fast convergence speed for RL policy evaluation with nonlinear function approximation. To lower the high sample complexity limitation of variance-reduced approaches (due to the periodic full gradient evaluation with all training data), we further propose an enhanced VRPD method with an adaptive-batch adjustment (VRPD$^+$). The main features of VRPD include: i) VRPD allows the use of {\em{constant}} step sizes and achieves the $\mathcal{O}(1/K)$ convergence rate to the first-order stationary points of non-convex policy evaluation problems; ii) VRPD is a generic {\em{single}}-timescale algorithm that is also applicable for solving a large class of non-convex strongly-concave minimax optimization problems; iii) By adaptively adjusting the batch size via historical stochastic gradient information, VRPD$^+$ is more sample-efficient in practice without loss of theoretical convergence rate. Our extensive numerical experiments verify our theoretical findings and showcase the high efficiency of the proposed VRPD and VRPD$^+$ algorithms compared with the state-of-the-art methods.

On the Implicit Bias Towards Depth Minimization in Deep Neural Networks

Tomer Galanti,Liane Galanti,Ido Ben-Shaul

Recent results in the literature suggest that the penultimate (second-to-last) layer representations of neural networks that are trained for classification exhibit a clustering property called neural collapse (NC). We study the implicit bias of stochastic gradient descent (SGD) in favor of low-depth solutions when training deep neural networks. We characterize a notion of effective depth that measures the first layer for which sample embeddings are separable using the nearest-class center classifier. Furthermore, we hypothesize and empirically show that SGD implicitly selects neural networks of small effective depths.

Secondly, while neural collapse emerges even when generalization should be impossible - we argue that the \emph{degree of separability} in the intermediate layers is related to generalization. We derive a generalization bound based on comparing the effective depth of the network with the minimal depth required to fit the same dataset with partially corrupted labels. Remarkably, this bound provides non-trivial estimations of the test performance. Finally, we empirically show that the effective depth of a trained neural network monotonically increases when increasing the number of random labels in data.

Prometheus: Endowing Low Sample and Communication Complexities to Constrained Decentralized Stochastic Bilevel Learning

Zhuqing Liu,Xin Zhang,Prashant Khanduri,Songtao Lu,Jia Liu

■In recent years, constrained decentralized stochastic bilevel optimization has become increasingly important due to its versatility in modeling a wide range of multi-agent learning problems, such as multi-agent reinforcement learning and multi-agent meta-learning with safety constraints. However, one under-explored and fundamental challenge in constrained decentralized stochastic bilevel optimization is how to achieve low sample and communication complexities, which, if not addressed appropriately, could affect the long-term prospect of many emerging multi-agent learning paradigms that use decentralized bilevel optimization as a bedrock. In this paper, we investigate a class of constrained decentralized bileve l optimization problems, where multiple agents collectively solve a nonconvex-strongly-convex bilevel problem with constraints in the upper-level variables. Such problems arise naturally in many multi-agent reinforcement learning and meta learning problems. In this paper, we propose an algorithm called Prometheus (proximal tracked stochastic recursive estimator) that achieves the first $\mathcal{O}(\epsilon^{-1})$ results in both sample and communication complexities for constrained decentralized bilevel optimization, where $\epsilon>0$ is the desired stationarity error. Collectively, the results in this work contribute to a theoretical foundation for low sample- and communication-complexity constrained decentralized bilevel learning.

SGD and Weight Decay Provably Induce a Low-Rank Bias in Neural Networks

Tomer Galanti,Zachary S Siegel,Aparna Gupte,Tomaso Poggio

We analyze deep ReLU neural networks trained with mini-batch Stochastic Gradient Descent (SGD) and weight decay. We show, both theoretically and empirically, that when training a neural network using SGD with weight decay and small batch size, the resulting weight matrices tend to be of small rank. Our analysis relies on a minimal set of assumptions; the neural networks may be arbitrarily wide or deep and may include residual connections, as well as convolutional layers.

The same analysis implies the inherent presence of SGD ``noise'', defined as the inability of SGD to converge to a stationary point. In particular, we prove that SGD noise must always be present, even asymptotically, as long as we incorporate weight decay and the batch size is smaller than the total number of training samples.

MobileViTv3: Mobile-Friendly Vision Transformer with Simple and Effective Fusion of Local, Global and Input Features

Shakti Nagnath Wadekar,Abhishek Chaurasia

MobileViT (MobileViTv1) combines convolutional neural networks (CNNs) and vision transformers (ViTs) to create light-weight models for mobile vision tasks. Though the main MobileViTv1-block helps to achieve competitive state-of-the-art results, the fusion block inside MobileViTv1-block, creates scaling challenges and has a complex learning task. We propose changes to the fusion block that are simple and effective to create MobileViTv3-block, which addresses the scaling and simplifies the learning task. Our proposed MobileViTv3-block used to create MobileViTv3-XXS, XS and S models outperform MobileViTv1 on ImageNet-1k, ADE20K, COCO and PascalVOC2012 datasets. On ImageNet-1K, MobileViTv3-XXS and MobileViTv3-XS surpasses MobileViTv1-XXS and MobileViTv1-XS by 2% and 1.9% respectively. Recently published MobileViTv2 architecture removes fusion block and uses linear complexity transformers to perform better than MobileViTv1. We add our proposed fusion block to MobileViTv2 to create MobileViTv3-0.5, 0.75 and 1.0 models. MobileViTv3-0.5 and MobileViTv3-0.75 outperforms MobileViTv2-0.5 and MobileViTv2-0.75 by 2.1% and 1.0% respectively on ImageNet-1K dataset. For segmentation task, MobileViTv3-1.0 achieves 2.07% and 1.1% better mIOU compared to MobileViTv2-1.0 on ADE20K dataset and PascalVOC2012 dataset respectively.

****

PiFold: Toward effective and efficient protein inverse folding

Zhangyang Gao,Cheng Tan,Stan Z. Li

How can we design protein sequences folding into the desired structures effectively and efficiently? Structure-based protein design has attracted increasing attention in recent years; however, few methods can simultaneously improve the accuracy and efficiency due to the lack of expressive features and autoregressive sequence decoder. To address these issues, we propose PiFold, which contains a novel residue featurizer and PiGNN layers to generate protein sequences in a one-shot way with improved recovery. Experiments show that PiFold could achieve 51.66\% recovery on CATH 4.2, while the inference speed is 70 times faster than the autoregressive competitors. In addition, PiFold achieves 58.72\% and 60.42\% recovery scores on TS50 and TS500, respectively. We conduct comprehensive ablation studies to reveal the role of different types of protein features and model designs, inspiring further simplification and improvement.

A Theoretical Understanding of Shallow Vision Transformers: Learning, Generalization, and Sample Complexity

Hongkang Li,Meng Wang,Sijia Liu,Pin-Yu Chen

Vision Transformers (ViTs) with self-attention modules have recently achieved great empirical success in many vision tasks. Due to non-convex interactions across layers, however, the theoretical learning and generalization analysis is mostly elusive. Based on a data model characterizing both label-relevant and label-irrelevant tokens, this paper provides the first theoretical analysis of training a three-layer ViT, i.e., one self-attention layer followed by a two-layer perceptron, for a classification task. We characterize the sample complexity to achieve a zero generalization error. Our sample complexity bound is positively correlated with the inverse of the fraction of label-relevant tokens, the token noise level, and the initial model error. We also prove that a training process using stochastic gradient descent (SGD) leads to a sparse attention map, which is a formal verification of the general intuition about the success of attention. Moreover, this paper indicates that a proper token sparsification can improve the test performance by removing label-irrelevant and/or noisy tokens, including spurious correlations. Empirical experiments on synthetic data and CIFAR-10 dataset justify our theoretical results and generalize to deeper ViTs.

****

AlphaDesign: A graph protein design method and benchmark on AlphaFold DB

Zhangyang Gao,Cheng Tan,Stan Z. Li

While AlphaFold has remarkably advanced protein folding, the inverse problem, protein design, by which protein sequences are predicted from the corresponding 3D structures, still faces significant challenges. First of all, there lacks a large-scale benchmark covering the vast protein space for evaluating methods and models; secondly, existing methods are still low in prediction accuracy and time-inefficient inference. This paper establishes a new benchmark based on AlphaFold DB, one of the world's largest protein structure databases. Moreover, we propose a new baseline method called AlphaDesign, which achieves 5\% higher recovery than previous methods and about 70 times inference speed-up in designing long protein sequences. We also reveal AlphaDesign's potential for practical protein design tasks, where the designed proteins achieve good structural compatibility with native structures. The open-source code will be released.

Transfer Learning with Context-aware Feature Compensation

Long Bo,Su Yang

Transfer learning aims to reuse the learnt representations or subnetworks to a new domain with minimum effort for adaption. Here, the challenge lies in the mismatch between source domain and target domain, which is the major gap to be tackled by transfer learning. Hence, how to identify the mismatch between source and target domain becomes a critical problem. We propose an end-to-end framework to learn feature compensation for transfer learning with soft gating to decide whether and how much feature compensation is needed, accounting for the mismatch between source domain and target domain. To enable identifying the position of the input in reference to the overall data distribution of source domain, we perform clustering at first to figure out the data distribution in a compact form represented by cluster centers, and then use the similarities between the input and the cluster centers to describe the relative position of the input in reference to the cluster centers. This acts as the context to indicate whether and how much feature compensation is needed for the input to compensate for the mismatch between source domain and target domain. To approach that, we add only two subnetworks in the form of Multilayer Perceptron, one for computing the feature compensation and the other for soft gating the compensation, where both are computed based on the context. The experiments show that such minor change to backbone network can result in significant performance improvements compared with the baselines on some widely used benchmarks.

Contrastive Learning Can Find An Optimal Basis For Approximately View-Invariant

Functions
Daniel D. Johnson,Ayoub El Hanchi,Chris J. Maddison

Contrastive learning is a powerful framework for learning self-supervised representations that generalize well to downstream supervised tasks. We show that multiple existing contrastive learning methods can be reinterpeted as learning kernel functions that approximate a fixed *positive-pair kernel*. We then prove that a simple representation obtained by combining this kernel with PCA provably minimizes the worst-case approximation error of linear predictors, under a straightforward assumption that positive pairs have similar labels. Our analysis is based on a decomposition of the target function in terms of the eigenfunctions of a positive-pair Markov chain, and a surprising equivalence between these eigenfunctions and the output of Kernel PCA. We give generalization bounds for downstream linear prediction using our kernel PCA representation, and show empirically on a set of synthetic tasks that applying kernel PCA to contrastive learning models can indeed approximately recover the Markov chain eigenfunctions, although the accuracy depends on the kernel parameterization as well as on the augmentation strength.

Learning Unsupervised Forward Models from Object Keypoints
Alireza Rezazadeh,Changhyun Choi

Object-centric representation is an essential abstraction for forward prediction. Most existing forward models learn this representation through extensive supervision (e.g., object class and bounding box) although such ground-truth information is not readily accessible in reality. To address this, we introduce KINet (Keypoint Interaction Network)---an end-to-end unsupervised framework to reason about object interactions based on a keypoint representation. Using visual observations, our model learns to associate objects with keypoint coordinates and discovers a graph representation of the system as a set of keypoint embeddings and their relations. It then learns an action-conditioned forward model using contrastive estimation to predict future keypoint states. By learning to perform physical reasoning in the keypoint space, our model automatically generalizes to scenarios with a different number of objects, novel backgrounds, and unseen object geometries. Experiments demonstrate the effectiveness of our model in accurately performing forward prediction and learning plannable object-centric representations which can also be used in downstream robotic manipulation tasks.

****

K-SAM: Sharpness-Aware Minimization at the Speed of SGD
Renkun Ni,Ping-yeh Chiang,Jonas Geiping,Micah Goldblum,Andrew Gordon Wilson,Tom Goldstein

Sharpness-Aware Minimization (SAM) has recently emerged as a robust technique for improving the accuracy of deep neural networks. However, SAM incurs a high computational cost in practice, requiring up to twice as much computation as vanilla SGD. The computational challenge posed by SAM arises because each iteration requires both ascent and descent steps and thus double the gradient computations. To address this challenge, we propose to compute gradients in both stages of SAM on only the top-k samples with highest loss. K-SAM is simple and extremely easy-to-implement while providing significant generalization boosts over vanilla SGD at little to no additional cost.

****

Copula Conformal Prediction for Multi-step Time Series Forecasting
Sophia Huiwen Sun,Rose Yu

Accurate uncertainty measurement is a key step to building robust and reliable machine learning systems. Conformal prediction is a distribution-free uncertainty quantification algorithm popular for its ease of implementation, statistical coverage guarantees, and versatility for underlying forecasters. However, existing conformal prediction algorithms for time series are limited to single-step prediction without considering the temporal dependency. In this paper we propose a Copula-based Conformal Prediction algorithm for multivariate, multi-step Time Series forecasting, CopulaCPTS. On several synthetic and real-world multivariate time series datasets, we show that CopulaCPTS produces more calibrated and sharp c onfidence intervals for multi-step prediction tasks than existing techniques.

Multi-Epoch Matrix Factorization Mechanisms for Private Machine Learning

Christopher A. Choquette-Choo,Hugh Brendan McMahan,J Keith Rush,Abhradeep Guha Thakurta

We introduce new differentially private (DP) mechanisms for gradient-based machine learning (ML) training involving multiple passes (epochs) of a dataset, substantially improving the achievable privacy-utility-computation tradeoffs. Our key contribution is an extension of the online matrix factorization DP mechanism to multiple participations, substantially generalizing the approach of DMRST2022. We first give a non-trivial reduction of the problem with per-iteration vector contributions to the simpler one of scalar contributions. Using this, we formulate the construction of optimal (in total squared error at each iterate) matrix mechanisms for SGD variants as a convex program. We provide a closed form solution to the dual function, leading directly to an efficient optimization algorithms.

While tractable, both solving the convex problem offline and computing the necessary noise masks during training can become prohibitively expensive when many training steps are necessary. To address this, we design a Fourier-transform-based mechanism with significantly less computation and only a minor utility decrease.

Extensive empirical evaluation on two tasks, example-level DP for image classification and user-level DP for language modeling, demonstrate substantial improvements over the previous state-of-the-art. Though our primary application is to ML, we note our main DP results are applicable to arbitrary linear queries and hence may have much broader applicability.

Quantum 3D graph structure learning with applications to molecule computing

Ge Yan,Huaijin Wu,Junchi Yan

Graph representation learning has been extensively studied over the last decades, and recent models start to focus on an under-explored area of 3D graph learning with 3D spatial position as well as node attributes. Despite the progress, the ability to understand the physical meaning of the 3D topology data is still a bottleneck for existing models. On the other hand, quantum computing is known to be a promising direction for theoretically verified supremacy as well as increasing evidence for access to a physical quantum device in the near term. For the first time, we propose a quantum 3D embedding ansatz that learns the latent representation of 3D structures from the Hilbert space composed of the Bloch sphere of each qubit. We convert the 3D Cartesian coordinates of nodes into rotation and torsion angles and then encode them into the form of qubits. Moreover, Parameterized Quantum Circuit (PQC) is applied to serve as the trainable layers and we take the output of the PQC as the node embedding. Experimental results on two downstream tasks, molecular property prediction and 3D molecular geometries generation, demonstrate the effectiveness of our model. Though the results are still restricted by computational power, we have shown the capability of our model with very few parameters and the potential to execute on a real quantum device.

Distributional Signals for Node Classification in Graph Neural Networks

Feng Ji,See Hian Lee,Zhao Kai,Wee Peng Tay,Jielong Yang

In graph neural networks (GNNs), both node features and labels are examples of graph signals, a key notion in graph signal processing (GSP). While it is common in GSP to impose signal smoothness constraints in learning and estimation tasks, it is unclear how this can be done for discrete node labels. We bridge this gap by introducing the concept of distributional graph signals. In our framework, we work with the distributions of node labels instead of their values and propose notions of smoothness and non-uniformity of such distributional graph signals. We then propose a general regularization method for GNNs that allows us to encode distributional smoothness and non-uniformity of the model output in semi-supervised node classification tasks. Numerical experiments demonstrate that our meth od can significantly improve the performance of most base GNN models in different problem settings.

Vector Quantized Wasserstein Auto-Encoder

Long Tung Vuong,Trung Le,He Zhao,Chuanxia Zheng,Mehrtash Harandi,Jianfei Cai,Dinh Phung

Learning deep discrete latent presentations offers a promise of better symbolic and summarized abstractions that are more useful to subsequent downstream tasks. Recent work on Vector Quantized Variational Auto-Encoder (VQ-VAE) has made substantial progress in this direction. However, this quantizes latent representations using the online k-means algorithm which suffers from poor initialization and non-stationary clusters. To strengthen the clustering quality for the latent representations, we propose Vector Quantized Wasserstein Auto-Encoder (VQ-WAE) intuitively developed based on the clustering viewpoint of Wasserstein (WS) distance. Specifically, we endow a discrete distribution over the codewords and learn a deterministic decoder that transports the codeword distribution to the data distribution via minimizing a WS distance between them. We develop further theories to connect it with the clustering viewpoint of WS distance, allowing us to have a better and more controllable clustering solution. Finally, we empirically evaluate our method on several well-known benchmarks, where it achieves better qualitative and quantitative performances than the baselines in terms of the codebook utilization and image reconstruction/generation.

Exact Representation of Sparse Networks with Symmetric Nonnegative Embeddings

Sudhanshu Chanpuriya,Ryan A. Rossi,Anup Rao,Tung Mai,Nedim Lipka,Zhao Song,Cameron N Musco

Many models for undirected graphs are based on factorizing the graph's adjacency matrix; these models find a vector representation of each node such that the predicted probability of a link between two nodes increases with the similarity (dot product) of their associated vectors. Recent work has shown that these models are unable to capture key structures in real-world graphs, particularly heterophilous structures, wherein links occur between dissimilar nodes. In contrast, a factorization with two vectors per node, based on logistic principal components analysis (LPCA), has been proven not only to represent such structures, but also to provide exact low-rank factorization of any graph with bounded max degree. However, this bound has limited applicability to real-world networks, which often have power law degree distributions with high max degree. Further, the LPCA model lacks interpretability since its asymmetric factorization does not reflect the undirectedness of the graph. We address the above issues in two ways. First, we prove a new bound for the LPCA model in terms of arboricity rather than max degree; this greatly increases the bound's applicability to many sparse real-world networks. Second, we propose an alternative graph model whose factorization is symmetric and nonnegative, which allows for link predictions to be interpreted in terms of node clusters. We show that the bounds for exact representation in the LPCA model extend to our new model. On the empirical side, our model is optimized effectively on real-world graphs with gradient descent on a cross-entropy loss. We demonstrate its effectiveness on a variety of foundational tasks, such as community detection and link prediction.

****

Skill-Based Reinforcement Learning with Intrinsic Reward Matching

Ademi Adeniji,Amber Xie,Pieter Abbeel

While unsupervised skill discovery has shown promise in autonomously acquiring behavioral primitives, there is still a large methodological disconnect between task-agnostic skill pretraining and downstream, task-aware finetuning. We present Intrinsic Reward Matching (IRM), which unifies these two phases of learning via the $\textit{skill discriminator}$, a pretraining model component often discarded during finetuning. Conventional approaches finetune pretrained agents directly at the policy level, often relying on expensive environment rollouts to empirically determine the optimal skill. However, often the most concise yet complete description of a task is the reward function itself, and skill learning methods learn an $\textit{intrinsic}$ reward function via the discriminator that corresponds to the skill policy. We propose to leverage the skill discriminator to $\textit{match}$ the intrinsic and downstream task rewards and determine the optimal skill for an unseen task without environment samples, consequently finetuning with greater sample-efficiency. Furthermore, we generalize IRM to sequence skills and solve more complex, long-horizon tasks. We demonstrate that IRM is competitive with previous skill selection methods on the Unsupervised Reinforcement Learning Benchmark and enables us to utilize pretrained skills far more effectively on challenging tabletop manipulation tasks.

TuneUp: A Training Strategy for Improving Generalization of Graph Neural Networks

Weihua Hu,Kaidi Cao,Kexin Huang,Edward W Huang,Karthik Subbian,Jure Leskovec

Despite many advances in Graph Neural Networks (GNNs), their training strategies simply focus on minimizing a loss over nodes in a graph. However, such simplistic training strategies may be sub-optimal as they neglect that certain nodes are much harder to make accurate predictions on than others. Here we present TuneUp, a curriculum learning strategy for better training GNNs. Crucially, TuneUp trains a GNN in two stages. The first stage aims to produce a strong base GNN. Such base GNNs tend to perform well on head nodes (nodes with large degrees) but less so on tail nodes (nodes with small degrees). So, the second stage of TuneUp specifically focuses on improving prediction on tail nodes. Concretely, TuneUp synthesizes many additional supervised tail node data by dropping edges from head nodes and reusing the supervision on the original head nodes. TuneUp then minimizes the loss over the synthetic tail nodes to finetune the base GNN. TuneUp is a general training strategy that can be used with any GNN architecture and any loss, making TuneUp applicable to a wide range of prediction tasks. Extensive evaluation of TuneUp on two GNN architectures, three types of prediction tasks, and both inductive and transductive settings shows that TuneUp significantly improves the performance of the base GNN on tail nodes, while often even improving the performance on head nodes, which together leads up to 58.5% relative improvement in GNN predictive performance. Moreover, TuneUp significantly outperforms its variants without the two-stage curriculum learning, existing graph data augmentation techniques, as well as other specialized methods for tail nodes.

****

A Scalable and Exact Gaussian Process Sampler via Kernel Packets

Haoyuan Chen,Rui Tuo

In view of the widespread use of Gaussian processes (GPs) in machine learning models, generating random sample paths of GPs is crucial for many machine learning applications. Sampling from a GP essentially requires generating high-dimensional Gaussian random vectors, which is computationally challenging if a direct method, such as the one based on Cholesky decomposition, is implemented. We develop a scalable algorithm to sample random realizations of the prior and the posterior of GP models with Matérn correlation functions. Unlike existing scalable sampling algorithms, the proposed approach draws samples from the theoretical distributions exactly. The algorithm exploits a novel structure called the kernel packets (KP), which gives an exact sparse representation of the dense covariance matrices. The proposed method is applicable for one-dimensional GPs, and multi-dimensional GPs under some conditions such as separable kernels with full grid designs. Via a series of experiments and comparisons with other recent works, we demonstrate the efficiency and accuracy of the proposed method.

Model ChangeLists: Characterizing Changes in ML Prediction APIs

Sabri Eyuboglu,Karan Goel,Arjun D Desai,Lingjiao Chen,Mathew Monfort,Matei Zaharia,Christopher Re,James Zou

Updates to Machine Learning as a Service (MLaaS) APIs may affect downstream systems that depend on their predictions. However, performance changes introduced by these updates are poorly documented by providers and seldom studied in the literature. As a result, users are left wondering: do model updates introduce subtle performance changes that could adversely affect my system? Ideally, users would have access to a detailed ChangeList specifying the slices of data where model performance has improved and degraded since the update. But, producing a ChangeList is challenging because it requires (1) discovering slices in the absence of detailed annotations or metadata, (2) accurately attributing coherent concepts to the discovered slices, and (3) communicating them to the user in a digestable manner. We introduce Mocha, an interactive framework for building, verifying and releasing ChangeLists that addresses these challenges. Using it, we perform a large-scale analysis of three real-world MLaaS API updates. We produce a ChangeList for each, identifying over 100 coherent data slices on which the model’s performance changed significantly. Notably, we find 63 instances where an update improves performance globally, but hurts performance on a coherent slice – a phenomenon not previously documented at scale in the literature. These findings underscore the importance of producing a detailed ChangeList when the model behind an API is updated.

****

Provably Auditing Ordinary Least Squares in Low Dimensions

Ankur Moitra,Dhruv Rohatgi

Auditing the stability of a machine learning model to small changes in the training procedure is critical for engendering trust in practical applications. For example, a model should not be overly sensitive to removing a small fraction of its training data. However, algorithmically validating this property seems computationally challenging, even for the simplest of models: Ordinary Least Squares (OLS) linear regression. Concretely, recent work defines the stability of a regression as the minimum number of samples that need to be removed so that rerunning the analysis overturns the conclusion (Broderick et al., 2020), specifically meaning that the sign of a particular coefficient of the OLS regressor changes. But the only known approach for estimating this metric, besides the obvious exponential-time algorithm, is a greedy heuristic that may produce severe overestimates and therefore cannot certify stability. We show that stability can be efficiently certified in the low-dimensional regime: when the number of covariates is a constant but the number of samples is large, there are polynomial-time algorithms for estimating (a fractional version of) stability, with provable approximation guarantees. Applying our algorithms to the Boston Housing dataset, we exhibit regression analyses where our estimator outperforms the greedy heuristic, and can successfully certify stability even in the regime where a constant fraction of the samples are dropped.

Exploring semantic information in disease: Simple Data Augmentation Techniques for Chinese Disease Normalization

Wenqian Cui,Xiangling Fu,Shaohui Liu,Xien Liu,Ji Wu

Disease is a core concept in the medical field, and the task of normalizing disease names is the basis of all disease-related tasks. However, due to the multi-axis and multi-grain nature of disease names, incorrect information is often injected and harms the performance when using general text data augmentation techniques. To address the above problem, we propose a set of data augmentation techniques that work together as an augmented training task for disease normalization, which is called Disease Data Augmentation (DDA). Our data augmentation methods are based on both the clinical disease corpus and standard disease corpus derived from ICD-10 coding. Extensive experiments are conducted to show the effectiveness of our proposed methods. The results demonstrate that our method can have up to 3\% performance gain compared to non-augmented counterparts, and they can work even better on smaller datasets.

Planning Goals for Exploration

Edward S. Hu,Richard Chang,Oleh Rybkin,Dinesh Jayaraman

Dropped into an unknown environment, what should an agent do to quickly learn about the environment and how to accomplish diverse tasks within it? We address this question within the goal-conditioned reinforcement learning paradigm, by identifying how the agent should set its goals at training time to maximize exploration. We propose "Planning Exploratory Goals" (PEG), a method that sets goals for each training episode to directly optimize an intrinsic exploration reward. PEG first chooses goal commands such that the agent's goal-conditioned policy, at its current level of training, will end up in states with high exploration potential. It then launches an exploration policy starting at those promising states. To enable this direct optimization, PEG learns world models and adapts sampling-based planning algorithms to "plan goal commands". In challenging simulated robotics environments including a multi-legged ant robot in a maze, and a robot arm on a cluttered tabletop, PEG exploration enables more efficient and effective training of goal-conditioned policies relative to baselines and ablations. Our ant successfully navigates a long maze, and the robot arm successfully builds a stack of three blocks upon command. Website: https://sites.google.com/view/exploratory-goals

Learning Sparse Group Models Through Boolean Relaxation

Yijie Wang,Yuan Zhou,Xiaoqing Huang,Kun Huang,Jie Zhang,Jianzhu Ma

We introduce an efficient algorithmic framework for learning sparse group models formulated as the natural convex relaxation of a cardinality-constrained program with Boolean variables. We provide theoretical techniques to characterize the equivalent condition when the relaxation achieves the exact integral optimal solution, as well as a rounding algorithm to produce a feasible integral solution once the optimal relaxation solution is fractional. We demonstrate the power of our equivalent condition by applying it to two ensembles of random problem instances that are challenging and popularly used in literature and prove that our method achieves exactness with overwhelming probability and nearly optimal sample complexity. Empirically, we use synthetic datasets to demonstrate that our proposed method significantly outperforms the state-of-the-art group sparse learning models in terms of individual and group support recovery when the number of samples is small. Furthermore, we show the out-performance of our method in cancer drug response prediction.

LVQ-VAE:End-to-end Hyperprior-based Variational Image Compression with Lattice Vector Quantization

Shinobu Kudo,Yukihiro Bandoh,Seishi Takamura,Masaki Kitahara

Image compression technology has become more important research topic. In recent years, learning-based methods have been extensively studied and variational autoencoder (VAE)-based methods using hyperprior-based context-adaptive entropy model have been reported to be comparable to the latest video coding standard H.266/VVC in terms of RD performance.

We think there is room for improvement in quantization process of latent features by adopting vector quantization (VQ). Many VAE-based methods use scalar quantization for latent features and do not exploit correlation between the features. Although there are methods that incorporate VQ into learning-based methods, to the best our knowledge, there are no studies that utilizes the hyperprior-based VAE with VQ because incorporating VQ into a hyperprior-based VAE makes it difficult to estimate the likelihood.

In this paper, we propose a new VAE-based image compression method using VQ based latent representation for hyperprior-based context-adaptive entropy model to improve the coding efficiency. The proposed method resolves problem faced by conventional VQ-based methods due to codebook size bloat by adopting Lattice VQ as the basis quantization method and achieves end-to-end optimization with hyperprior-based context-adaptive entropy model by approximating the likelihood calculation of latent feature vectors with high accuracy using Monte Carlo integration. Furthermore, in likelihood estimation, we model each latent feature vector with multivariate normal distribution including covariance matrix parameters, which improves the likelihood estimation accuracy and RD performance.

Experimental results show that the proposed method achieves a state-of-the-art RD performance exceeding existing learning-based methods and the latest video coding standard H.266/VVC by 18.0%.

Direct Embedding of Temporal Network Edges via Time-Decayed Line Graphs

Sudhanshu Chanpuriya,Ryan A. Rossi,Sungchul Kim,Tong Yu,Jane Hoffswell,Nedim Lipka,Shunan Guo,Cameron N Musco
Temporal networks model a variety of important phenomena involving timed interactions between entities. Existing methods for machine learning on temporal networks generally exhibit at least one of two limitations. First, many methods assume time to be discretized, so if the time data is continuous, the user must determine the discretization and discard precise time information. Second, edge representations can only be calculated indirectly from the nodes, which may be suboptimal for tasks like edge classification. We present a simple method that avoids both shortcomings: construct the line graph of the network, which includes a node for each interaction, and weigh the edges of this graph based on the difference in time between interactions. From this derived graph, edge representations for the original network can be computed with efficient classical methods. The simplicity of this approach facilitates explicit theoretical analysis: we can constructively show the effectiveness of our method's representations for a natural synthetic model of temporal networks. Empirical results on real-world networks demonstrate our method's efficacy and efficiency on both link classification and prediction.
****
Neural DAG Scheduling via One-Shot Priority Sampling
Wonseok Jeon,Mukul Gagrani,Burak Bartan,Weiliang Will Zeng,Harris Teague,Piero Zappi,Christopher Lott
We consider the problem of scheduling operations/nodes, the dependency among which is characterized by a Directed Acyclic Graph (DAG). Due to its NP-hard nature, heuristic algorithms were traditionally used to acquire reasonably good solutions, and more recent works have proposed Machine Learning (ML) heuristics that can generalize to unseen graphs and outperform the non-ML heuristics. However, it is computationally costly to generate solutions using existing ML schedulers since they adopt the episodic reinforcement learning framework that necessitates multi-round neural network processing. We propose a novel ML scheduler that uses a one-shot neural network encoder to sample node priorities which are converted by list scheduling to the final schedules. Since the one-shot encoder can efficiently sample the priorities in parallel, our algorithm runs significantly faster than existing ML baselines and has comparable run time with the fast traditional heuristics. We empirically show that our algorithm generates better schedules than both non-neural and neural baselines across various real-world and synthetic scheduling tasks.

Efficiently Computing Nash Equilibria in Adversarial Team Markov Games
Fivos Kalogiannis,Ioannis Anagnostides,Ioannis Panageas,Emmanouil-Vasileios Vlatakis-Gkaragkounis,Vaggos Chatziafratis,Stelios Andrew Stavroulakis

Computing Nash equilibrium policies is a central problem in multi-agent reinforcement learning that has received extensive attention both in theory and in practice. However, in light of computational intractability barriers in general-sum games, provable guarantees have been thus far either limited to fully competitive or cooperative scenarios or impose strong assumptions that are difficult to meet in most practical applications.

In this work, we depart from those prior results by investigating infinite-horizon \emph{adversarial team Markov games}, a natural and well-motivated class of games in which a team of identically-interested players---in the absence of any explicit coordination or communication---is competing against an adversarial player. This setting allows for a unifying treatment of zero-sum Markov games and Markov potential games, and serves as a step to model more realistic strategic interactions that feature both competing and cooperative interests. Our main contribution is the first algorithm for computing stationary ϵ-approximate Nash equilibria in adversarial team Markov games with computational complexity that is polynomial in all the natural parameters of the game, as well as $1/\epsilon$.

The proposed algorithm is based on performing independent policy gradient steps for each player in the team, in tandem with best responses from the side of the adversary; in turn, the policy for the adversary is then obtained by solving a carefully constructed linear program. Our analysis leverages non-standard techniques to establish the KKT optimality conditions for a nonlinear program with nonconvex constraints, thereby leading to a natural interpretation of the induced Lagrange multipliers.

Meta Temporal Point Processes

Wonho Bae,Mohamed Osama Ahmed,Frederick Tung,Gabriel L. Oliveira

A temporal point process (TPP) is a stochastic process where its realization is a sequence of discrete events in time. Recent work in TPPs model the process using a neural network in a supervised learning framework, where a training set is a collection of all the sequences. In this work, we propose to train TPPs in a meta learning framework, where each sequence is treated as a different task, via a novel framing of TPPs as neural processes (NPs). We introduce context sets to model TPPs as an instantiation of NPs. Motivated by attentive NP, we also introduce local history matching to help learn more informative features. We demonstrate the potential of the proposed method on popular public benchmark datasets and tasks, and compare with state-of-the-art TPP methods.

EmbedDistill: A geometric knowledge distillation for information retrieval

Seungyeon Kim,Ankit Singh Rawat,Manzil Zaheer,Sadeep Jayasumana,Veeranjaneyulu Sadhanala,Wittawat Jitkrittum,Aditya Krishna Menon,Rob Fergus,Sanjiv Kumar

Large neural models (such as Transformers) achieve state-of-the-art performance for information retrieval. In this paper, we aim to improve distillation methods that pave the way for the deployment of such models in practice. The proposed distillation approach supports both retrieval and re-ranking stages and crucially leverages the relative geometry among queries and documents learned by the large teacher model. It goes beyond existing distillation methods in the information retrieval literature, which simply rely on the teacher's scalar scores over the training data, on two fronts: providing stronger signals about local geometry via embedding matching and attaining better coverage of data manifold globally via query generation. Embedding matching provides a stronger signal to align the representations of the teacher and student models. At the same time, query generation explores the data manifold to reduce the discrepancies between the student and teacher where the training data is sparse. Our distillation approach is theoretically justified and applies to both dual encoder (DE) and cross-encoder (CE) models. Furthermore, for distilling a CE model to a DE model via embedding matching, we propose a novel dual pooling-based scorer for the CE model that facilitates a more distillation-friendly embedding geometry, especially for DE student models.

Graph Neural Network-Inspired Kernels for Gaussian Processes in Semi-Supervised Learning

Zehao Niu,Mihai Anitescu,Jie Chen

Gaussian processes (GPs) are an attractive class of machine learning models because of their simplicity and flexibility as building blocks of more complex Bayesian models. Meanwhile, graph neural networks (GNNs) emerged recently as a promising class of models for graph-structured data in semi-supervised learning and beyond. Their competitive performance is often attributed to a proper capturing of the graph inductive bias. In this work, we introduce this inductive bias into GPs to improve their predictive performance for graph-structured data. We show that a prominent example of GNNs, the graph convolutional network, is equivalent to some GP when its layers are infinitely wide; and we analyze the kernel universality and the limiting behavior in depth. We further present a programmable procedure to compose covariance kernels inspired by this equivalence and derive example kernels corresponding to several interesting members of the GNN family. We also propose a computationally efficient approximation of the covariance matrix for scalable posterior inference with large-scale data. We demonstrate that these

graph-based kernels lead to competitive classification and regression performance, as well as advantages in computation time, compared with the respective GNNs.
****
Deconstructing Distributions: A Pointwise Framework of Learning
Gal Kaplun,Nikhil Ghosh,Saurabh Garg,Boaz Barak,Preetum Nakkiran
In machine learning, we traditionally evaluate the performance of a single model, averaged over a collection of test inputs. In this work, we propose a new approach: we measure the performance of a collection of models when evaluated at *single input point*. Specifically, we study a point's *profile*: the relationship between models' average performance on the test distribution and their pointwise performance on this individual point. We find that profiles can yield new insights into the structure of both models and data---in and out-of-distribution. For example, we empirically show that real data distributions consist of points with qualitatively different profiles. On one hand, there are ``compatible'' points with strong correlation between the pointwise and average performance. On the other hand, there are points with weak and even *negative* correlation: cases where improving overall model accuracy actually *hurts* performance on these inputs. As an application, we use profiles to construct a dataset we call CIFAR-10-NEG: a subset of CINIC-10 such that for standard models, accuracy on CIFAR-10-NEG is *negatively correlated* with CIFAR-10 accuracy. Illustrating for the first time an OOD dataset that completely inverts ``accuracy-on-the-line'' (Miller et al., 2021).

Logical view on fairness of a binary classification task
Serge Berger
Ethical, Interpretable/Explainable, and Responsible AI are an active area of research and important social initiative.

We prove that, with no regards to data, fairness and trustworthiness are algorithmically undecidable for a basic machine learning task, the binary classification. Therefore, even the approach based on not only improving but fully solving the three usually assumed issues -- the insufficient quality of measurements, the complex consequences of (mis)measurements, and the limits of existing social theories -- is only heuristics. We show that, effectively, the fairness of a classifier is not even a (version of bias-variance) trade-off since it is a logical phenomenon.
Namely, we reveal a language L and an $L-$theory T for binary classification task such that the very notion of loss is not expressible in the first-order logic formula in L.
****
Revisiting Instance-Reweighted Adversarial Training
Hiroki Adachi,Tsubasa Hirakawa,Takayoshi Yamashita,Hironobu Fujiyoshi
Instance-reweighted adversarial training (IRAT) is a type of adversarial training that assigns large weights to high-importance examples and then minimizes the weighted loss. The importance often uses the margins between decision boundaries and each example. In particular, IRAT can alleviate robust overfitting and obtain excellent robustness by computing margins with an estimated probability. However, previous works implicitly dealt with binary classification even in the multi-class cases, because they computed margins with only the true class and the most confusing class. The computed margins can become equal even with different true probability examples, because of the complex decision boundaries in multi-class classification. In this paper, first, we clarify the above problem with a specific example. Then, we propose \textit{margin reweighting}, which can transform the previous margins into appropriate representations for multi-class classification by leveraging the relations between the most confusing class and other classes. Experimental results on the CIFAR-10/100 datasets demonstrate that the proposed method is effective in boosting the robustness against several attacks as compared to the previous methods.

Diffusion Models for Causal Discovery via Topological Ordering

Pedro Sanchez,Xiao Liu,Alison Q O'Neil,Sotirios A. Tsaftaris

Discovering causal relations from observational data becomes possible with additional assumptions such as considering the functional relations to be constrained as nonlinear with additive noise (ANM). Even with strong assumptions, causal discovery involves an expensive search problem over the space of directed acyclic graphs (DAGs). \emph{Topological ordering} approaches reduce the optimisation space of causal discovery by searching over a permutation rather than graph space. For ANMs, the \emph{Hessian} of the data log-likelihood can be used for finding leaf nodes in a causal graph, allowing its topological ordering. However, existing computational methods for obtaining the Hessian still do not scale as the number of variables and the number of samples are increased. Therefore, inspired by recent innovations in diffusion probabilistic models (DPMs), we propose \emph{DiffAN}, a topological ordering algorithm that leverages DPMs for learning a Hessian function. We introduce theory for updating the learned Hessian without re-training the neural network, and we show that computing with a subset of samples gives an accurate approximation of the ordering, which allows scaling to datasets with more samples and variables. We show empirically that our method scales exceptionally well to datasets with up to 500 nodes and up to 10^5 samples while still performing on par over small datasets with state-of-the-art causal discovery methods.

Implementation is available at \url{https://github.com/vios-s/DiffAN} .

Scalable and Equivariant Spherical CNNs by Discrete-Continuous (DISCO) Convolutions

Jeremy Ocampo,Matthew Alexander Price,Jason McEwen

No existing spherical convolutional neural network (CNN) framework is both computationally scalable and rotationally equivariant. Continuous approaches capture rotational equivariance but are often prohibitively computationally demanding. Discrete approaches offer more favorable computational performance but at the cost of equivariance. We develop a hybrid discrete-continuous (DISCO) group convolution that is simultaneously equivariant and computationally scalable to high-resolution. While our framework can be applied to any compact group, we specialize to the sphere. Our DISCO spherical convolutions exhibit $\text{SO}(3)$ rotational equivariance, where $\text{SO}(n)$ is the special orthogonal group representing rotations in n-dimensions. When restricting rotations of the convolution to the quotient space $\text{SO}(3)/\text{SO}(2)$ for further computational enhancements, we recover a form of asymptotic $\text{SO}(3)$ rotational equivariance. Through a sparse tensor implementation we achieve linear scaling in number of pixels on the sphere for both computational cost and memory usage. For 4k spherical images we realize a saving of 10^9 in computational cost and 10^4 in memory usage when compared to the most efficient alternative equivariant spherical convolution. We apply the DISCO spherical CNN framework to a number of benchmark dense-prediction problems on the sphere, such as semantic segmentation and depth estimation, on all of which we achieve the state-of-the-art performance.

Towards Solving Industrial Sequential Decision-making Tasks under Near-predictable Dynamics via Reinforcement Learning: an Implicit Corrective Value Estimation Approach

Jianyong Yuan,Jiayi Zhang,Junchi Yan

Learning to plan and schedule is receiving increasing attention for industrial decision-making tasks for its potential for outperforming heuristics, especially under dynamic uncertainty, as well as its efficiency in problem-solving, especially with the adoption of neural networks and the behind GPU computing. Naturally, reinforcement learning (RL) with the Markov decision process (MDP) becomes a popular paradigm. Rather than handling the near-stationary environments like Atari games or the opposite case for open world dynamics with high uncertainty. In this paper, we aim to devise a tailored RL-based approach for the setting in the between: the near-predictable dynamics which often hold in many industrial applications, e.g., elevator scheduling and bin packing, as empirical case studies te sted in this paper. We formulate a two-stage MDP by decoupling the data dynamics from the industrial environment. Specifically, we design a bi-critic framework for estimating the state value in stages according to the two-stage MDP.

Graph Convolutional Normalizing Flows for Semi-Supervised Classification and Clustering

Tianchun Wang,Farzaneh Mirzazadeh,Xiang Zhang,Jie Chen

Graph neural networks (GNNs) are \emph{discriminative models} that directly model the class posterior $p(y|\mathbf{x})$ for semi-supervised classification of graph data. While being effective for prediction, as a representation learning approach, the node representations extracted from a GNN often miss useful information for effective clustering, because that is not necessary for a good classification. In this work, we replace a GNN layer by a combination of graph convolutions and normalizing flows under a Gaussian mixture representation space, which allows us to build a \emph{generative model} that models both the class conditional likelihood $p(\mathbf{x}|y)$ and the class prior $p(y)$. The resulting neural network, GC-Flow, enjoys two benefits: it not only maintains the predictive power because of the retention of graph convolutions, but also produces high-quality clusters in the representation space, due to the structuring of the representation as a mixture of Gaussians. We demonstrate these benefits on a variety of benchmark data sets. Moreover, we show that additional parameterization, such as that on the adjacency matrix used for graph convolutions, yields additional improvement in classification and clustering.

Weakly Supervised Explainable Phrasal Reasoning with Neural Fuzzy Logic

Zijun Wu,Zi Xuan Zhang,Atharva Naik,Zhijian Mei,Mauajama Firdaus,Lili Mou

Natural language inference (NLI) aims to determine the logical relationship between two sentences, such as Entailment, Contradiction, and Neutral. In recent years, deep learning models have become a prevailing approach to NLI, but they lack interpretability and explainability. In this work, we address the explainability of NLI by weakly supervised logical reasoning, and propose an Explainable Phrasal Reasoning (EPR) approach. Our model first detects phrases as the semantic unit and aligns corresponding phrases in the two sentences. Then, the model predicts the NLI label for the aligned phrases, and induces the sentence label by fuzzy logic formulas. Our EPR is almost everywhere differentiable and thus the system can be trained end to end. In this way, we are able to provide explicit explanations of phrasal logical relationships in a weakly supervised manner. We further show that such reasoning results help textual explanation generation.

Simplified State Space Layers for Sequence Modeling

Jimmy T.H. Smith,Andrew Warrington,Scott Linderman

Models using structured state space sequence (S4) layers have achieved state-of-the-art performance on long-range sequence modeling tasks. An S4 layer combines linear state space models (SSMs), the HiPPO framework, and deep learning to achieve high performance. We build on the design of the S4 layer and introduce a new state space layer, the S5 layer. Whereas an S4 layer uses many independent single-input, single-output SSMs, the S5 layer uses one multi-input, multi-output SSM. We establish a connection between S5 and S4, and use this to develop the initialization and parameterization used by the S5 model. The result is a state space layer that can leverage efficient and widely implemented parallel scans, allowing S5 to match the computational efficiency of S4, while also achieving state-of-the-art performance on several long-range sequence modeling tasks. S5 averages 87.4% on the long range arena benchmark, and 98.5% on the most difficult Path-X task.

Learning Listwise Domain-Invariant Representations for Ranking

Ruicheng Xian,Honglei Zhuang,Zhen Qin,Hamed Zamani,Jing Lu,Ji Ma,Kai Hui,Han Zhao,Xuanhui Wang,Michael Bendersky

Domain adaptation aims to transfer models trained on data-rich domains to low-re

source ones, for which a popular method is invariant representation learning. While they have been studied extensively for classification and regression problems, how they would apply to ranking problems, where the metrics and data follow a list structure, is not well understood. Theoretically, we establish a generalization bound for ranking problems under metrics including MRR and NDCG, leading to a method based on learning listwise invariant feature representations. The main novelty of our results is that they are tailored to the listwise approach of learning to rank: the invariant representations our method learns are for each list of items as a whole, instead of the individual items they contain. Our method is evaluated on the passage reranking task, where we adapt neural text rankers trained on a general domain to various specialized domains.

DCI-ES: An Extended Disentanglement Framework with Connections to Identifiability
Cian Eastwood,Andrei Liviu Nicolicioiu,Julius Von Kügelgen,Armin Keki■,Frederik Träuble,Andrea Dittadi,Bernhard Schölkopf
In representation learning, a common approach is to seek representations which disentangle the underlying factors of variation. Eastwood & Williams (2018) proposed three metrics for quantifying the quality of such disentangled representations: disentanglement (D), completeness (C) and informativeness (I). In this work, we first connect this DCI framework to two common notions of linear and nonlinear identifiability, thereby establishing a formal link between disentanglement and the closely-related field of independent component analysis. We then propose an extended DCI-ES framework with two new measures of representation quality—explicitness (E) and size (S)—and point out how D and C can be computed for black-box predictors. Our main idea is that the functional capacity required to use a representation is an important but thus-far neglected aspect of representation quality, which we quantify using explicitness or ease-of-use (E). We illustrate the relevance of our extensions on the MPI3D and Cars3D datasets.
****
Eigenvalue Initialisation and Regularisation for Koopman Autoencoders
Jack William Miller,Charles O'Neill,Navid C Constantinou,Omri Azencot
Regularising the parameter matrices of neural networks is ubiquitous in training deep models. Typical regularisation approaches suggest initialising weights using small random values, and to penalise weights to promote sparsity. However, these widely used techniques may be less effective in certain scenarios. Here, we study the Koopman autoencoder model which includes an encoder, a Koopman operator layer, and a decoder. These models have been designed and dedicated to tackle physics-related problems with interpretable dynamics and an ability to incorporate physics-related constraints. However, the majority of existing work employs standard regularisation practices. In our work, we take a step toward augmenting Koopman autoencoders with initialisation and penalty schemes tailored for physics-related settings. Specifically, we propose the "eigeninit" initialisation scheme that samples initial Koopman operators from specific eigenvalue distributions. In addition, we suggest the "eigenloss" penalty scheme that penalises the eigenvalues of the Koopman operator during training. We demonstrate the utility of these schemes on two synthetic data sets: a driven pendulum and flow past a cylinder; and two real-world problems: ocean surface temperatures and cyclone wind fields. We find on these datasets that eigenloss and eigeninit improves the convergence rate by a factor of 2 to 5, and that they reduce the cumulative long-term prediction error by up to a factor of 2.5. Such a finding points to the utility of incorporating similar schemes as an inductive bias in other physics-related deep learning approaches.
****
Learning from Labeled Images and Unlabeled Videos for Video Segmentation
Cristina Mata,Michael S Ryoo
Performance on video object segmentation still lags behind that of image segmentation due to a paucity of labeled videos. Annotations are time-consuming and laborious to collect, and may not be feasibly obtained in certain situations. However there is a growing amount of freely available unlabeled video data which has

spurred interest in unsupervised video representation learning. In this work we focus on the setting in which there is no/little access to labeled videos for video object segmentation. To this end we leverage large-scale image segmentation datasets and adversarial learning to train 2D/3D networks for video object segmentation. We first motivate the treatment of images and videos as two separate domains by analyzing the performance gap of an image segmentation network trained on images and applied to videos. Through studies using several image and video segmentation datasets, we show how an adversarial loss placed at various locations within the network can make feature representations invariant to these domains and improve the performance when the network has access to only labeled images and unlabeled videos. To prevent the loss of discriminative semantic class information we apply our adversarial loss within clusters of features and show this boosts our method's performance within Transformer-based models.

****

MeshDiffusion: Score-based Generative 3D Mesh Modeling
Zhen Liu,Yao Feng,Michael J. Black,Derek Nowrouzezahrai,Liam Paull,Weiyang Liu
We consider the task of generating realistic 3D shapes, which is useful for a variety of applications such as automatic scene generation and physical simulation. Compared to other 3D representations like voxels and point clouds, meshes are more desirable in practice, because (1) they enable easy and arbitrary manipulation of shapes for relighting and simulation, and (2) they can fully leverage the power of modern graphics pipelines which are mostly optimized for meshes. Previous scalable methods for generating meshes typically rely on sub-optimal post-processing, and they tend to produce overly-smooth or noisy surfaces without fine-grained geometric details. To overcome these shortcomings, we take advantage of the graph structure of meshes and use a simple yet very effective generative modeling method to generate 3D meshes. Specifically, we represent meshes with deformable tetrahedral grids, and then train a diffusion model on this direct parameterization. We demonstrate the effectiveness of our model on multiple generative tasks.

Faster federated optimization under second-order similarity
Ahmed Khaled,Chi Jin
Federated learning (FL) is a subfield of machine learning where multiple clients try to collaboratively learn a model over a network under communication constraints. We consider finite-sum federated optimization under a second-order function similarity condition and strong convexity, and propose two new algorithms: SVRP and Catalyzed SVRP. This second-order similarity condition has grown popular recently, and is satisfied in many applications including distributed statistical learning and differentially private empirical risk minimization. The first algorithm, SVRP, combines approximate stochastic proximal point evaluations, client sampling, and variance reduction. We show that SVRP is communication efficient and achieves superior performance to many existing algorithms when function similarity is high enough. Our second algorithm, Catalyzed SVRP, is a Catalyst-accelerated variant of SVRP that achieves even better performance and uniformly improves upon existing algorithms for federated optimization under second-order similarity and strong convexity. In the course of analyzing these algorithms, we provide a new analysis of the Stochastic Proximal Point Method (SPPM) that might be of independent interest. Our analysis of SPPM is simple, allows for approximate proximal point evaluations, does not require any smoothness assumptions, and shows a clear benefit in communication complexity over ordinary distributed stochastic gradient descent.

****

A Quasistatic Derivation of Optimization Algorithms' Exploration on Minima Manifolds
Chao Ma,Daniel Kunin,Lexing Ying
A quasistatic approach is proposed to derive the optimization algorithms' effective dynamics on the manifold of minima when the iterator oscillates around the manifold. Compared with existing strict analysis, our derivation method is simple and intuitive, has wide applicability, and produces easy-to-interpret results.

As examples, we derive the manifold dynamics for SGD, SGD with momentum (SGDm) and Adam with different noise covariances, and justify the closeness of the derived manifold dynamics with the true dynamics through numerical experiments. We then use minima manifold dynamics to study and compare the properties of optimization algorithms. For SGDm, we show that scaling up learning rate and batch size simultaneously accelerates exploration without affecting generalization, which confirms a benefit of large batch training. For Adam, we show that the speed of its manifold dynamics changes with the direction of the manifold, because Adam is not rotationally invariant. This may cause slow exploration in high dimensional parameter spaces.

Mutual Partial Label Learning with Competitive Label Noise

Yan Yan,Yuhong Guo

Partial label learning (PLL) is an important weakly supervised learning problem, where each training instance is associated with a set of candidate labels that include both the true label and additional noisy labels. Most existing PLL methods assume the candidate noisy labels are randomly chosen, which hardly holds in real-world learning scenarios. In this paper, we consider a more realistic PLL scenario with competitive label noise that is more difficult to distinguish from the true label than the random label noise. We propose a novel Mutual Learning based PLL approach named ML-PLL to address this challenging problem. ML-PLL learns a prediction network based classifier and a class-prototype based classifier cooperatively through interactive mutual learning and label correction. Moreover, we use a transformation network to model the association relationships between the true label and candidate labels, and learn it together with the prediction network to match the observed candidate labels in the training data and enhance label correction. Extensive experiments are conducted on several benchmark PLL datasets, and the proposed ML-PLL approach demonstrates state-of-the-art performance for partial label learning.

****

The Graph Learning Attention Mechanism: Learnable Sparsification Without Heuristics

Mattson Thieme,Yada Zhu,Han Liu

Graph Neural Networks (GNNs) are local aggregators that derive their expressive power from their sensitivity to network structure. However, this sensitivity comes at a cost: noisy edges degrade performance. In response, many GNNs include edge-weighting mechanisms that scale the contribution of each edge in the aggregation step. However, to account for neighborhoods of varying size, node-embedding mechanisms must normalize these edge-weights across each neighborhood. As such, the impact of noisy edges cannot be eliminated without removing those edges altogether. Motivated by this issue, we introduce the Graph Learning Attention Mechanism (GLAM): a drop-in, differentiable structure learning layer for GNNs that separates the distinct tasks of structure learning and node embedding. In contrast to existing graph learning approaches, GLAM does not require the addition of exogenous structural regularizers or edge-selection heuristics to learn optimal graph structures. In experiments on citation and co-purchase datasets, we demonstrate that our approach can match state of the art semi-supervised node classification accuracies while inducing an order of magnitude greater sparsity than existing graph learning methods.

****

Partial Label Unsupervised Domain Adaptation with Class-Prototype Alignment

Yan Yan,Yuhong Guo

Partial label learning (PLL) tackles the problem where each instance is associated with a set of candidate labels, only one of which is the ground-truth label. Most existing PLL approaches assume that both the training and test sets share an identical data distribution. However, this assumption does not hold in many real-world scenarios where the training and test data come from different distributions. In this paper, we formalize this learning scenario as a new problem called partial label unsupervised domain adaptation (PLUDA). To address this challenging PLUDA problem, we propose a novel Prototype Alignment based PLUDA method nam ed PAPLUDA, which dynamically refines the pseudo-labels of instances from both the source and target domains by consulting the outputs of a teacher-student model in a moving-average manner, and bridges the cross-domain discrepancy through inter-domain class-prototype alignment. In addition, a teacher-student model based contrastive regularization is deployed to enhance prediction stability and hence improve the class-prototypes in both domains for PLUDA. Comprehensive experimental results demonstrate that PAPLUDA achieves state-of-the-art performance on the widely used benchmark datasets.

****

Why Self Attention is Natural for Sequence-to-Sequence Problems? A Perspective from Symmetries

Chao Ma,Lexing Ying

In this paper, we show that structures similar to self-attention are natural to learn many sequence-to-sequence problems from the perspective of symmetry. Inspired by language processing applications, we study the orthogonal equivariance of {\it seq2seq functions with knowledge}, which are functions taking two inputs---an input sequence and a ``knowledge''---and outputting another sequence.

The knowledge consists of a set of vectors in the same embedding space as the input sequence, containing the information of the language used to process the input sequence. We show that orthogonal equivariance in the embedding space is natural for seq2seq functions with knowledge, and under such equivariance the function must take the form close to the self-attention. This shows that network structures similar to self-attention are the right structures to represent the target function of many seq2seq problems. The representation can be further refined if a ``finite information principle'' is considered, or a permutation equivariance holds for the elements of the input sequence.

simpleKT: A Simple But Tough-to-Beat Baseline for Knowledge Tracing

Zitao Liu,Qiongqiong Liu,Jiahao Chen,Shuyan Huang,Weiqi Luo

Knowledge tracing (KT) is the problem of predicting students' future performance based on their historical interactions with intelligent tutoring systems. Recently, many works present lots of special methods for applying deep neural networks to KT from different perspectives like model architecture, adversarial augmentation and etc., which make the overall algorithm and system become more and more complex. Furthermore, due to the lack of standardized evaluation protocol \citep{liu2022pykt}, there is no widely agreed KT baselines and published experimental comparisons become inconsistent and self-contradictory, i.e., the reported AUC scores of DKT on ASSISTments2009 range from 0.721 to 0.821 \citep{minn2018deep,yeung2018addressing}. Therefore, in this paper, we provide a strong but simple baseline method to deal with the KT task named \textsc{simpleKT}. Inspired by the Rasch model in psychometrics, we explicitly model question-specific variations to capture the individual differences among questions covering the same set of knowledge components that are a generalization of terms of concepts or skills needed for learners to accomplish steps in a task or a problem. Furthermore, instead of using sophisticated representations to capture student forgetting behaviors, we use the ordinary dot-product attention function to extract the time-aware information embedded in the student learning interactions. Extensive experiments show that such a simple baseline is able to always rank top 3 in terms of AUC scores and achieve 57 wins, 3 ties and 16 loss against 12 DLKT baseline methods on 7 public datasets of different domains. We believe this work serves as a strong baseline for future KT research. Code is available at \url{https://github.com/pykt-team/pykt-toolkit}\footnote{We merged our model to the \textsc{pyKT} benchmark at \url{https://pykt.org/}.}.

Exp-α: Beyond Proportional Aggregation in Federated Learning

Junjiao Tian,Xiaoliang Dai,Chih-Yao Ma,Zecheng He,Yen-Cheng Liu,Sayan Ghosh,Peter Vajda,Anqi Wu,Zsolt Kira

Federated Learning (FL) is a distributed learning paradigm, which computes gradients of a model locally on different clients and aggregates the updates to construct a new model collectively. Typically, the updates from local clients are agg regated with weights proportional to the size of clients' local datasets. In practice, clients have different local datasets suffering from data heterogeneity, such as imbalance. Although proportional aggregation still theoretically converges to the global optimum, it is provably slower when non-IID data is present (under convexity assumptions), the effect of which is exacerbated in practice. We posit that this analysis ignores convergence rate, which is especially important under such settings in the more realistic non-convex real world. To account for this, we analyze a generic and time-varying aggregation strategy to reveal a surprising trade-off between convergence rate and convergence error under convexity assumptions. Inspired by the theory, we propose a new aggregation strategy, Exp-α, which weights clients differently based on their severity of data heterogeneity. It achieves stronger convergence rates at the theoretical cost of a non-vanishing convergence error. Through a series of controlled experiments, we empirically demonstrate the superior convergence behavior (both in terms of rate and, in practice, even error) of the proposed aggregation on three types of data heterogeneity: imbalance, label-flipping, and domain shift when combined with existing FL algorithms. For example, on our imbalance benchmark, Exp-α, combined with FedAvg, achieves a relative 12% increase in convergence rate and a relative 3% reduction in error across four FL communication settings.

Learning Efficient Hybrid Particle-continuum Representations of Non-equilibrium N-body Systems

Tailin Wu,Michael Sun,H.G. Jason Chou,Pranay Samala,Sithipont Cholsaipant,Sophia Kivelson,Jacqueline Yau,Zhitao Ying,E. Paulo Alves,Jure Leskovec,Frederico Fiuza

An important class of multi-scale, non-equilibrium, N-body physical systems deals with an interplay between particle and continuum phenomena. These include hypersonic flow and plasma dynamics, materials science, and astrophysics. Hybrid solvers that combine particle and continuum representations could provide an efficient framework to model these systems. However, the coupling between these two representations has been a key challenge, which is often limited to inaccurate or incomplete prescriptions. In this work, we introduce a method for Learning Hybrid Particle-Continuum (LHPC) models from the data of first-principles particle simulations. LHPC analyzes the local velocity-space particle distribution function and separates it into near-equilibrium (thermal) and far-from-equilibrium (non-thermal) components. The most computationally-intensive particle solver is used to advance the non-thermal particles, whereas a neural network solver is used to efficiently advance the thermal component using a continuum representation. Most importantly, an additional neural network learns the particle-continuum coupling: the dynamical exchange of mass, momentum, and energy between the particle and continuum representations. Training of the different neural network components is done in an integrated manner to ensure global consistency and stability of the LHPC model. We demonstrate our method in an intense laser-plasma interaction problem involving highly nonlinear, far-from-equilibrium dynamics associated with the coupling between electromagnetic fields and multiple particle species. More efficient modeling of these interactions is critical for the design and optimization of compact accelerators for material science and medical applications. Our method achieves an important balance between accuracy and speed: LHPC is 8 times faster than a classical particle solver and achieves up to 6.8-fold reduction of long-term prediction error for key quantities of interest compared to deep-learning baselines using uniform representations.

Neural Network Approximation of Lipschitz Functions in High Dimensions with Applications to Inverse Problems

Santhosh Karnik,Rongrong Wang,Mark Iwen

The remarkable successes of neural networks in a huge variety of inverse problems have fueled their adoption in disciplines ranging from medical imaging to seismic analysis over the past decade. However, the high dimensionality of such inverse problems has simultaneously left current theory, which predicts that networks should scale exponentially in the dimension of the problem, unable to explain why the seemingly small networks used in these settings work as well as they do in practice. To reduce this gap between theory and practice, a general method for bounding the complexity required for a neural network to approximate a Lipschitz function on a high-dimensional set with a low-complexity structure is provided herein. The approach is based on the observation that the existence of a linear Johnson-Lindenstrauss embedding $\mathbf{A} \in \mathbb{R}^{d \times D}$ of a given high-dimensional set $\mathcal{S} \subset \mathbb{R}^D$ into a low dimensional cube $[-M,M]^d$ implies that for any Lipschitz function $f : \mathcal{S} \to \mathbb{R}^p$, there exists a Lipschitz function $g : [-M,M]^d \to \mathbb{R}^p$ such that $g(\mathbf{A}\mathbf{x}) = f(\mathbf{x})$ for all $\mathbf{x} \in \mathcal{S}$. Hence, if one has a neural network which approximates $g : [-M,M]^d \to \mathbb{R}^p$, then a layer can be added which implements the JL embedding $\mathbf{A}$ to obtain a neural network which approximates $f : \mathcal{S} \to \mathbb{R}^p$. By pairing JL embedding results along with results on approximation of Lipschitz functions by neural networks, one then obtains results which bound the complexity required for a neural network to approximate Lipschitz functions on high dimensional sets. The end result is a general theoretical framework which can then be used to better explain the observed empirical successes of smaller networks in a wider variety of inverse problems than current theory allows.

Weighted Ensemble Self-Supervised Learning

Yangjun Ruan,Saurabh Singh,Warren Richard Morningstar,Alexander A Alemi,Sergey Ioffe,Ian Fischer,Joshua V. Dillon

Ensembling has proven to be a powerful technique for boosting model performance, uncertainty estimation, and robustness in supervised learning. Advances in self-supervised learning (SSL) enable leveraging large unlabeled corpora for state-of-the-art few-shot and supervised learning performance. In this paper, we explore how ensemble methods can improve recent SSL techniques by developing a framework that permits data-dependent weighted cross-entropy losses. We refrain from ensembling the representation backbone; this choice yields an efficient ensemble method that incurs a small training cost and requires no architectural changes or computational overhead to downstream evaluation. The effectiveness of our method is demonstrated with two state-of-the-art SSL methods, DINO (Caron et al., 2021) and MSN (Assran et al., 2022). Our method outperforms both in multiple evaluation metrics on ImageNet-1K, particularly in the few-shot setting. We explore several weighting schemes and find that those which increase the diversity of ensemble heads lead to better downstream evaluation results. Thorough experiments yield improved prior art baselines which our method still surpasses; e.g., our overall improvement with MSN ViT-B/16 is 3.9 p.p. for 1-shot learning.

Partially Observable RL with B-Stability: Unified Structural Condition and Sharp Sample-Efficient Algorithms

Fan Chen,Yu Bai,Song Mei

Partial Observability---where agents can only observe partial information about the true underlying state of the system---is ubiquitous in real-world applications of Reinforcement Learning (RL). Theoretically, learning a near-optimal policy under partial observability is known to be hard in the worst case due to an exponential sample complexity lower bound. Recent work has identified several tractable subclasses that are learnable with polynomial samples, such as Partially Observable Markov Decision Processes (POMDPs) with certain revealing or decodability conditions. However, this line of research is still in its infancy, where (1) unified structural conditions enabling sample-efficient learning are lacking; (2) existing sample complexities for known tractable subclasses are far from sharp; and (3) fewer sample-efficient algorithms are available than in fully observable RL.

This paper advances all three aspects above for Partially Observable RL in the general setting of Predictive State Representations (PSRs). First, we propose a natural and unified structural condition for PSRs called \emph{B-stability}. B-stable PSRs encompasses the vast majority of known tractable subclasses such as we akly revealing POMDPs, low-rank future-sufficient POMDPs, decodable POMDPs, and regular PSRs. Next, we show that any B-stable PSR can be learned with polynomial samples in relevant problem parameters. When instantiated in the aforementioned subclasses, our sample complexities improve substantially over the current best ones. Finally, our results are achieved by three algorithms simultaneously: Optimistic Maximum Likelihood Estimation, Estimation-to-Decisions, and Model-Based Optimistic Posterior Sampling. The latter two algorithms are new for sample-efficient learning of POMDPs/PSRs.

We additionally design a variant of the Estimation-to-Decisions algorithm to perform sample-efficient \emph{all-policy model estimation} for B-stable PSRs, which also yields guarantees for reward-free learning as an implication.

Bias Amplification Improves Worst-Group Accuracy without Group Information

Gaotang Li,Jiarui Liu,Wei Hu

Neural networks produced by standard training are known to suffer from poor accuracy on rare subgroups despite achieving high accuracy on average, due to the correlations between certain spurious features and labels. Previous approaches based on worst-group loss minimization (\textit{e.g.} Group-DRO) are effective in improving worse-group accuracy but require expensive group annotations for all the training samples. In this paper, we focus on the more challenging and realistic setting where group annotations are only available on a small validation set or are not available at all. We propose \bam, a novel two-stage training algorithm: in the first stage, the model is trained using a \emph{bias amplification} scheme via introducing a learnable \emph{auxiliary variable} for each training sample together with the adoption of squared loss; in the second stage, we upweight the samples that the bias-amplified model misclassifies, and then continue training the same model on the reweighted dataset. Empirically, \bam leads to consistent improvement over its counterparts in worst-group accuracy, resulting in state-of-the-art performance in spurious correlation benchmarks in computer vision and natural language processing. Moreover, we find a simple stopping criterion that completely removes the need for group annotations, with little or no loss in worst-group accuracy.

Actionable Recourse Guided by User Preference

Jayanth Yetukuri,Ian Hardy,Yang Liu

The growing popularity of machine learning models has led to their increased application in domains directly impacting human lives. In critical fields such as healthcare, banking, and criminal justice, tools that ensure trust and transparency are vital for the responsible adoption of these models. One such tool is \emph{actionable recourse} (AR) for negatively impacted users. AR describes recommendations of cost-efficient changes to a user's \emph{actionable} features to help them obtain favorable outcomes. Existing approaches for providing recourse optimize for properties such as proximity, sparsity, validity, and distance-based costs. However, an often-overlooked but crucial requirement for actionability is a consideration of \emph{User Preference} to guide the recourse generation process. Moreover, existing works considering a user's preferences require users to precisely specify their costs for taking actions. This requirement raises questions about the practicality of the corresponding solutions due to the high cognitive loads imposed. In this work, we attempt to capture user preferences via soft constraints in three simple forms: \textit{i) scoring continuous features, ii) bounding feature values} and \textit{iii) ranking categorical features}. We propose an optimization framework that is sensitive to {user preference} and a gradient-based approach to identify \emph{User Preferred Actionable Recourse (UP-AR)}.

We empirically demonstrate the proposed approach's superiority in adhering to user preference while maintaining competitive performance in traditional metrics with extensive experiments.

Large Learning Rate Matters for Non-Convex Optimization

Amirkeivan Mohtashami,Martin Jaggi,Sebastian U Stich

When training neural networks, it has been widely observed that a large step siz

e is essential in stochastic gradient descent (SGD) for obtaining superior models. However, the effect of large step sizes on the success of SGD is not well understood theoretically.
Several previous works have attributed this success to the stochastic noise present in SGD. However, we show through a novel set of experiments that the stochastic noise is not sufficient to explain good non-convex training, and that instead the effect of a large learning rate itself is essential for obtaining best performance.
We demonstrate the same effects also in the noise-less case, i.e. for full-batch GD. We formally prove that GD with large step size---on certain non-convex function classes---follows a different trajectory than GD with a small step size, which can lead to convergence to a global minimum instead of a local one.
Finally, we also demonstrate the difference in trajectories for small and large learning rates for real neural networks, again observing that large learning rates allow escaping from a local minimum, confirming this behavior is indeed relevant in practice.

A Deep Learning Framework for Musical Acoustics Simulations

Jiafeng Chen,George Hagopian,K■vanç Tatar,Victor Zappi

The acoustic modeling of musical instruments is a heavy computational process, often bound to the solution of complex systems of partial differential equations (PDEs). Numerical models can achieve a high level of accuracy, but they may take up to several hours to complete a full simulation, especially in the case of intricate musical mechanisms. The application of deep learning, and in particular of neural operators that learn mappings between function spaces, has the potential to revolutionize how acoustics PDEs are solved and noticeably speed up musical simulations. However, such operators require large datasets, capable of exemplifying the relationship between input parameters (excitation) and output solutions (acoustic wave propagation) per each target musical instrument/configuration. With this work, we present an open-access, open-source framework designed for the generation of numerical musical acoustics datasets and for the training/benchmarking of acoustics neural operators. We first describe the overall structure of the framework and the proposed data generation workflow. Then, we detail the first numerical models that were ported to the framework. Finally, we conclude by sharing some preliminary results obtained by means of training a state-of-the-art neural operator with a dataset generated via the framework. This work is a first step towards the gathering of a research community that focuses on deep learning applied to musical acoustics, and shares workflows and benchmarking tools.

Domain Generalization via Heckman-type Selection Models

Hyungu Kahng,Hyungrok Do,Judy Zhong

The domain generalization (DG) setup considers the problem where models are trained on data sampled from multiple domains and evaluated on test domains unseen during training. In this paper, we formulate DG as a sample selection problem where each domain is sampled from a common underlying population through non-random sampling probabilities that correlate with both the features and the outcome. Under this setting, the fundamental iid assumption of the empirical risk minimization (ERM) is violated, so it often performs worse on test domains whose non-random sampling probabilities differ from the domains in the training dataset. We propose a Selection-Guided DG (SGDG) framework to learn the selection probability of each domain and the joint distribution of the outcome and domain selection variables. The proposed SGDG is domain generalizable as it intends to minimize the risk under the population distribution. We theoretically proved that, under certain regular conditions, SGDG can achieve smaller risk than ERM. Furthermore, we present a class of parametric SGDG (HeckmanDG) estimators applicable to continuous, binary, and multinomial outcomes. We also demonstrated its efficacy empirically through simulations and experiments on a set of benchmark datasets comparing with other well-known DG methods.

Moving Forward by Moving Backward: Embedding Action Impact over Action Semantics

Kuo-Hao Zeng,Luca Weihs,Roozbeh Mottaghi,Ali Farhadi

A common assumption when training embodied agents is that the impact of taking an action is stable; for instance, executing the ``move ahead'' action will always move the agent forward by a fixed distance, perhaps with some small amount of actuator-induced noise. This assumption is limiting; an agent may encounter settings that dramatically alter the impact of actions: a move ahead action on a wet floor may send the agent twice as far as it expects and using the same action with a broken wheel might transform the expected translation into a rotation. Instead of relying that the impact of an action stably reflects its pre-defined semantic meaning, we propose to model the impact of actions on-the-fly using latent embeddings. By combining these latent action embeddings with a novel, transformer-based, policy head, we design an Action Adaptive Policy (AAP). We evaluate our AAP on two challenging visual navigation tasks in the AI2-THOR and Habitat environments and show that our AAP is highly performant even when faced, at inference-time, with missing actions and, previously unseen, perturbed action spaces. Moreover, we observe significant improvement in robustness against these actions when evaluating in real-world scenarios.

****

Guiding Safe Exploration with Weakest Preconditions

Greg Anderson,Swarat Chaudhuri,Isil Dillig

In reinforcement learning for safety-critical settings, it is often desirable for the agent to obey safety constraints at all points in time, including during training. We present a novel neurosymbolic approach called SPICE to solve this safe exploration problem. SPICE uses an online shielding layer based on symbolic weakest preconditions to achieve a more precise safety analysis than existing tools without unduly impacting the training process. We evaluate the approach on a suite of continuous control benchmarks and show that it can achieve comparable performance to existing safe learning techniques while incurring fewer safety violations. Additionally, we present theoretical results showing that SPICE converges to the optimal safe policy under reasonable assumptions.

****

MetaMD: Principled Optimiser Meta-Learning for Deep Learning

Boyan Gao,Henry Gouk,Jan Stuehmer,massimiliano pontil,Timothy Hospedales

Optimiser design influences learning speed and generalisation in training machine learning models. Several studies have attempted to learn more effective gradient-descent optimisers via solving a bi-level optimisation problem where generalisation error is minimised with respect to optimiser parameters. However, most existing neural network oriented optimiser learning methods are intuitively motivated, without clear theoretical support, and focus on learning implicit biases that improve generalisation, rather than speed of convergence. We take a different perspective starting from mirror descent rather than gradient descent, and meta-learning the corresponding Bregman divergence. Within this paradigm, we formalise a novel meta-learning objective of optimising the rate of convergence. The resulting framework, termed Meta Mirror Descent (MetaMD), learns to accelerate optimisation speed. Unlike many meta-learned neural network optimisers, it also supports convergence guarantees and uniquely does so without requiring validation data. We empirically evaluate our framework on a variety of tasks and architectures in terms of convergence rate and generalisation error and demonstrate strong performance.

A Sample Based Method for Understanding The Decisions of Neural Networks Semantically

Ohi Dibua,Jonathan Mbuya,Mackenzie Austin,Kushal Kafle

Interpretability in deep learning is one of the largest obstacles to its more widespread adoption in critical applications. A variety of methods have been introduced to understand and explain decisions made by Deep Models. A class of these methods highlights which features are most influential to model predictions. These methods have some key weaknesses. First, most of these methods are applicable only to the atomic elements that make up raw inputs to the model (e.g., pixels or words). Second, these methods generally don't distinguish between the importa

nce of features individually versus due to interactions with other features. As a result, it is difficult to explore high level questions about how models use features. We tackle these issues by proposing Sample-Based Semantic Analysis (SBSA). We use Sobol sensitivity analysis as our sample-based method. Sobol-SBSA allows us to quantify the importance of semantic combinations of raw inputs and highlight the extent to which these features are important individually as opposed to due to interactions with other features. We demonstrate the ability of Sobol-SBSA to answer a richer class of questions about the behavior of Deep Learning models by exploring how CNN models from AlexNet to DenseNet use regions when classifying images. We present two key findings. 1) The architectural improvements from AlexNet to DenseNet manifested themselves in CNN models utilizing greater levels of region interactions for predictions. 2) Adversarially robust CNNs resist exploiting spurious correlations in ImageNet data by forcing these architectures to rely less on region-to-region interaction. Our proposed method is generalizable to a wide variety of network and input types and can help provide greater clarity about model decisions.

Deep Biological Pathway Informed Pathology-Genomic Multimodal Survival Prediction

Lin Qiu,Aminollah Khormali,Kai Liu

The integration of multi-modal data, such as pathological images and genomic data, is essential for understanding cancer heterogeneity and complexity for personalized treatments, as well as for enhancing survival predictions. Despite the progress made in integrating pathology and genomic data, most existing methods cannot mine the complex inter-modality relations thoroughly. Additionally, identifying explainable features from these models that govern preclinical discovery and clinical prediction is crucial for cancer diagnosis, prognosis, and therapeutic response studies. We propose PONET- a novel biological pathway informed pathology-genomic deep model that integrates pathological images and genomic data not only to improve survival prediction but also to identify genes and pathways that cause different survival rates in patients. Empirical results on six of The Cancer Genome Atlas (TCGA) datasets show that our proposed method achieves superior predictive performance and reveals meaningful biological interpretations. The proposed method establishes insight on how to train biological informed deep networks on multimodal biomedical data which will have general applicability for understanding diseases and predicting response and resistance to treatment.
****

A CMDP-within-online framework for Meta-Safe Reinforcement Learning

Vanshaj Khattar,Yuhao Ding,Bilgehan Sel,Javad Lavaei,Ming Jin

Meta-reinforcement learning has widely been used as a learning-to-learn framework to solve unseen tasks with limited experience. However, the aspect of constraint violations has not been adequately addressed in the existing works, making their application restricted in real-world settings. In this paper, we study the problem of meta-safe reinforcement learning (meta-SRL) through the CMDP-within-online framework. We obtain task-averaged regret guarantees for the reward maximization (optimality gap) and constraint violations using gradient-based meta-learning and show that the task-averaged optimality gap and constraint satisfaction improve with task-similarity in the static environment, or task-relatedness in the changing environment. Several technical challenges arise when making this framework practical while still having strong theoretical guarantees. To address these challenges, we propose a meta-algorithm that performs inexact online learning on the upper bounds of intra-task optimality gap and constraint violations estimated by off-policy stationary distribution corrections. Furthermore, we enable the learning rates to be adapted for every task and extend our approach to settings with the dynamically changing task environments. Finally, experiments are conducted to demonstrate the effectiveness of our approach. The proposed theoretical framework is the first to handle the nonconvexity and stochastic nature of within-task CMDPs, while exploiting inter-task dependency for multi-task safe learning.

Active Sampling for Node Attribute Completion on Graphs

Benyuan Liu,Xu Chen,Yanfeng Wang,Ya Zhang,Zhi Cao,Ivor Tsang

Node attribute is one kind of crucial information on graphs, but real-world graphs usually face attribute-missing problem where attributes of partial nodes are missing and attributes of the other nodes are available. It is meaningful to restore the missing attributes so as to benefit downstream graph learning tasks. Popular GNN is not designed for this node attribute completion issue and is not capable of solving it. Recent proposed Structure-attribute Transformer (SAT) framework decouples the input of graph structures and node attributes by a distribution matching technique, and can work on it properly. However, SAT leverages nodes with observed attributes in an equally-treated way and neglects the different contributions of different nodes in learning. In this paper, we propose a novel active sampling algorithm (ATS) to more efficiently utilize the nodes with observed attributes and better restore the missing node attributes. Specifically, ATS contains two metrics that measure the representativeness and uncertainty of each node's information by considering the graph structures, representation similarity and learning bias. Then, these two metrics are linearly combined by a Beta distribution controlled weighting scheme to finally determine which nodes are selected into the train set in the next optimization step. This ATS algorithm can be combined with SAT framework together, and is learned in an iterative manner. Through extensive experiments on 4 public benchmark datasets and two downstream tasks, we show the superiority of ATS in node attribute completion.

Effects of Graph Convolutions in Multi-layer Networks

Aseem Baranwal,Kimon Fountoulakis,Aukosh Jagannath

Graph Convolutional Networks (GCNs) are one of the most popular architectures that are used to solve classification problems accompanied by graphical information. We present a rigorous theoretical understanding of the effects of graph convolutions in multi-layer networks. We study these effects through the node classification problem of a non-linearly separable Gaussian mixture model coupled with a stochastic block model. First, we show that a single graph convolution expands the regime of the distance between the means where multi-layer networks can classify the data by a factor of at least $1/\sqrt[4]{\rm deg}$, where ${\rm deg}$ denotes the expected degree of a node. Second, we show that with a slightly stronger graph density, two graph convolutions improve this factor to at least $1/\sqrt[4]{n}$, where n is the number of nodes in the graph. Finally, we provide both theoretical and empirical insights into the performance of graph convolutions placed in different combinations among the layers of a neural network, concluding that the performance is mutually similar for all combinations of the placement. We present extensive experiments on both synthetic and real-world data that illustrate our results.

SimPer: Simple Self-Supervised Learning of Periodic Targets

Yuzhe Yang,Xin Liu,Jiang Wu,Silviu Borac,Dina Katabi,Ming-Zher Poh,Daniel McDuff

From human physiology to environmental evolution, important processes in nature often exhibit meaningful and strong periodic or quasi-periodic changes. Due to their inherent label scarcity, learning useful representations for periodic tasks with limited or no supervision is of great benefit. Yet, existing self-supervised learning (SSL) methods overlook the intrinsic periodicity in data, and fail to learn representations that capture periodic or frequency attributes. In this paper, we present SimPer, a simple contrastive SSL regime for learning periodic information in data. To exploit the periodic inductive bias, SimPer introduces customized augmentations, feature similarity measures, and a generalized contrastive loss for learning efficient and robust periodic representations. Extensive experiments on common real-world tasks in human behavior analysis, environmental sensing, and healthcare domains verify the superior performance of SimPer compared to state-of-the-art SSL methods, highlighting its intriguing properties including better data efficiency, robustness to spurious correlations, and generalization to distribution shifts.

Explaining Patterns in Data with Language Models via Interpretable Autoprompting

Chandan Singh,John Xavier Morris,Jyoti Aneja,Alexander M Rush,Jianfeng Gao

Large language models (LLMs) have displayed an impressive ability to harness natural language to perform complex tasks. In this work, we explore whether we can leverage this learned ability to find and explain patterns in data. Specifically, given a pre-trained LLM and data examples, we introduce interpretable autoprompting (iPrompt), an algorithm that generates a natural-language string explaining the data. iPrompt iteratively alternates between generating explanations with an LLM and reranking them based on their performance when used as a prompt. Experiments on a wide range of datasets, from synthetic mathematics to natural-language understanding, show that iPrompt can yield meaningful insights by accurately finding groundtruth dataset descriptions. Moreover, the prompts produced by iPrompt are simultaneously human-interpretable and highly effective for generalization: on real-world sentiment classification datasets, iPrompt produces prompts that match or even improve upon human-written prompts for GPT-3. Finally, experiments with an fMRI dataset show the potential for iPrompt to aid in scientific discovery.

Lipschitz regularized gradient flows and latent generative particles

Hyemin Gu,Panagiota Birmpa,Yannis Pantazis,Markos Katsoulakis,Luc Rey-Bellet

Lipschitz regularized f-divergences are constructed by imposing a bound on the Lipschitz constant of the discriminator in the variational representation. These divergences interpolate between the Wasserstein metric and f-divergences and provide a flexible family of loss functions for non-absolutely continuous (e.g. empirical) distributions, possibly with heavy tails. We first construct Lipschitz regularized gradient flows on the space of probability measures based on these divergences. Examples of such gradient flows are Lipschitz regularized Fokker-Planck and porous medium partial differential equations (PDEs) for the Kullback-Leibler and α-divergences, respectively. The regularization corresponds to imposing a Courant–Friedrichs–Lewy numerical stability condition on the PDEs. For empirical measures, the Lipschitz regularization on gradient flows induces a numerically stable transporter/discriminator particle algorithm, where the generative particles are transported along the gradient of the discriminator. The gradient structure leads to a regularized Fisher information which is the total kinetic energy of the particles and can be used to track the convergence of the algorithm. The Lipschitz regularized discriminator can be implemented via neural network spectral normalization and the particle algorithm generates approximate samples from possibly high-dimensional distributions known only from data. Notably, our particle algorithm can generate synthetic data even in small sample size regimes. A new data processing inequality for the regularized divergence allows us to combine our particle algorithm with representation learning, e.g. autoencoder architectures. The resulting particle algorithm in latent space yields markedly improved generative properties in terms of efficiency and quality of the synthetic samples. From a statistical mechanics perspective the encoding can be interpreted dynamically as learning a better mobility for the generative particles.

****

Post-hoc Concept Bottleneck Models

Mert Yuksekgonul,Maggie Wang,James Zou

Concept Bottleneck Models (CBMs) map the inputs onto a set of interpretable concepts (``the bottleneck'') and use the concepts to make predictions. A concept bottleneck enhances interpretability since it can be investigated to understand what concepts the model "sees" in an input and which of these concepts are deemed important. However, CBMs are restrictive in practice as they require dense concept annotations in the training data to learn the bottleneck. Moreover, CBMs often do not match the accuracy of an unrestricted neural network, reducing the incentive to deploy them in practice. In this work, we address these limitations of CBMs by introducing Post-hoc Concept Bottleneck models (PCBMs). We show that we can turn any neural network into a PCBM without sacrificing model performance while still retaining the interpretability benefits. When concept annotations are not available on the training data, we show that PCBM can transfer concepts from other datasets or from natural language descriptions of concepts via multimodal models. A key benefit of PCBM is that it enables users to quickly debug and update the model to reduce spurious correlations and improve generalization to new distributions. PCBM allows for global model edits, which can be more efficient than previous works on local interventions that fix a specific prediction. Through a model-editing user study, we show that editing PCBMs via concept-level feedback can provide significant performance gains without using data from the target domain or model retraining.

Undersampling is a Minimax Optimal Robustness Intervention in Nonparametric Classification

Niladri Shekhar Chatterji,Saminul Haque,Tatsunori Hashimoto

While a broad range of techniques have been proposed to tackle distribution shift, the simple baseline of training on an undersampled balanced dataset often achieves close to state-of-the-art-accuracy across several popular benchmarks. This is rather surprising, since undersampling algorithms discard excess majority group data. To understand this phenomenon, we ask if learning is fundamentally constrained by a lack of minority group samples. We prove that this is indeed the case in the setting of nonparametric binary classification. Our results show that in the worst case, an algorithm cannot outperform undersampling unless there is a high degree of overlap between the train and test distributions (which is unlikely to be the case in real-world datasets), or if the algorithm leverages additional structure about the distribution shift. In particular, in the case of label shift we show that there is always an undersampling algorithm that is minimax optimal. In the case of group-covariate shift we show that there is an undersampling algorithm that is minimax optimal when the overlap between the group distributions is small. We also perform an experimental case study on a label shift dataset and find that in line with our theory, the test accuracy of robust neural network classifiers is constrained by the number of minority samples.

****

Emb-GAM: an Interpretable and Efficient Predictor using Pre-trained Language Models

Chandan Singh,Jianfeng Gao

Deep learning models have achieved impressive prediction performance but often sacrifice interpretability, a critical consideration in high-stakes domains such as healthcare or policymaking. In contrast, generalized additive models (GAMs) can maintain interpretability, but often suffer from poor prediction performance due to their inability to effectively capture feature interactions. In this work, we aim to bridge this gap by using pre-trained large-language models to extract embeddings for each input before learning a linear model in the embedding space. The final model (which we call Emb-GAM) is a transparent, linear function of its input features and feature interactions.

Leveraging the language model allows Emb-GAM to learn far fewer linear coefficients, model larger interactions, and generalize well to novel inputs (e.g. unseen ngrams in text). Across a variety of natural-language-processing datasets, Emb-GAM achieves strong prediction performance without sacrificing interpretability. All code for using Emb-GAM and reproducing our results is made available on github.

When Source-Free Domain Adaptation Meets Learning with Noisy Labels

Li Yi,Gezheng Xu,Pengcheng Xu,Jiaqi Li,Ruizhi Pu,Charles Ling,Ian McLeod,Boyu Wang

Recent state-of-the-art source-free domain adaptation (SFDA) methods have focused on learning meaningful cluster structures in the feature space, which have succeeded in adapting the knowledge from source domain to unlabeled target domain without accessing the private source data. However, existing methods rely on the pseudo-labels generated by source models that can be noisy due to domain shift.

In this paper, we study SFDA from the perspective of learning with label noise (LLN). Unlike the label noise in the conventional LLN scenario, we prove that the label noise in SFDA follows a different distribution assumption. We also prove that such a difference makes existing LLN methods that rely on their distribution assumptions unable to address the label noise in SFDA. Empirical evidence suggests that only marginal improvements are achieved when applying the existing LLN methods to solve the SFDA problem. On the other hand, although there exists a fundamental difference between the label noise in the two scenarios, we demonstrate theoretically that the early-time training phenomenon (ETP), which has been previously observed in conventional label noise settings, can also be observed in the SFDA problem. Extensive experiments demonstrate significant improvements to existing SFDA algorithms by leveraging ETP to address the label noise in SFDA.

Is a Caption Worth a Thousand Images? A Study on Representation Learning
Shibani Santurkar,Yann Dubois,Rohan Taori,Percy Liang,Tatsunori Hashimoto
The development of CLIP [Radford et al., 2021] has sparked a debate on whether adding language supervision can yield vision models with more transferable representations than traditional image-only methods. Our work studies this question through a carefully controlled comparison of two approaches, in terms of their ability to learn representations that generalize to downstream classification tasks. We find that when the pre-training data meets certain criteria---it is sufficiently large and contains descriptive captions with low variability----image-only methods do not match CLIP's performance even when they are trained with more image data. However, contrary to what one might expect, there are practical settings in which these criteria are not met, wherein added supervision through captions is actually detrimental.
Motivated by our findings, we devise simple data and algorithmic interventions to improve the transfer performance of CLIP-style models.

Parameter-Efficient Fine-Tuning Design Spaces
Jiaao Chen,Aston Zhang,Xingjian Shi,Mu Li,Alex Smola,Diyi Yang
Parameter-efficient fine-tuning aims to achieve comparable performances of fine-tuning with much fewer trainable parameters. Recently, various tuning strategies (e.g., Adapters, Prefix Tuning, BitFit, and LoRA) have been proposed. However, their designs are hand-crafted separately, and it remains unclear whether certain design patterns exist for parameter-efficient fine-tuning. Thus, we present a parameter-efficient fine-tuning design paradigm and discover design patterns that are applicable to different experimental settings. Instead of focusing on designing another individual tuning strategy, we introduce parameter-efficient fine-tuning design spaces that parameterize tuning structures and tuning strategies. Specifically, any design space is characterized by four components: layer grouping, trainable parameter allocation, tunable groups, and strategy assignment. Our comprehensive empirical study leads to the discovery of design patterns: (i) grouping layers in a spindle pattern, (ii) uniformly allocating the number of trainable parameters to layers, (ii) tuning all the groups, and (iv) tuning different groups with proper strategies. Our discovered design patterns result in new parameter-efficient fine-tuning methods. Experiments show that these methods consistently outperform investigated parameter-efficient fine-tuning strategies across different backbone models and different tasks in natural language processing.

Concept Gradient: Concept-based Interpretation Without Linear Assumption
Andrew Bai,Chih-Kuan Yeh,Neil Y.C. Lin,Pradeep Kumar Ravikumar,Cho-Jui Hsieh
Concept-based interpretations of black-box models are often more intuitive for humans to understand. The most widely adopted approach for concept-based, gradient interpretation is Concept Activation Vector (CAV). CAV relies on learning a linear relation between some latent representation of a given model and concepts. The premise of meaningful concepts lying in a linear subspace of model layers is usually implicitly assumed but does not hold true in general. In this work we proposed Concept Gradient (CG), which extends concept-based, gradient interpretation methods to non-linear concept functions. We showed that for a general (poten

tially non-linear) concept, we can mathematically measure how a small change of concept affects the model’s prediction, which is an extension of gradient-based interpretation to the concept space. We demonstrated empirically that CG outperforms CAV in attributing concept importance on real world datasets and performed case study on a medical dataset. The code is available at github.com/jybai/concept-gradients.

Constraining Representations Yields Models That Know What They Don't Know

Joao Monteiro,Pau Rodriguez,Pierre-Andre Noel,Issam H. Laradji,David Vazquez

A well-known failure mode of neural networks is that they may confidently return erroneous predictions. Such unsafe behaviour is particularly frequent when the use case slightly differs from the training context, and/or in the presence of an adversary. This work presents a novel direction to address these issues in a broad, general manner: imposing class-aware constraints on a model's internal activation patterns. Specifically, we assign to each class a unique, fixed, randomly-generated binary vector - hereafter called class code - and train the model so that its cross-depths activation patterns predict the appropriate class code according to the input sample's class. The resulting predictors are dubbed total activation classifiers (TAC), and TACs may either be trained from scratch, or used with negligible cost as a thin add-on on top of a frozen, pre-trained neural network. The distance between a TAC's activation pattern and the closest valid code acts as an additional confidence score, besides the default unTAC'ed prediction head's. In the add-on case, the original neural network's inference head is completely unaffected (so its accuracy remains the same) but we now have the option to use TAC's own confidence and prediction when determining which course of action to take in an hypothetical production workflow. In particular, we show that TAC strictly improves the value derived from models allowed to reject/defer. We provide further empirical evidence that TAC works well on multiple types of architectures and data modalities and that it is at least as good as state-of-the-art alternative confidence scores derived from existing models.

Neural Networks Efficiently Learn Low-Dimensional Representations with SGD

Alireza Mousavi-Hosseini,Sejun Park,Manuela Girotti,Ioannis Mitliagkas,Murat A Erdogdu

We study the problem of training a two-layer neural network (NN) of arbitrary width using stochastic gradient descent (SGD) where the input $\boldsymbol{x}\in \mathbb{R}^d$ is Gaussian and the target $y \in \mathbb{R}$ follows a multiple-index model, i.e., $y=g(\langle\boldsymbol{u_1},\boldsymbol{x}\rangle,...,\langle\boldsymbol{u_k},\boldsymbol{x}\rangle)$ with a noisy link function g. We prove that the first-layer weights in the NN converge to the k-dimensional principal subspace spanned by the vectors $\boldsymbol{u_1},...,\boldsymbol{u_k}$ of the true model, when online SGD with weight decay is used for training. This phenomenon has several important consequences when $k \ll d$. First, by employing uniform convergence on this smaller subspace, we establish a generalization error bound of $\mathcal{O}(\sqrt{{kd}/{T}})$ after T iterations of SGD, which is independent of the width of the NN. We further demonstrate that, by recovering the principal direction, SGD-trained ReLU NNs can learn a single-index target of the form $y=f(\langle\boldsymbol{u},\boldsymbol{x}\rangle) + \epsilon$ with a sample complexity linear in d (up to log factors), where f is a monotonic function with at most polynomial growth, and ϵ is the noise. This is in contrast to the known $d^{\Omega(p)}$ samples required to learn any degree p polynomial in the kernel regime, and shows that SGD-trained NNs can outperform the Neural Tangent Kernel at initialization. Finally, we establish compressibility guarantees for NNs using that SGD produces an approximately rank-k first-layer weight matrix.

Mixed Federated Learning: Joint Decentralized and Centralized Learning

Sean Augenstein,Andrew Hard,Lin Ning,Karan Singhal,Satyen Kale,Kurt Partridge,Rajiv Mathews

Federated learning (FL) enables learning from decentralized privacy-sensitive da ta, with computations on raw data confined to take place at edge clients. This paper introduces mixed FL, which incorporates an additional loss term calculated at the coordinating server (while maintaining FL’s private data restrictions). For example, additional datacenter data can be leveraged to jointly learn from centralized (datacenter) and decentralized (federated) training data and better match an expected inference data distribution.Mixed FL also enables offloading some intensive computations (e.g., embedding regularization) to the server, greatly reducing communication and client computation load. For these and other mixed FL use cases, we present three algorithms: PARALLEL TRAINING, 1-WAY GRADIENT TRANSFER, and 2-WAY GRADIENT TRANSFER. We perform extensive experiments of the algorithms on three tasks, demonstrating that mixed FL can blend training data to achieve an oracle’s accuracy on an inference distribution, and can reduce communication and computation overhead by more than 90%. Finally, we state convergence bounds for all algorithms, and give intuition on the mixed FL problems best suited to each. The theory confirms our empirical observations of how the algorithms perform under different mixed FL problem settings.

OTCOP: Learning optimal transport maps via constraint optimizations

Xiaokai Huo,Hailiang Liu

The approximation power of neural networks makes it an ideal tool to learn optimal transport maps. However, existing methods are mostly based on the Kantorovich duality and require regularization and/or special network structures such as Input Convex Neural Networks (ICNN). In this paper, we propose a direct constraint optimization algorithm for the computation of optimal transport maps based on the Monge formulation. We solve this constraint optimization problem by using three different methods: the penalty method, the augmented Lagrangian method, and the alternating direction method of multipliers method (AMDD). We demonstrate a significant improvement in the accuracy of learned optimal transport maps on benchmarks. Moreover, we show that our methods reduce the regularization effects and accurately learn the target distributions at lower transport cost.

An Extensible Multi-modal Multi-task Object Dataset with Materials

Trevor Scott Standley,Ruohan Gao,Dawn Chen,Jiajun Wu,Silvio Savarese

We present EMMa, an Extensible, Multimodal dataset of Amazon product listings that contains rich Material annotations. It contains more than 2.8 million objects, each with image(s), listing text, mass, price, product ratings, and position in Amazon’s product-category taxonomy. We also design a comprehensive taxonomy of 182 physical materials (e.g., Plastic → Thermoplastic → Acrylic). Objects areannotated with one or more materials from this taxonomy. With the numerous attributes available for each object, we develop a Smart Labeling framework to quickly add new binary labels to all objects with very little manual labeling effort, making the dataset extensible. Each object attribute in our dataset can be included in either the model inputs or outputs, leading to combinatorial possibilities in task configurations. For example, we can train a model to predict the object category from the listing text, or the mass and price from the product listing image. EMMa offers a new benchmark for multi-task learning in computer vision and NLP, and allows practitioners to efficiently add new tasks and object attributes at scale.

Sampling with Mollified Interaction Energy Descent

Lingxiao Li,qiang liu,Anna Korba,Mikhail Yurochkin,Justin Solomon

Sampling from a target measure whose density is only known up to a normalization constant is a fundamental problem in computational statistics and machine learning. In this paper, we present a new optimization-based method for sampling called mollified interaction energy descent (MIED). MIED minimizes a new class of energies on probability measures called mollified interaction energies (MIEs). These energies rely on mollifier functions---smooth approximations of the Dirac delta originated from PDE theory. We show that as the mollifier approaches the Dirac delta, the MIE converges to the chi-square divergence with respect to the targ et measure and the gradient flow of the MIE agrees with that of the chi-square divergence. Optimizing this energy with proper discretization yields a practical first-order particle-based algorithm for sampling in both unconstrained and constrained domains. We show experimentally that for unconstrained sampling problems our algorithm performs on par with existing particle-based algorithms like SVGD, while for constrained sampling problems our method readily incorporates constrained optimization techniques to handle more flexible constraints with strong performance compared to alternatives.

Does Zero-Shot Reinforcement Learning Exist?

Ahmed Touati,Jérémy Rapin,Yann Ollivier

A zero-shot RL agent is an agent that can solve any RL task in a given environment, instantly with no additional planning or learning, after an initial reward-free learning phase. This marks a shift from the reward-centric RL paradigm towards controllable agents that can follow arbitrary instructions in an environment. Current RL agents can solve families of related tasks at best, or require planning anew for each task. Strategies for approximate zero-shot RL have been suggested using successor features (SFs) (Borsa et al., 2018) or forward-backward (FB) representations (Touati & Ollivier, 2021), but testing has been limited.

After clarifying the relationships between these schemes, we introduce improved losses and new SF models, and test the viability of zero-shot RL schemes systematically on tasks from the Unsupervised RL benchmark (Laskin et al., 2021). To disentangle universal representation learning from exploration, we work in an offline setting and repeat the tests on several existing replay buffers.

SFs appear to suffer from the choice of the elementary state features. SFs with Laplacian eigenfunctions do well, while SFs based on auto-encoders, inverse curiosity, transition models, low-rank transition matrix, contrastive learning, or diversity (APS), perform unconsistently. In contrast, FB representations jointly learn the elementary and successor features from a single, principled criterion. They perform best and consistently across the board, reaching 85% of supervised RL performance with a good replay buffer, in a zero-shot manner.

****

Few-Shot Text Classification with Dual Contrastive Consistency Training

Liwen Sun

In this paper, we explore how to utilize pre-trained language model to perform few-shot text classification where only a few annotated examples are given for each class. Since using traditional cross-entropy loss to fine-tune language model under this scenario causes serious overfitting and leads to sub-optimal generalization of model, we adopt supervised contrastive learning on few labeled data and consistency-regularization on vast unlabeled data. Moreover, we propose a novel contrastive consistency to further boost model performance and refine sentence representation. After conducting extensive experiments on four datasets, we demonstrate that our model (FTCC) can outperform state-of-the-art methods and has better robustness.

****

Self-Stabilization: The Implicit Bias of Gradient Descent at the Edge of Stability

Alex Damian,Eshaan Nichani,Jason D. Lee

Traditional analyses of gradient descent show that when the largest eigenvalue of the Hessian, also known as the sharpness $S(\theta)$, is bounded by $2/\eta$, training is "stable" and the training loss decreases monotonically. Recent works, however, have observed that this assumption does not hold when training modern neural networks with full batch or large batch gradient descent. Most recently, Cohen at al. (2021) detailed two important phenomena. The first, dubbed \emph{progressive sharpening}, is that the sharpness steadily increases throughout training until it reaches the instability cutoff $2/\eta$. The second, dubbed \emph{edge of stability}, is that the sharpness hovers at $2/\eta$ for the remainder of training while the loss continues decreasing, albeit non-monotonically. We demonstrate that, far from being chaotic, the dynamics of gradient descent at the e dge of stability can be captured by a cubic Taylor expansion: as the iterates diverge in direction of the top eigenvector of the Hessian due to instability, the cubic term in the local Taylor expansion of the loss function causes the curvature to decrease until stability is restored. This property, which we call \emph{self-stabilization}, is a general property of gradient descent and explains its behavior at the edge of stability. A key consequence of self-stabilization is that gradient descent at the edge of stability implicitly follows \emph{projected} gradient descent (PGD) under the constraint $S(\theta) \le 2/\eta$. Our analysis provides precise predictions for the loss, sharpness, and deviation from the PGD trajectory throughout training, which we verify both empirically in a number of standard settings and theoretically under mild conditions. Our analysis uncovers the mechanism for gradient descent's implicit bias towards stability.

Conditional Permutation Invariant Flows

Berend Zwartsenberg,Adam Scibior,Matthew Niedoba,Vasileios Lioutas,Justice Sefas,Yunpeng Liu,Setareh Dabiri,Jonathan Wilder Lavington,Trevor Campbell,Frank Wood

We present a novel, conditional generative probabilistic model of set-valued data with a tractable log density. This model is a continuous normalizing flow governed by permutation equivariant dynamics. These dynamics are driven by a learnable per-set-element term and pairwise interactions, both parametrized by deep neural networks. We illustrate the utility of this model via applications including (1) complex traffic scene generation conditioned on visually specified map information, and (2) object bounding box generation conditioned directly on images. We train our model by maximizing the expected likelihood of labeled conditional data under our flow, with the aid of a penalty that ensures the dynamics are smooth and hence efficiently solvable. Our method significantly outperforms non-permutation invariant baselines in terms of log likelihood and domain-specific metrics (offroad, collision, and combined infractions), yielding realistic samples that are difficult to distinguish from real data.

TILP: Differentiable Learning of Temporal Logical Rules on Knowledge Graphs

Siheng Xiong,Yuan Yang,Faramarz Fekri,James Clayton Kerce

Compared with static knowledge graphs, temporal knowledge graphs (tKG), which can capture the evolution and change of information over time, are more realistic and general. However, due to the complexity that the notion of time introduces to the learning of the rules, an accurate graph reasoning, e.g., predicting new links between entities, is still a difficult problem. In this paper, we propose TILP, a differentiable framework for temporal logical rules learning. By designing a constrained random walk mechanism and the introduction of temporal operators, we ensure the efficiency of our model. We present temporal features modeling in tKG, e.g., recurrence, temporal order, interval between pair of relations, and duration, and incorporate it into our learning process. We compare TILP with state-of-the-art methods on two benchmark datasets. We show that our proposed framework can improve upon the performance of baseline methods while providing interpretable results. In particular, we consider various scenarios in which training samples are limited, data is biased, and the time range between training and inference are different. In all these cases, TILP works much better than the state-of-the-art methods.

Hyperbolic Deep Reinforcement Learning

Edoardo Cetin,Benjamin Paul Chamberlain,Michael M. Bronstein,Jonathan J Hunt

In deep reinforcement learning (RL), useful information about the state is inherently tied to its possible future successors. Consequently, encoding features that capture the hierarchical relationships between states into the model's latent representations is often conducive to recovering effective policies. In this work, we study a new class of deep RL algorithms that promote encoding such relationships by using hyperbolic space to model latent representations. However, we find that a naive application of existing methodology from the hyperbolic deep learning literature leads to fatal instabilities due to the non-stationarity and variance characterizing common gradient estimators in RL. Hence, we design a new

general method that directly addresses such optimization challenges and enables stable end-to-end learning with deep hyperbolic representations. We empirically validate our framework by applying it to popular on-policy and off-policy RL algorithms on the Procgen and Atari 100K benchmarks, attaining near universal performance and generalization benefits. Given its natural fit, we hope this work will inspire future RL research to consider hyperbolic representations as a standard tool.

Learning Controllable Adaptive Simulation for Multi-resolution Physics
Tailin Wu,Takashi Maruyama,Qingqing Zhao,Gordon Wetzstein,Jure Leskovec
Simulating the time evolution of physical systems is pivotal in many scientific and engineering problems. An open challenge in simulating such systems is their multi-resolution dynamics: a small fraction of the system is extremely dynamic, and requires very fine-grained resolution, while a majority of the system is changing slowly and can be modeled by coarser spatial scales. Typical learning-based surrogate models use a uniform spatial scale, which needs to resolve to the finest required scale and can waste a huge compute to achieve required accuracy. In this work, we introduce Learning controllable Adaptive simulation for Multi-resolution Physics (LAMP) as the first full deep learning-based surrogate model that jointly learns the evolution model and optimizes appropriate spatial resolutions that devote more compute to the highly dynamic regions. LAMP consists of a Graph Neural Network (GNN) for learning the forward evolution, and a GNN-based actor-critic for learning the policy of spatial refinement and coarsening. We introduce learning techniques that optimizes LAMP with weighted sum of error and computational cost as objective, allowing LAMP to adapt to varying relative importance of error vs. computation tradeoff at inference time. We evaluate our method in a 1D benchmark of nonlinear PDEs and a challenging 2D mesh-based simulation. We demonstrate that our LAMP outperforms state-of-the-art deep learning surrogate models, and can adaptively trade-off computation to improve long-term prediction error: it achieves an average of 33.7% error reduction for 1D nonlinear PDEs, and outperforms MeshGraphNets + classical Adaptive Mesh Refinement (AMR) in 2D mesh-based simulations. Project website with data and code can be found at: http://snap.stanford.edu/lamp.

Gated Neural ODEs: Trainability, Expressivity and Interpretability
Timothy Doyeon Kim,Tankut Can,Kamesh Krishnamurthy
Understanding how the dynamics in biological and artificial neural networks implement the computations required for a task is a salient open question in machine learning and neuroscience. In particular, computations requiring complex memory storage and retrieval pose significant challenge for these networks to implement or learn. Recently, a family of models described by neural ordinary differential equations (nODEs) has emerged as powerful dynamical neural network models capable of capturing complex dynamics. Here, we extend nODEs by endowing them with adaptive timescales using gating interactions. We refer to these as gated neural ODEs (gnODEs). Using a task that requires memory of continuous quantities, we demonstrate the inductive bias of the gnODEs to learn (approximate) continuous attractors. We further show how reduced-dimensional gnODEs retain their modeling power while greatly improving interpretability, even allowing explicit visualization of the structure of learned attractors. We introduce a novel measure of expressivity which probes the capacity of a neural network to generate complex trajectories. Using this measure, we explore how the phase-space dimension of the nODEs and the complexity of the function modeling the flow field contribute to expressivity. We see that a more complex function for modeling the flow field allows a lower-dimensional nODE to capture a given target dynamics. Finally, we demonstrate the benefit of gating in nODEs on several real-world tasks.

Value-Based Membership Inference Attack on Actor-Critic Reinforcement Learning
Yunhao Yang,ufuk topcu
In actor-critic reinforcement learning (RL), the so-called actor and critic, respectively, compute candidate policies and a value function that evaluates the ca

ndidate policies. Such RL algorithms may be vulnerable to membership inference attacks (MIAs), a privacy attack that infers the data membership, i.e., whether a specific data record belongs to the training dataset. We investigate the vulnerability of value function in actor-critic to MIAs. We develop \textit{CriticAttack}, a new MIA that targets black-box RL agents by examining the correlation between the expected reward and the value function. We empirically show that \textit{CriticAttack} can correctly infer approximately 90\% of the training data membership, i.e., it achieves 90\% attack accuracy. Such accuracy is far beyond the 50\% random guessing accuracy, indicating a severe privacy vulnerability of the value function. To defend against \textit{CriticAttack}, we design a method called \textit{CriticDefense} that inserts uniform noise to the value function. \textit{CriticDefense} can reduce the attack accuracy to 60\% without significantly affecting the agent’s performance.

Open-Vocabulary Object Detection upon Frozen Vision and Language Models
Weicheng Kuo,Yin Cui,Xiuye Gu,AJ Piergiovanni,Anelia Angelova

We present F-VLM, a simple open-vocabulary object detection method built uponFrozenVision andLanguageModels. F-VLM simplifies the current multi-stage training pipeline by eliminating the need for knowledge distillation or detection-tailored pretraining. Surprisingly, we observe that a frozen VLM: 1) retains the locality-sensitive features necessary for detection, and 2) is a strong region classifier. We finetune only the detector head and combine the detector and VLM outputs for each region at inference time. F-VLM shows compelling scaling behavior and achieves +6.5 mask AP improvement over the previous state of theart on novel categories of LVIS open-vocabulary detection benchmark. In addition, we demonstrate very competitive results on COCO open-vocabulary detection benchmark and cross-dataset transfer detection, in addition to significant training speed-up and compute savings. Code will be released.

Learned Neural Network Representations are Spread Diffusely with Redundancy
Vedant Nanda,Till Speicher,John P Dickerson,Soheil Feizi,Krishna Gummadi,Adrian Weller

Representations learned by pre-training a neural network on a large dataset are increasingly used successfully to perform a variety of downstream tasks. In this work, we take a closer look at how features are encoded in such pre-trained representations. We find that learned representations in a given layer exhibit a degree of diffuse redundancy, ie, any randomly chosen subset of neurons in the layer that is larger than a threshold size shares a large degree of similarity with the full layer and is able to perform similarly as the whole layer on a variety of downstream tasks. For example, a linear probe trained on 20% of randomly picked neurons from a ResNet50 pre-trained on ImageNet1k achieves an accuracy within 5% of a linear probe trained on the full layer of neurons for downstream CIFAR10 classification. We conduct experiments on different neural architectures (including CNNs and Transformers) pre-trained on both ImageNet1k and ImageNet21k and evaluate a variety of downstream tasks taken from the VTAB benchmark. We find that the loss & dataset used during pre-training largely govern the degree of diffuse redundancy and the "critical mass" of neurons needed often depends on the downstream task, suggesting that there is a task-inherent sparsity-performance Pareto frontier. Our findings shed light on the nature of representations learned by pre-trained deep neural networks and suggest that entire layers might not be necessary to perform many downstream tasks. We investigate the potential for exploiting this redundancy to achieve efficient generalization for downstream tasks and also draw caution to certain possible unintended consequences.

Neural DAEs: Constrained neural networks
Tue Boesen,Eldad Haber,Uri M. Ascher

In this article we investigate the effect of explicitly adding auxiliary trajectory information to neural networks for dynamical systems. We draw inspiration from the field of differential-algebraic equations and differential equations on m anifolds and implement similar methods in residual neural networks. We discuss constraints through stabilization as well as projection methods, and show when to use which method based on experiments involving simulations of multi-body pendulums and molecular dynamics scenarios. Several of our methods are easy to implement in existing code and have limited impact on performance while giving significant boosts in terms of inference.

Revisiting the Assumption of Latent Separability for Backdoor Defenses
Xiangyu Qi,Tinghao Xie,Yiming Li,Saeed Mahloujifar,Prateek Mittal

Recent studies revealed that deep learning is susceptible to backdoor poisoning attacks. An adversary can embed a hidden backdoor into a model to manipulate its predictions by only modifying a few training data, without controlling the training process. Currently, a tangible signature has been widely observed across a diverse set of backdoor poisoning attacks --- models trained on a poisoned dataset tend to learn separable latent representations for poison and clean samples. This latent separation is so pervasive that a family of backdoor defenses directly take it as a default assumption (dubbed latent separability assumption), based on which to identify poison samples via cluster analysis in the latent space. An intriguing question consequently follows: is the latent separation unavoidable for backdoor poisoning attacks? This question is central to understanding whether the assumption of latent separability provides a reliable foundation for defending against backdoor poisoning attacks. In this paper, we design adaptive backdoor poisoning attacks to present counter-examples against this assumption. Our methods include two key components: (1) a set of trigger-planted samples correctly labeled to their semantic classes (other than the target class) that can regularize backdoor learning; (2) asymmetric trigger planting strategies that help to boost attack success rate (ASR) as well as to diversify latent representations of poison samples. Extensive experiments on benchmark datasets verify the effectiveness of our adaptive attacks in bypassing existing latent separation based backdoor defenses. Moreover, our attacks still maintain a high attack success rate with negligible clean accuracy drop. Our studies call for defense designers to take caution when leveraging latent separation as an assumption in their defenses. Our codes are available at https://github.com/Unispac/Circumventing-Backdoor-Defenses.

Restricted Strong Convexity of Deep Learning Models with Smooth Activations
Arindam Banerjee,Pedro Cisneros,Libin Zhu,Misha Belkin

We consider the problem of optimization of deep learning models with smooth activation functions. While there exist influential results on the problem from the ``near initialization'' perspective, we shed considerable new light on the problem. In particular, we make two key technical contributions for such models with L layers, m width, and σ_0^2 initialization variance. First, for suitable σ_0^2, we establish a $O(\frac{\text{poly}(L)}{\sqrt{m}})$ upper bound on the spectral norm of the Hessian of such models, considerably sharpening prior results. Second, we introduce a new analysis of optimization based on Restricted Strong Convexity (RSC) which holds as long as the squared norm of the average gradient of predictors is $\Omega(\frac{\text{poly}(L)}{\sqrt{m}})$ for the square loss. We also present results for more general losses. The RSC based analysis does not need the ``near initialization" perspective and guarantees geometric convergence for gradient descent (GD). To the best of our knowledge, ours is the first result on establishing geometric convergence of GD based on RSC for deep learning models, thus becoming an alternative sufficient condition for convergence that does not depend on the widely-used Neural Tangent Kernel (NTK). We share preliminary experimental results supporting our theoretical advances.

Koopman Neural Operator Forecaster for Time-series with Temporal Distributional Shifts
Rui Wang,Yihe Dong,Sercan O Arik,Rose Yu

Temporal distributional shifts, with underlying dynamics changing over time, frequently occur in real-world time series and pose a fundamental challenge for dee p neural networks (DNNs). In this paper, we propose a novel deep sequence model based on the Koopman theory for time series forecasting: Koopman Neural Forecaster (KNF) that leverages DNNs to learn the linear Koopman space and the coefficients of chosen measurement functions. KNF imposes appropriate inductive biases for improved robustness against distributional shifts, employing both a global operator to learn shared characteristics and a local operator to capture changing dynamics, as well as a specially-designed feedback loop to continuously update the learnt operators over time for rapidly varying behaviors. We demonstrate that KNF achieves superior performance compared to the alternatives, on multiple time series datasets that are shown to suffer from distribution shifts.

Uncertainty-Driven Exploration for Generalization in Reinforcement Learning

Yiding Jiang,J Zico Kolter,Roberta Raileanu

Value-based methods tend to outperform policy optimization methods when trained and tested in single environments; however, they significantly underperform when trained on multiple environments with similar characteristics and tested on new ones from the same distribution. We investigate the potential reasons behind the poor generalization performance of value-based methods and discover that exploration plays a crucial role in these settings. Exploration is helpful not only for finding optimal solutions to the training environments, but also for acquiring knowledge that helps generalization to other unseen environments. We show how to make value-based methods competitive with policy optimization methods in these settings by using uncertainty-driven exploration and distribtutional RL. Our algorithm is the first value-based method to achieve state-of-the-art on both Procgen and Crafter, two challenging benchmarks for generalization in RL.

On Convergence of Federated Averaging Langevin Dynamics

Wei Deng,Qian Zhang,Yian Ma,Zhao Song,Guang Lin

We propose a federated averaging Langevin algorithm (FA-LD) for uncertainty quantification and mean predictions with distributed clients. In particular, we generalize beyond normal posterior distributions and consider a general class of models. We develop theoretical guarantees for FA-LD for strongly log-concave distributions with non-i.i.d data and study how the injected noise and the stochastic-gradient noise, the heterogeneity of data, and the varying learning rates affect the convergence. Such an analysis sheds light on the optimal choice of local updates to minimize communication cost. Important to our approach is that the communication efficiency does not deteriorate with the injected noise in the Langevin algorithms. In addition, we examine in our FA-LD algorithm both independent and correlated noise used over different clients. We observe there is a trade-off between the pairs among communication, accuracy, and data privacy. As local devices may become inactive in federated networks, we also show convergence results based on different averaging schemes where only partial device updates are available. In such a case, we discover an additional bias that does not decay to zero.

Posthoc Privacy guarantees for neural network queries

Abhishek Singh,Praneeth Vepakomma,Vivek Sharma,Ramesh Raskar

Cloud based machine learning inference is an emerging paradigm where users share their data with a service provider. Due to increased concerns over data privacy, recent works have proposed using Adversarial Representation Learning (ARL) to learn a privacy-preserving encoding of sensitive user data before it is shared with an untrusted service provider. Traditionally, the privacy of these encodings is evaluated empirically as they lack formal guarantees. In this work, we develop a new framework that provides formal privacy guarantees for an arbitrarily trained neural network by linking its local Lipschitz constant with its local sensitivity. To utilize local sensitivity for guaranteeing privacy, we extend the Propose-Test-Release(PTR) framework to make it tractable for neural network based queries. We verify the efficacy of our framework experimentally on real-world datasets and elucidate the role of ARL in improving the privacy-utility tradeoff.

MetaGL: Evaluation-Free Selection of Graph Learning Models via Meta-Learning
Namyong Park,Ryan A. Rossi,Nesreen Ahmed,Christos Faloutsos

Given a graph learning task, such as link prediction, on a new graph, how can we select the best method as well as its hyperparameters (collectively called a model) without having to train or evaluate any model on the new graph? Model selection for graph learning has been largely ad hoc. A typical approach has been to apply popular methods to new datasets, but this is often suboptimal. On the other hand, systematically comparing models on the new graph quickly becomes too costly, or even impractical. In this work, we develop the first meta-learning approach for evaluation-free graph learning model selection, called MetaGL, which utilizes the prior performances of existing methods on various benchmark graph datasets to automatically select an effective model for the new graph, without any model training or evaluations. To quantify similarities across a wide variety of graphs, we introduce specialized meta-graph features that capture the structural characteristics of a graph. Then we design G-M network, which represents the relations among graphs and models, and develop a graph-based meta-learner operating on this G-M network, which estimates the relevance of each model to different graphs. Extensive experiments show that using MetaGL to select a model for the new graph greatly outperforms several existing meta-learning techniques tailed for graph learning model selection (up to 47% better), while being extremely fast at test time (~1 sec).

FOCUS: Fairness via Agent-Awareness for Federated Learning on Heterogeneous Data
Wenda Chu,Chulin Xie,Boxin Wang,Linyi Li,Lang Yin,Han Zhao,Bo Li

Federated learning (FL) provides an effective collaborative training paradigm, allowing local agents to train a global model jointly without sharing their local data to protect privacy.

On the other hand, due to the heterogeneous nature of local agents, it is challenging to optimize or even define the fairness for agents, which may discourage valuable participation. For instance, the trained global model may sacrifice the performance of a minority user with high-quality data based on loss optimization over all users.

Existing work usually considers accuracy equity as fairness for different users in FL, which is limited especially under the heterogeneous setting, since it is intuitively "unfair" that agents with low-quality data would achieve similar accuracy.

In this work, we aim to address such limitations and propose a formal fairness definition in FL, fairness via agent-awareness (FAA), which takes the heterogeneous data contributions of local agents into account. In addition, we propose a fair FL training algorithm based on agent clustering (FOCUS) to achieve FAA. Theoretically, we prove the convergence and optimality of FOCUS under mild conditions for linear and general convex loss functions with bounded smoothness. We also prove that FOCUS always achieves higher fairness measured by FAA compared with standard FedAvg protocol under both linear and general convex loss functions. Empirically, we evaluate FOCUS on four datasets, including synthetic data, images, and texts under different settings, and we show that FOCUS achieves significantly higher fairness based on FAA while maintaining similar or even higher prediction accuracy compared with FedAvg and other existing fair FL algorithms.

Co-Evolution As More Than a Scalable Alternative for Multi-Agent Reinforcement Learning
Patrick Grzywok

In recent years, gradient based multi-agent reinforcement learning is growing in success. One contributing factor is the use of shared parameters for learning policy networks. While this approach scales well with the number of agents during execution it lacks this ambiguity for training as the number of produced samples grows linearly with the number of agents. For a very large number of agents, this could lead to an inefficient use of the circumstantial amount of produced samples. Moreover in single-agent reinforcement learning policy search with evolut

ionary algorithms showed viable success when sampling can be parallelized on a larger scale. The here proposed method does not only consider sampling in concurrent environments but further investigates sampling diverse parameters from the population in co-evolution in joint environments during training. This co-evolutionary policy search has shown to be capable of training a large number of agents. Beyond that, it has been shown to produce competitive results in smaller environments in comparison to gradient descent based methods. This surprising result make evolutionary algorithms a promising candidate for further research in the context of multi-agent reinforcement learning.

Adaptive Parametric Prototype Learning for Cross-Domain Few-Shot Classification
Marzi Heidari,Abdullah Alchihabi,Qing En,Yuhong Guo
Cross-domain few-shot classification induces a much more challenging problem than its in-domain counterpart due to the existence of domain shifts between the training and test tasks.
In this paper, we develop a novel Adaptive Parametric Prototype Learning (APPL) method under the meta-learning convention for cross-domain few-shot classification.
Different from existing prototypical few-shot methods that use the averages of support instances to calculate the class prototypes, we propose to learn class prototypes from the concatenated features of the support set in a parametric fashion and meta-learn the model by enforcing prototype-based regularization on the query set.
In addition, we fine-tune the model in the target domain in a transductive manner using a weighted-moving-average self-training approach on the query instances.

We conduct experiments on multiple cross-domain few-shot benchmark datasets.
The empirical results demonstrate that APPL yields superior performance than many state-of-the-art methods.

Minimum Description Length Control
Ted Moskovitz,Ta-Chu Kao,Maneesh Sahani,Matthew Botvinick
We propose a novel framework for multitask reinforcement learning based on the minimum description length (MDL) principle. In this approach, which we term MDL-control (MDL-C), the agent learns the common structure among the tasks with which it is faced and then distills it into a simpler representation which facilitates faster convergence and generalization to new tasks. In doing so, MDL-C naturally balances adaptation to each task with epistemic uncertainty about the task distribution. We motivate MDL-C via formal connections between the MDL principle and Bayesian inference, derive theoretical performance guarantees, and demonstrate MDL-C's empirical effectiveness on both discrete and high-dimensional continuous control tasks.

RainProof: An Umbrella to Shield Text Generator from Out-Of-Distribution Data
Maxime DARRIN,Pablo Piantanida,Pierre Colombo
As more and more conversational and translation systems are deployed in production, it is essential to implement and develop effective control mechanisms to ensure their proper functioning and security. An essential component to ensure the safe behavior of the system is out-of-distribution (OOD) detection, which aims to detect whether an input sample is statistically far from the training distribution. While OOD detection is a widely covered topic in classification tasks, it has received much less attention in text generation. This paper addresses the problem of OOD detection for machine translation and dialog generation from an operational perspective. Our contribution includes (i) RAINPROOF a Relative informAItioN Projection Out OF distribution detection framework and (ii) a more operational evaluation setting for OOD detection. Surprisingly, we find that OOD detection is not necessarily aligned with task-specific measures. The OOD detector may filter out samples that are well processed by the model and keep samples that are not, leading to weaker performance. Our results show that RAINPROOF breaks this curse and achieve good results in OOD detection while increasing system perfo

rmance.

Variance Double-Down: The Small Batch Size Anomaly in Multistep Deep Reinforcement Learning

Johan Samir Obando Ceron,Marc G Bellemare,Pablo Samuel Castro

State of the art results in reinforcement learning suggest that multi-step learning is necessary. However, the increased variance that comes with it makes it difficult to increase the update horizon beyond relatively small numbers. In this paper, we report the counterintuitive finding that decreasing the batch size substantially improves performance across a large swath of deep RL agents. It is well-known that gradient variance decreases with increasing batch sizes, so obtaining improved performance by increasing variance on two fronts is a rather surprising finding. We conduct a broad set of experiments to better understand this variance double-down phenomenon.

PerFedMask: Personalized Federated Learning with Optimized Masking Vectors

Mehdi Setayesh,Xiaoxiao Li,Vincent W.S. Wong

Recently, various personalized federated learning (FL) algorithms have been proposed to tackle data heterogeneity. To mitigate device heterogeneity, a common approach is to use masking. In this paper, we first show that using random masking can lead to a bias in the obtained solution of the learning model. To this end, we propose a personalized FL algorithm with optimized masking vectors called PerFedMask. In particular, PerFedMask facilitates each device to obtain its optimized masking vector based on its computational capability before training. Fine-tuning is performed after training. PerFedMask is a generalization of a recently proposed personalized FL algorithm, FedBABU (Oh et al., 2022). PerFedMask can be combined with other FL algorithms including HeteroFL (Diao et al., 2021) and Split-Mix FL (Hong et al., 2022). Results based on CIFAR-10 and CIFAR-100 datasets show that the proposed PerFedMask algorithm provides a higher test accuracy after fine-tuning and lower average number of trainable parameters when compared with six existing state-of-the-art FL algorithms in the literature. The codes are available at https://github.com/MehdiSet/PerFedMask.

Variational Latent Branching Model for Off-Policy Evaluation

Qitong Gao,Ge Gao,Min Chi,Miroslav Pajic

Model-based methods have recently shown great potential for off-policy evaluation (OPE); offline trajectories induced by behavioral policies are fitted to transitions of Markov decision processes (MDPs), which are used to rollout simulated trajectories and estimate the performance of policies. Model-based OPE methods face two key challenges. First, as offline trajectories are usually fixed, they tend to cover limited state and action space. Second, the performance of model-based methods can be sensitive to the initialization of their parameters. In this work, we propose the variational latent branching model (VLBM) to learn the transition function of MDPs by formulating the environmental dynamics as a compact latent space, from which the next states and rewards are then sampled. Specifically, VLBM leverages and extends the variational inference framework with the recurrent state alignment (RSA), which is designed to capture as much information underlying the limited training data, by smoothing out the information flow between the variational (encoding) and generative (decoding) part of VLBM. Moreover, we also introduce the branching architecture to improve the model’s robustness against randomly initialized model weights. The effectiveness of the VLBM is evaluated on the deep OPE (DOPE) benchmark, from which the training trajectories are designed to result in varied coverage of the state-action space. We show that the VLBM outperforms existing state-of-the-art OPE methods in general.

Discretization Invariant Learning on Neural Fields

Clinton Wang,Polina Golland

While neural fields have emerged as powerful representations of continuous data, there is a need for neural networks that can perform inference on such data without being sensitive to how the field is sampled, a property called discretizati

on invariance. We develop DI-Net, a framework for learning discretization invariant operators on neural fields of any type. Whereas current theoretical analyses of discretization invariant networks are restricted to the limit of infinite samples, our analysis does not require infinite samples and establishes upper bounds on the variation in DI-Net outputs given different finite discretizations. Our framework leads to a family of neural networks driven by numerical integration via quasi-Monte Carlo sampling with discretizations of low discrepancy. DI-Nets enjoy several desirable theoretical properties such as universal approximation of a large class of maps between L^2 functions with gradients that are also discretization invariant. DI-Nets can also be seen as generalizations of many existing network families as they bridge discrete and continuous network classes, such as convolutional neural networks (CNNs) and neural operators respectively. Experimentally, DI-Nets derived from CNNs are demonstrated to classify and segment visual data represented by neural fields under various discretizations, and sometimes even generalize to new types of discretizations at test time.

Tuning Frequency Bias in Neural Network Training with Nonuniform Data
Annan Yu,Yunan Yang,Alex Townsend
Small generalization errors of over-parameterized neural networks (NNs) can be partially explained by the frequency biasing phenomenon, where gradient-based algorithms minimize the low-frequency misfit before reducing the high-frequency residuals. Using the Neural Tangent Kernel (NTK), one can provide a theoretically rigorous analysis for training where data are drawn from constant or piecewise-constant probability densities. Since most training data sets are not drawn from such distributions, we use the NTK model and a data-dependent quadrature rule to theoretically quantify the frequency biasing of NN training given fully nonuniform data. By replacing the loss function with a carefully selected Sobolev norm, we can further amplify, dampen, counterbalance, or reverse the intrinsic frequency biasing in NN training.

Global Counterfactual Explanations Are Reliable Or Efficient, But Not Both
Dan Ley,Saumitra Mishra,Daniele Magazzeni
Counterfactual explanations have been widely studied in explainability, with a range of application dependent methods emerging in fairness, recourse and model understanding. The major shortcoming associated with these methods, however, is their inability to provide explanations beyond the local or instance-level. While many works touch upon the notion of a global explanation, typically suggesting to aggregate masses of local explanations in the hope of ascertaining global properties, few provide frameworks that are both reliable and computationally tractable. Meanwhile, practitioners are requesting more efficient and interactive explainability tools. We take this opportunity to investigate existing methods, improving the efficiency of Actionable Recourse Summaries (AReS), one of the only known global recourse frameworks, and proposing Global & Efficient Counterfactual Explanations (GLOBE-CE), a novel and flexible framework that tackles the scalability issues associated with current state-of-the-art, particularly on higher dimensional datasets and in the presence of continuous features. Furthermore, we provide a unique mathematical analysis of categorical feature translations, utilising it in our method. Experimental evaluation with real world datasets and user studies verify the speed, reliability and interpretability improvements of our framework.

Learning Multimodal Data Augmentation in Feature Space
Zichang Liu,Zhiqiang Tang,Xingjian Shi,Aston Zhang,Mu Li,Anshumali Shrivastava,Andrew Gordon Wilson
The ability to jointly learn from multiple modalities, such as text, audio, and visual data, is a defining feature of intelligent systems. While there have been promising advances in designing neural networks to harness multimodal data, the enormous success of data augmentation currently remains limited to single-modality tasks like image classification. Indeed, it is particularly difficult to augment each modality while preserving the overall semantic structure of the data;

for example, a caption may no longer be a good description of an image after standard augmentations have been applied, such as translation. Moreover, it is challenging to specify reasonable transformations that are not tailored to a particular modality. In this paper, we introduce LeMDA, Learning Multimodal Data Augmentation, an easy-to-use method that automatically learns to jointly augment multimodal data in feature space, with no constraints on the identities of the modalities or the relationship between modalities. We show that LeMDA can (1) profoundly improve the performance of multimodal deep learning architectures, (2) apply to combinations of modalities that have not been previously considered, and (3) achieve state-of-the-art results on a wide range of applications comprised of image, text, and tabular data.

Where to Begin? On the Impact of Pre-Training and Initialization in Federated Learning

John Nguyen,Jianyu Wang,Kshitiz Malik,Maziar Sanjabi,Michael Rabbat

An oft-cited challenge of federated learning is the presence of heterogeneity. \emph{Data heterogeneity} refers to the fact that data from different clients may follow very different distributions. \emph{System heterogeneity} refers to client devices having different system capabilities. A considerable number of federated optimization methods address this challenge. In the literature, empirical evaluations usually start federated training from random initialization. However, in many practical applications of federated learning, the server has access to proxy data for the training task that can be used to pre-train a model before starting federated training. Using four standard federated learning benchmark datasets, we empirically study the impact of starting from a pre-trained model in federated learning. Unsurprisingly, starting from a pre-trained model reduces the training time required to reach a target error rate and enables the training of more accurate models (up to 40\%) than is possible when starting from random initialization. Surprisingly, we also find that starting federated learning from a pre-trained initialization reduces the effect of both data and system heterogeneity. We recommend future work proposing and evaluating federated optimization methods to evaluate the performance when starting from random and pre-trained initializations. This study raises several questions for further work on understanding the role of heterogeneity in federated optimization.

BigVGAN: A Universal Neural Vocoder with Large-Scale Training

Sang-gil Lee,Wei Ping,Boris Ginsburg,Bryan Catanzaro,Sungroh Yoon

Despite recent progress in generative adversarial network (GAN)-based vocoders, where the model generates raw waveform conditioned on acoustic features, it is challenging to synthesize high-fidelity audio for numerous speakers across various recording environments. In this work, we present BigVGAN, a universal vocoder that generalizes well for various out-of-distribution scenarios without fine-tuning. We introduce periodic activation function and anti-aliased representation into the GAN generator, which brings the desired inductive bias for audio synthesis and significantly improves audio quality. In addition, we train our GAN vocoder at the largest scale up to 112M parameters, which is unprecedented in the literature. We identify and address the failure modes in large-scale GAN training for audio, while maintaining high-fidelity output without over-regularization. Our BigVGAN, trained only on clean speech (LibriTTS), achieves the state-of-the-art performance for various zero-shot (out-of-distribution) conditions, including unseen speakers, languages, recording environments, singing voices, music, and instrumental audio. We release our code and model at: https://github.com/NVIDIA/BigVGAN

PaLI: A Jointly-Scaled Multilingual Language-Image Model

Xi Chen,Xiao Wang,Soravit Changpinyo,AJ Piergiovanni,Piotr Padlewski,Daniel Salz,Sebastian Goodman,Adam Grycner,Basil Mustafa,Lucas Beyer,Alexander Kolesnikov,Joan Puigcerver,Nan Ding,Keran Rong,Hassan Akbari,Gaurav Mishra,Linting Xue,Ashish V Thapliyal,James Bradbury,Weicheng Kuo,Mojtaba Seyedhosseini,Chao Jia,Burcu Karagol Ayan,Carlos Riquelme Ruiz,Andreas Peter Steiner,Anelia Angelova,Xiaohua Z hai,Neil Houlsby,Radu Soricut

Effective scaling and a flexible task interface enable large language models to excel at many tasks. We present PaLI, a model that extends this approach to the joint modeling of language and vision. PaLI generates text based on visual and textual inputs, and with this interface performs many vision, language, and multimodal tasks, in many languages. To train PaLI, we make use of large pretrained encoder-decoder language models and Vision Transformers (ViTs). This allows us to capitalize on their existing capabilities and leverage the substantial cost of training them. We find that joint scaling of the vision and language components is important. Since existing Transformers for language are much larger than their vision counterparts, we train a large, 4-billion parameter ViT (ViT-e) to quantify the benefits from even larger-capacity vision models. To train PaLI, we create a large multilingual mix of pretraining tasks, based on a new image-text training set containing 10B images and texts in over 100 languages. PaLI achieves state-of-the-art in multiple vision and language tasks (such as captioning, visual question-answering, scene-text understanding), while retaining a simple, modular, and scalable design.

Achieving Sub-linear Regret in Infinite Horizon Average Reward Constrained MDP with Linear Function Approximation

Arnob Ghosh,Xingyu Zhou,Ness Shroff

We study the infinite horizon average reward constrained Markov Decision Process (CMDP). In contrast to existing works on model-based, finite state space, we consider the model-free linear CMDP setup. We first propose a computationally inefficient algorithm and show that $\tilde{\mathcal{O}}(\sqrt{d^3T})$ regret and constraint violation can be achieved, in which T is the number of interactions, and d is the dimension of the feature mapping. We also propose an efficient variant based on the primal-dual adaptation of the LSVI-UCB algorithm and show that $\tilde{\mathcal{O}}((dT)^{3/4})$ regret and constraint violation can be achieved.

This improves the known regret bound of $\tilde{\mathcal{O}}(T^{5/6})$ for the finite state-space model-free constrained RL which was obtained under a stronger assumption compared to ours. We also develop an efficient policy-based algorithm via novel adaptation of the MDP-EXP2 algorithm to our primal-dual set up with $\tilde{\mathcal{O}}(\sqrt{T})$ regret and even zero constraint violation bound under a stronger set of assumptions.

Causal Imitation Learning via Inverse Reinforcement Learning

Kangrui Ruan,Junzhe Zhang,Xuan Di,Elias Bareinboim

One of the most common ways children learn when unfamiliar with the environment is by mimicking adults. Imitation learning concerns an imitator learning to behave in an unknown environment from an expert's demonstration; reward signals remain latent to the imitator. This paper studies imitation learning through causal lenses and extends the analysis and tools developed for behavior cloning (Zhang, Kumor, Bareinboim, 2020) to inverse reinforcement learning. First, we propose novel graphical conditions that allow the imitator to learn a policy performing as well as the expert's behavior policy, even when the imitator and the expert's state-action space disagree, and unobserved confounders (UCs) are present. When provided with parametric knowledge about the unknown reward function, such a policy may outperform the expert's. Also, our method is easily extensible and allows one to leverage existing IRL algorithms even when UCs are present, including the multiplicative-weights algorithm (MWAL) (Syed & Schapire, 2008) and the generative adversarial imitation learning (GAIL) (Ho & Ermon, 2016). Finally, we validate our framework by simulations using real-world and synthetic data.

****

Amos: An Adam-style Optimizer with Adaptive Weight Decay towards Model-Oriented Scale

Ran Tian,Ankur P Parikh

We present Amos, a stochastic gradient-based optimizer designed for training deep neural networks. It can be viewed as an Adam optimizer with theoretically supp

orted, adaptive learning-rate decay and weight decay. A key insight behind Amos is that it leverages model-specific information to determine the initial learning-rate and decaying schedules. When used for pre-training BERT variants and T5, Amos consistently converges faster than the state-of-the-art settings of AdamW, achieving better validation loss within <=70% training steps and time, while requiring <=51% memory for slot variables.
****

The Surprising Computational Power of Nondeterministic Stack RNNs
Brian DuSell,David Chiang

Traditional recurrent neural networks (RNNs) have a fixed, finite number of memory cells. In theory (assuming bounded range and precision), this limits their formal language recognition power to regular languages, and in practice, RNNs have been shown to be unable to learn many context-free languages (CFLs). In order to expand the class of languages RNNs recognize, prior work has augmented RNNs with a nondeterministic stack data structure, putting them on par with pushdown automata and increasing their language recognition power to CFLs. Nondeterminism is needed for recognizing all CFLs (not just deterministic CFLs), but in this paper, we show that nondeterminism and the neural controller interact to produce two more unexpected abilities. First, the nondeterministic stack RNN can recognize not only CFLs, but also many non-context-free languages. Second, it can recognize languages with much larger alphabet sizes than one might expect given the size of its stack alphabet. Finally, to increase the information capacity in the stack and allow it to solve more complicated tasks with large alphabet sizes, we propose a new version of the nondeterministic stack that simulates stacks of vectors rather than discrete symbols. We demonstrate perplexity improvements with this new model on the Penn Treebank language modeling benchmark.

Critical Initialization of Wide and Deep Neural Networks through Partial Jacobians: General Theory and Applications
Darshil Doshi,Tianyu He,Andrey Gromov

Deep neural networks are notorious for defying theoretical treatment. However, when the number of parameters in each layer tends to infinity the network function is a Gaussian process (GP) and quantitatively predictive description is possible. Gaussian approximation allows to formulate criteria for selecting hyperparameters, such as variances of weights and biases, as well as the learning rate. These criteria rely on the notion of criticality defined for deep neural networks. In this work we describe a new practical way to diagnose criticality. We introduce *partial Jacobians* of a network, defined as derivatives of preactivations in layer l with respect to preactivations in layer $l_0\leq l$. We derive recurrence relations for the norms of partial Jacobians and utilize these relations to analyze criticality of deep fully connected neural networks with LayerNorm and/or residual connections. We derive and implement a simple and cheap numerical test that allows one to select optimal initialization for a broad class of deep neural networks. Using these tools we show quantitatively that proper stacking of the LayerNorm (applied to preactivations) and residual connections leads to an architecture that is critical for any initialization. Finally, we apply our methods to analyze the MLP-Mixer architecture and show that it is everywhere critical.
****

Agnostic Learning of General ReLU Activation Using Gradient Descent
Pranjal Awasthi,Alex Tang,Aravindan Vijayaraghavan

We provide a convergence analysis of gradient descent for the problem of agnostically learning a single ReLU function under Gaussian distributions. Unlike prior work that studies the setting of zero bias, we consider the more challenging scenario when the bias of the ReLU function is non-zero. Our main result establishes that starting from random initialization, in a polynomial number of iterations gradient descent outputs, with high probability, a ReLU function that achieves an error that is within a constant factor of the optimal i.e., it is guaranteed to achieve an error of $O(OPT)$, where OPT is the error of the best ReLU function. This is a significant improvement over existing guarantees for gradient de

scent, which only guarantee error of $O(\sqrt{d \cdot OPT})$ even in the zero-bias case (Frei et al., 2020). We also provide finite sample guarantees, and obtain similar guarantees for a broader class of marginal distributions beyond Gaussians.

Parametrizing Product Shape Manifolds by Composite Networks

Josua Sassen,Klaus Hildebrandt,Martin Rumpf,Benedikt Wirth

Parametrizations of data manifolds in shape spaces can be computed using the rich toolbox of Riemannian geometry. This, however, often comes with high computational costs, which raises the question if one can learn an efficient neural network approximation. We show that this is indeed possible for shape spaces with a special product structure, namely those smoothly approximable by a direct sum of low-dimensional manifolds. Our proposed architecture leverages this structure by separately learning approximations for the low-dimensional factors and a subsequent combination. After developing the approach as a general framework, we apply it to a shape space of triangular surfaces. Here, typical examples of data manifolds are given through datasets of articulated models and can be factorized, for example, by a Sparse Principal Geodesic Analysis (SPGA). We demonstrate the effectiveness of our proposed approach with experiments on synthetic data as well as manifolds extracted from data via SPGA.

CURE: A Pre-training Framework on Large-scale Patient Data for Treatment Effect Estimation

Ruoqi Liu,Pin-Yu Chen,Ping Zhang

Treatment effect estimation (TEE) refers to the estimation of causal effects, and it aims to compare the difference among treatment strategies on important outcomes. Current machine learning based methods are mainly trained on labeled data with specific treatments or outcomes of interest, which can be sub-optimal if the labeled data are limited. In this paper, we propose a novel transformer-based pre-training and fine-tuning framework called CURE for TEE from observational data. CURE is pre-trained on large-scale unlabeled patient data to learn representative contextual patient representations, and then fine-tuned on labeled patient data for TEE. We design a new sequence encoding for longitudinal (or structured) patient data and we incorporate structure and time into patient embeddings. Evaluated on 4 downstream TEE tasks, CURE outperforms the state-of-the-art methods in terms of an average of 3.8\% and 6.9\% absolute improvement in Area under the ROC Curve (AUC) and Area under the Precision-Recall Curve (AUPR), and 15.7\% absolute improvement in Influence function-based Precision of Estimating Heterogeneous Effects (IF-PEHE). We further demonstrate the data scalability of CURE and verify the results with corresponding randomized clinical trials. Our proposed method provides a new machine learning paradigm for TEE based on observational data.
****

A Probabilistic Approach to Self-Supervised Learning using Cyclical Stochastic Gradient MCMC

Masoumeh Javanbakhat,Christoph Lippert

In this paper we present a practical Bayesian formulation for self-supervised learning method with Cyclical Stochastic Gradient Hamiltonian Monte Carlo (cSGHMC). Within this framework, we place a prior over the parameters of a self-supervised learning model and use cSGHMC to approximate the high dimensional and multimodal posterior distribution over the embeddings. By exploring an expressive posterior over the embeddings, the Bayesian self-supervised learning produces interpretable and diverse representations. Marginalising over these representations results improvement in semi-supervised learning and out-of-distribution detection tasks. We provide experimental results on multiple classification tasks in semi-supervised learning including Cifar10 and Cifar100. Moreover we demonstrate the effectiveness of the proposed method in out-of distribution detection task using SVHN dataset.
****

Tabular Data to Image Generation: Benchmark Data, Approaches, and Evaluation

Alex Tang,Gromit Yeuk-Yin Chan,Ryan A. Rossi,Chang Xiao,Eunyee Koh

In this work, we study the problem of generating a set of images from an arbitrary tabular dataset. The set of generated images provides an intuitive visual summary of the tabular data that can be quickly and easily communicated and understood by the user.

More specifically, we formally introduce this new dataset to image generation task and discuss a few motivating applications including exploratory data analysis and understanding customer segments for creating better marketing campaigns.

We then curate a benchmark dataset for training such models, which we release publicly for others to use and develop new models for other important applications of interest.

Further, we describe a general and flexible framework that serves as a fundamental basis for studying and developing models for this new task of generating images from tabular data.

From the framework, we propose a few different approaches with varying levels of complexity and tradeoffs.

One such approach leverages both numerical and textual data as the input to our image generation pipeline.

The pipeline consists of an image decoder and a conditional auto-regressive sequence generation model which also includes a pre-trained tabular representation in the input layer.

We evaluate the performance of these approaches through several quantitative metrics (FID for image quality and LPIPS scores for image diversity).

Learning Hyper Label Model for Programmatic Weak Supervision

Renzhi Wu,Shen-En Chen,Jieyu Zhang,Xu Chu

To reduce the human annotation efforts, the programmatic weak supervision (PWS) paradigm abstracts weak supervision sources as labeling functions (LFs) and involves a label model to aggregate the output of multiple LFs to produce training labels. Most existing label models require a parameter learning step for each dataset. In this work, we present a hyper label model that (once learned) infers the ground-truth labels for each dataset in a single forward pass without dataset-specific parameter learning. The hyper label model approximates an optimal analytical (yet computationally intractable) solution of the ground-truth labels. We train the model on synthetic data generated in the way that ensures the model approximates the analytical optimal solution, and build the model upon Graph Neural Network (GNN) to ensure the model prediction being invariant (or equivariant) to the permutation of LFs (or data points). On 14 real-world datasets, our hyper label model outperforms the best existing methods in both accuracy (by 1.4 points on average) and efficiency (by six times on average). Our code is available at https://github.com/wurenzhi/hyper_label_model

SlenderGNN: Accurate, Robust, and Interpretable GNN, and the Reasons for its Success

Jaemin Yoo,Meng-Chieh Lee,Shubhranshu Shekhar,Christos Faloutsos

Can we design a GNN that is accurate and interpretable at the same time? Could it also be robust to handle the case of homophily, heterophily, or even noisy edges without network effects? We propose SlenderGNN that has all desirable properties: (a) accurate, (b) robust, and (c) interpretable. For the reasons of its success, we had to dig deeper: The result is our GNNLIN framework which highlights the fundamental differences among popular GNN models (e.g., feature combination, structural normalization, etc.) and thus reveals the reasons for the success of our SlenderGNN, as well as the reasons for occasional failures of other GNN variants. Thanks to our careful design, SlenderGNN passes all the 'sanity checks' we propose, and it achieves the highest overall accuracy on 9 real-world datasets of both homophily and heterophily graphs, when compared against 10 recent GNN models. Specifically, SlenderGNN exceeds the accuracy of linear GNNs and matches or exceeds the accuracy of nonlinear models with up to 64 times fewer parameters.

FedFA: Federated Feature Augmentation
Tianfei Zhou,Ender Konukoglu

Federated learning is a distributed paradigm that allows multiple parties to collaboratively train deep models without exchanging the raw data. However, the data distribution among clients is naturally non-i.i.d., which leads to severe degradation of the learnt model. The primary goal of this paper is to develop a robust federated learning algorithm to address feature shift in clients’ samples, which can be caused by various factors, e.g., acquisition differences in medical imaging. To reach this goal, we propose FedFA to tackle federated learning from a dis- tinct perspective of federated feature augmentation. FedFA is based on a major insight that each client’s data distribution can be characterized by statistics (i.e., mean and standard deviation) of latent features; and it is likely to manipulate these local statistics globally, i.e., based on information in the entire federation, to let clients have a better sense of the underlying distribution and therefore alleviate local data bias. Based on this insight, we propose to augment each local feature statistic probabilistically based on a normal distribution, whose mean is the original statistic and variance quantifies the augmentation scope. Key to our approach is the determination of a meaningful Gaussian variance, which is accomplished by taking into account not only biased data of each individual client, but also underlying feature statistics characterized by all participating clients. We offer both theoretical and empirical justifications to verify the effectiveness of FedFA. Our code is available at https://github.com/tfzhou/FedFA.

Show and Write: Entity-aware Article Generation with Image Information
Zhongping Zhang,Yiwen Gu,Bryan A. Plummer

Prior work for article generation has primarily focused on generating articles using a human-written prompt to provide topical context and metadata about the article. However, for many applications, such as generating news stories, these articles are also often paired with images and their captions or alt-text, which in turn are based on real-world events and may reference many different named entities that are difficult to be correctly recognized and predicted by language models. To address this shortcoming, this paper introduces an ENtity-aware article Generation method with Image iNformation, ENGIN, to incorporate an article's image information into language models. ENGIN represents articles that can be conditioned on metadata used by prior work and information such as captions and named entities extracted from images. Our key contribution is a novel Entity-aware mechanism to help our model recognize and predict the entity names in articles. We perform experiments on three public datasets, GoodNews, VisualNews, and WikiText. Quantitative results show that our approach improves generated article perplexity by 4-5 points over the base models. Qualitative results demonstrate the text generated by ENGIN is more consistent with embedded article images. We also perform article quality annotation experiments on the generated articles to validate that our model produces higher-quality articles. Finally, we investigate the effect ENGIN has on methods that automatically detect machine-generated articles.

Noise$^+$2Noise: Co-taught De-noising Autoencoders for Time-Series Data
Harry Rubin-Falcone,Joyce Lee,Jenna Wiens

We consider the task of learning to recover clean signals given only access to noisy data. Recent work in computer vision has addressed this problem in the context of images using denoising autoencoders (DAEs). However, to date DAEs for learning from noisy data have not been explored in the context of time-series data. DAEs for denoising images often rely on assumptions unlikely to hold in the context of time series, \textit{e.g.}, multiple noisy samples of the same example. Here, we adapt DAEs to cleaning time-series data with noisy samples only. To recover the clean target signal when only given access to noisy target data, we leverage a noise-free auxiliary time-series signal that is related to the target signal. In addition to leveraging the relationship between the target signal an d auxiliary signal, we iteratively filter and learn from clean samples using an approach based on co-teaching. Applied to the task of recovering carbohydrate values for blood glucose management, our approach reduces noise (MSE) in patient-reported carbohydrates from 72g^2 (95\% CI: 54,93) to 18g^2 (13,25), outperforming the best baseline (MSE = 33g^2 (27,43)). We demonstrate strong time-series denoising performance, extending the applicability of DAEs to a previously under-explored setting.

Adversarial Representation Learning for Canonical Correlation Analysis
Feng Bao,Steve J. Altschuler,Lani F. Wu

Canonical correlation analysis (CCA) provides a framework to map multimodality data into a maximally correlated latent space. The deep version of CCA has replaced linear maps with deep transformations to enable more flexible correlated data representations; however, this approach requires optimization over all samples for each iteration and poorly scales. Here, we present a deep, adversarial approach to CCA, adCCA, that can be efficiently solved by standard mini-batch training. We reformulate CCA under the constraint that the different modalities are embedded with identical latent distributions, derive a tractable deep CCA target, and use an adversarial framework to efficiently learn the canonical representations. A consequence of the new formation is that adCCA learns maximally correlated representations across multimodalities meanwhile preserves structure within individual modalities. Further, adCCA removes the need for feature transformation and normalization and can be directly applied to diverse modalities and feature encodings. Numerical studies show that the performance of adCCA is robust to data transformations, binary encodings, and corruptions. Together, adCCA provides a scalable approach to align data across modalities without compromising structure within each modality.

Neural Implicit Manifold Learning for Topology-Aware Generative Modelling
Brendan Leigh Ross,Gabriel Loaiza-Ganem,Anthony L. Caterini,Jesse C Cresswell

Natural data observed in $\mathbb{R}^n$ is often constrained to an m-dimensional manifold $\mathcal{M}$, where $m < n$. Current probabilistic models represent this manifold by mapping an m-dimensional latent variable through a neural network $f_\theta: \mathbb{R}^m \to \mathbb{R}^n$. Such procedures, which we call pushforward models, incur a straightforward limitation: manifolds cannot in general be represented with a single parameterization, meaning that attempts to do so will incur either computational instability or the inability to learn probability densities within the manifold. To remedy this problem, we propose to model $\mathcal{M}$ as a neural implicit manifold: the set of zeros of a neural network. To learn the data distribution within $\mathcal{M}$, we introduce constrained energy-based models, which use a constrained variant of Langevin dynamics to train and sample within a learned manifold. The resulting model can be manipulated with an arithmetic of manifolds, which allows practitioners to take unions and intersections of model manifolds. In experiments on synthetic and natural data, we show that constrained EBMs can learn manifold-supported distributions with complex topologies more accurately than pushforward models.

LT-SNN: Self-Adaptive Spiking Neural Network for Event-based Classification and Object Detection
Ahmed Hasssan,Jian Meng,Jae-sun Seo

Spiking neural networks (SNNs) have received increasing attention due to its high biological plausibility and energy efficiency. The binary spike-based information propagation enables efficient sparse computation with event-based computer vision applications. Prior works investigated direct SNN training algorithm to overcome the non-differentiability of spike generation. However, most of the existing works employ a fixed threshold value for the membrane potential throughout the entire training process, which limits the dynamics of SNNs towards further optimizing the performance. The adaptiveness in the membrane potential threshold and the mismatched mechanism between SNN and biological nervous system remain under-explored in prior works. In this work, we propose LT-SNN, a novel SNN trainin

g algorithm with self-adaptive learnable potential threshold to improve SNN performance. LT-SNN optimizes the layer-wise threshold value throughout SNN training, imitating the self-adaptiveness of the biological nervous system. To stabilize the SNN training even further, we propose separate surrogate gradient path (SGP), a simple-yet-effective method that enables the smooth learning process of SNN training. We validate the proposed LT-SNN algorithm on multiple event-based datasets, including both image classification and object detection tasks. Equipped with high adaptiveness that fully captures the dynamics of SNNs, LT-SNN achieves state-of-the-art performance with compact models. The proposed LT-SNN based classification network surpasses SoTA methods where we achieved 2.71% higher accuracy together with 10.48× smaller model size. Additionally, our LT-SNN-YOLOv2 object detection model demonstrates 0.11 mAP improvement compared to the SoTA SNN-based object detection.

Characterizing neural representation of cognitively-inspired deep RL agents during an evidence accumulation task

James Mochizuki-Freeman,Sahaj Singh Maini,Zoran Tiganj

Evidence accumulation is thought to be fundamental for decision-making in humans and other mammals. It has been extensively studied in neuroscience and cognitive science with the goal of explaining how sensory information is sequentially sampled until sufficient evidence has accumulated to favor one decision over others. Neuroscience studies suggest that the hippocampus encodes a low-dimensional ordered representation of evidence through sequential neural activity. Cognitive modelers have proposed a mechanism by which such sequential activity could emerge through the modulation of recurrent weights with a change in the amount of evidence. This gives rise to neurons tuned to a specific magnitude of evidence which resemble neurons recorded in the hippocampus. Here we integrated a cognitive science model inside a deep Reinforcement Learning (RL) agent and trained the agent to perform a simple evidence accumulation task inspired by the behavioral experiments on animals. We compared the agent's performance with the performance of agents equipped with GRUs and RNNs. We found that the agent based on a cognitive model was able to learn much faster and generalize better while having significantly fewer parameters. We also compared the emergent neural activity across agents and found that in some cases, GRU-based agents developed similar neural representations to agents based on a cognitive model. This study illustrates how integrating cognitive models and deep learning systems can lead to brain-like neural representations that can improve learning.

Epistemological Bias As a Means for the Automated Detection of Injustices in News Media

Kenya S. Andrews,Lamogha Chiazor

Injustice occurs when someone experiences unfair treatment or their rights are violated. In the context of news media, injustices represent a form of bias through which discriminatory narratives can arise and spread. The automated identification of injustice in text has received little attention, due in part to the fact that underlying stereotypes are rarely explicitly stated and that instances often occur unconsciously due to the pervasive nature of prejudice in society. Here, we leverage the combined use of a fine-tuned BERT-based bias detection model, two stereotype detection models, and a lexicon-based approach to show that epistemological biases (i.e., words, which through their use, presupposes, entails, asserts, hedges, or boosts text to erode or assert a person's capacity as a knower) can assist with the automatic detection of injustice in text.

Neural Constraint Inference: Inferring Energy Constraints in Interacting Systems

Armand Comas,Yilun Du,Sandesh Ghimire,Christian Fernandez Lopez,Mario Sznaier,Joshua B. Tenenbaum,Octavia Camps

Systems consisting of interacting agents are prevalent in the world, ranging from dynamical systems in physics to complex biological networks. To build systems which can interact robustly in the real world, it is thus important to be able to infer the precise interactions governing such systems. Existing approaches ty pically discover such interactions by explicitly modeling the feedforward dynamics of the trajectories. In this work, we propose Neural Constraint Inference (NCI) model as an alternative approach to discover such interactions: it discovers a set of relational constraints, represented as energy functions, which when optimized reconstruct the original trajectory. We illustrate how NCI can faithfully predict future trajectory dynamics, achieving more consistent long-rollouts than existing approaches. We show that the constraints discovered by NCI are disentangled and may be intermixed with constraints from other trajectories. Finally, we illustrate how those constraints enable the incorporation of external test-time constraints.

Self-supervised Continual Learning based on Batch-mode Novelty Detection

Jingbo Sun,Jiaxin Zhang,Frank Y Liu,Mahantesh M Halappanavar,Deliang Fan,Yu Cao

Continual learning (CL) plays a key role in dynamic systems in order to adapt to new tasks, while preserving previous knowledge. Most existing CL approaches focus on learning new knowledge in a supervised manner, while leaving the data gathering phase to the novelty detection (ND) algorithm. Such presumption limits the practical usage where new data needs to be quickly learned without being labeled. In this paper, we propose a unified approach of CL and ND, in which each new class of the out-of-distribution (ODD) data is first detected and then added to previous knowledge. Our method has three unique features: (1) a unified framework seamlessly tackling both ND and CL problems; (2) a self-supervised method for model adaptation, without the requirement of new data annotation; (3) batch-mode data feeding that maximizes the separation of new knowledge vs. previous learning, which in turn enables high accuracy in continual learning. By learning one class at each step, the new method achieves robust continual learning and consistently outperforms state-of-the-art CL methods in the single-head evaluation on MNIST, CIFAR-10, CIFAR-100 and TinyImageNet datasets.

Stable Optimization of Gaussian Likelihoods

Denis Megerle,Fabian Otto,Michael Volpp,Gerhard Neumann

Uncertainty-aware modeling has emerged as a key component in modern machine learning frameworks. The de-facto standard approach adopts heteroscedastic Gaussian distributions and minimizes the negative log-likelihood (NLL) under observed data. However, optimizing this objective turns out to be surprisingly intricate, and the current state-of-the-art reports several instabilities. This work breaks down the optimization problem, initially focusing on non-contextual settings where convergence can be analyzed analytically. We show that (1) in this learning scheme, the eigenvalues of the predictive covariance define stability in learning, and (2) coupling of gradients and predictions build up errors in both mean and covariance if either is poorly approximated. Building on these insights, we propose Trustable, a novel optimizer that overcomes instabilities methodically by combining systematic update restrictions in the form of trust regions with structured, tractable natural gradients. We demonstrate in several challenging experiments that Trustable outperforms current optimizers in regression with neural networks in terms of the NLL, MSE, and further performance metrics. Unlike other optimizers, Trustable yields an improved and more stable fit and can also be applied to multivariate outputs with full covariance matrices.

Representing Latent Dimensions Using Compressed Number Lines

Sahaj Singh Maini,James Mochizuki-Freeman,Chirag Shankar Indi,Brandon G Jacques,Per B Sederberg,Marc Howard,Zoran Tiganj

Humans use log-compressed number lines to represent different quantities, including elapsed time, traveled distance, numerosity, sound frequency, etc. Inspired by recent cognitive science and computational neuroscience work, we developed a neural network that learns to construct log-compressed number lines. The network computes a discrete approximation of a real-domain Laplace transform using an RNN with analytically derived weights giving rise to a log-compressed timeline of the past. The network learns to extract latent variables from the input and uses them for global modulation of the recurrent weights turning a timeline into a number line over relevant dimensions. The number line representation greatly simplifies learning on a set of problems that require learning associations in different spaces - problems that humans can typically solve easily. This approach illustrates how combining deep learning with cognitive models can result in systems that learn to represent latent variables in a brain-like manner and exhibit human-like behavior manifested through Weber-Fechner law.

Efficient Sequence Packing without Cross-contamination: Accelerating Large Language Models without Impacting Performance

Mario Michael Krell,Matej Kosec,Sergio P. Perez,Andrew William Fitzgibbon

Effective training of today's large language models (LLMs) depends on large batches and long sequences for throughput and accuracy. To handle variable-length sequences on hardware accelerators, it is common practice to introduce padding tokens, so that all sequences in a batch have the same length. We show in this paper that the variation in sequence lengths in common NLP datasets is such that up to 50% of all tokens can be padding. In less common, but not extreme, cases (e.g. GLUE-COLA with sequence length 128), the ratio is up to 89%. Existing methods to address the resulting inefficiency are complicated by the need to avoid "cross-contamination" in self-attention, by a reduction in accuracy when sequence ordering information is lost, or by customized kernel implementations only valid for specific accelerators.

This paper introduces a new formalization of sequence packing in the context of the well-studied bin packing problem, and presents new algorithms based on this formulation which, for example, confer a 2x speedup for phase 2 pretraining in BERT while preserving downstream performance. We show how existing models can be adapted to ensure mathematical equivalence between the original and packed models, meaning that packed models can be trained with existing pre-training and fine-tuning practices.

Cortically motivated recurrence enables task extrapolation

Vijay Veerabadran,Yuan Tang,Ritik Raina,Virginia R. de Sa

Feedforward deep neural networks have become the standard class of models in the field of computer vision. Yet, they possess a striking difference relative to their biological counterparts which predominantly perform “recurrent” computations. Why do biological neurons evolve to employ recurrence pervasively? In this paper, we show that a recurrent network is able to flexibly adapt its computational budget during inference and generalize within-task across difficulties. Simultaneously in this study, we contribute a recurrent module we call LocRNN that is designed based on a prior computational model of local recurrent intracortical connections in primates to support such dynamic task extrapolation. LocRNN learns highly accurate solutions to the challenging visual reasoning problems of Mazes and PathFinder that we use here. More importantly, it is able to flexibly use less or more recurrent iterations during inference to zero-shot generalize to less- and more difficult instantiations of each task without requiring extra training data, a potential functional advantage of recurrence that biological visual systems capitalize on. Feedforward networks on the other hand with their fixed computational graphs only partially exhibit this trend, potentially owing to image-level similarities across difficulties. We also posit an intriguing tradeoff between recurrent networks’ representational capacity and their stability in the recurrent state space. Our work encourages further study of the role of recurrence in deep learning models – especially from the context of out-of-distribution generalization & task extrapolation – and their properties of task performance and stability.

Is Adversarial Training Really a Silver Bullet for Mitigating Data Poisoning?

Rui Wen,Zhengyu Zhao,Zhuoran Liu,Michael Backes,Tianhao Wang,Yang Zhang

Indiscriminate data poisoning can decrease the clean test accuracy of a deep learning model by slightly perturbing its training samples.

There is a consensus that such poisons can hardly harm adversarially-trained (AT

) models when the adversarial training budget is no less than the poison budget, i.e., $\epsilon_\mathrm{adv}\geq\epsilon_\mathrm{poi}$. This consensus, however, is challenged in this paper based on our new attack strategy that induces \textit{entangled features} (EntF). The existence of entangled features makes the poisoned data become less useful for training a model, no matter if AT is applied or not. We demonstrate that for attacking a CIFAR-10 AT model under a reasonable setting with $\epsilon_\mathrm{adv}=\epsilon_\mathrm{poi}=8/255$, our EntF yields an accuracy drop of 13.31%, which is $7\times$ better than existing methods and equal to discarding 83% training data. We further show the generalizability of EntF to more challenging settings, e.g., higher AT budgets, partial poisoning, unseen model architectures, and stronger (ensemble or adaptive) defenses. We finally provide new insights into the distinct roles of non-robust vs. robust features in poisoning standard vs. AT models and demonstrate the possibility of using a hybrid attack to poison standard and AT models simultaneously. Our code is available at~\url{https://github.com/WenRuiUSTC/EntF}.

Offline Congestion Games: How Feedback Type Affects Data Coverage Requirement

Haozhe Jiang,Qiwen Cui,Zhihan Xiong,Maryam Fazel,Simon Shaolei Du

This paper investigates when one can efficiently recover an approximate Nash Equilibrium (NE) in offline congestion games. The existing dataset coverage assumption in offline general-sum games inevitably incurs a dependency on the number of actions, which can be exponentially large in congestion games. We consider three different types of feedback with decreasing revealed information. Starting from the facility-level (a.k.a., semi-bandit) feedback, we propose a novel one-unit deviation coverage condition and show a pessimism-type algorithm that can recover an approximate NE. For the agent-level (a.k.a., bandit) feedback setting, interestingly, we show the one-unit deviation coverage condition is not sufficient. On the other hand, we convert the game to multi-agent linear bandits and show that with a generalized data coverage assumption in offline linear bandits, we can efficiently recover the approximate NE. Lastly, we consider a novel type of feedback, the game-level feedback where only the total reward from all agents is revealed. Again, we show the coverage assumption for the agent-level feedback setting is insufficient in the game-level feedback setting, and with a stronger version of the data coverage assumption for linear bandits, we can recover an approximate NE. Together, our results constitute the first study of offline congestion games and imply formal separations between different types of feedback.

Learning with Stochastic Orders

Carles Domingo-Enrich,Yair Schiff,Youssef Mroueh

Learning high-dimensional distributions is often done with explicit likelihood modeling or implicit modeling via minimizing integral probability metrics (IPMs). In this paper, we expand this learning paradigm to stochastic orders, namely, the convex or Choquet order between probability measures. Towards this end, exploiting the relation between convex orders and optimal transport, we introduce the Choquet-Toland distance between probability measures, that can be used as a drop-in replacement for IPMs. We also introduce the Variational Dominance Criterion (VDC) to learn probability measures with dominance constraints, that encode the desired stochastic order between the learned measure and a known baseline. We analyze both quantities and show that they suffer from the curse of dimensionality and propose surrogates via input convex maxout networks (ICMNs), that enjoy parametric rates. We provide a min-max framework for learning with stochastic orders and validate it experimentally on synthetic and high-dimensional image generation, with promising results. Finally, our ICMNs class of convex functions and its derived Rademacher Complexity are of independent interest beyond their application in convex orders. Code to reproduce experimental results is available at https://github.com/yair-schiff/stochastic-orders-ICMN.

MEDFAIR: Benchmarking Fairness for Medical Imaging

Yongshuo Zong,Yongxin Yang,Timothy Hospedales

A multitude of work has shown that machine learning-based medical diagnosis syst ems can be biased against certain subgroups of people. This has motivated a growing number of bias mitigation algorithms that aim to address fairness issues in machine learning. However, it is difficult to compare their effectiveness in medical imaging for two reasons. First, there is little consensus on the criteria to assess fairness. Second, existing bias mitigation algorithms are developed under different settings, e.g., datasets, model selection strategies, backbones, and fairness metrics, making a direct comparison and evaluation based on existing results impossible. In this work, we introduce MEDFAIR, a framework to benchmark the fairness of machine learning models for medical imaging. MEDFAIR covers eleven algorithms from various categories, ten datasets from different imaging modalities, and three model selection criteria. Through extensive experiments, we find that the under-studied issue of model selection criterion can have a significant impact on fairness outcomes; while in contrast, state-of-the-art bias mitigation algorithms do not significantly improve fairness outcomes over empirical risk minimization (ERM) in both in-distribution and out-of-distribution settings. We evaluate fairness from various perspectives and make recommendations for different medical application scenarios that require different ethical principles. Our framework provides a reproducible and easy-to-use entry point for the development and evaluation of future bias mitigation algorithms in deep learning. Code is available at https://github.com/ys-zong/MEDFAIR.

Does Learning from Decentralized Non-IID Unlabeled Data Benefit from Self Supervision?

Lirui Wang,Kaiqing Zhang,Yunzhu Li,Yonglong Tian,Russ Tedrake

The success of machine learning relies heavily on massive amounts of data, which are usually generated and stored across a range of diverse and distributed data sources. Decentralized learning has thus been advocated and widely deployed to make efficient use of distributed datasets, with an extensive focus on supervised learning (SL) problems. Unfortunately, the majority of real-world data are unlabeled and can be highly heterogeneous across sources. In this work, we carefully study decentralized learning with unlabeled data through the lens of self-supervised learning (SSL), specifically contrastive visual representation learning. We study the effectiveness of a range of contrastive learning algorithms under a decentralized learning setting, on relatively large-scale datasets including ImageNet-100, MS-COCO, and a new real-world robotic warehouse dataset. Our experiments show that the decentralized SSL (Dec-SSL) approach is robust to the heterogeneity of decentralized datasets, and learns useful representation for object classification, detection, and segmentation tasks, even when combined with the simple and standard decentralized learning algorithm of Federated Averaging (FedAvg). This robustness makes it possible to significantly reduce communication and to reduce the participation ratio of data sources with only minimal drops in performance. Interestingly, using the same amount of data, the representation learned by Dec-SSL can not only perform on par with that learned by centralized SSL which requires communication and excessive data storage costs, but also sometimes outperform representations extracted from decentralized SL which requires extra knowledge about the data labels. Finally, we provide theoretical insights into understanding why data heterogeneity is less of a concern for Dec-SSL objectives, and introduce feature alignment and clustering techniques to develop a new Dec-SSL algorithm that further improves the performance, in the face of highly non-IID data. Our study presents positive evidence to embrace unlabeled data in decentralized learning, and we hope to provide new insights into whether and why decentralized SSL is effective and/or even advantageous.

****

Polarity is all you need to learn and transfer faster

Qingyang Wang,Michael Alan Powell,Ali Geisa,Eric W Bridgeford,Joshua T Vogelstein

Natural intelligences (NIs) thrive in a dynamic world – they learn quickly, sometimes with only a few samples. In contrast, Artificial intelligence (AI) has achieved supra (-human) level performance in certain AI settings, typically dependent on a prohibitive amount of training samples and computational power. What des ign principle difference between NI and AI could contribute to such a discrepancy? Here, we propose a research avenue based on a simple observation from NIs: post-development, neuronal connections in the brain rarely see polarity switch. Why? Our answer is: to learn and transfer more efficiently. We demonstrate with theory and simulations that if weight polarities are adequately set $\textit{a priori}$, then networks learn with less time and data. We extend such findings onto image classification tasks and demonstrate that polarity, not weight, is a more effective medium for knowledge transfer between networks. We also explicitly illustrate situations in which $\textit{a priori}$ setting the weight polarities is disadvantageous for networks. Our work illustrates the value of weight polarities from the perspective of statistical and computational efficiency for both NI and AI.

On the Geometry of Reinforcement Learning in Continuous State and Action Spaces

Saket Tiwari,Omer Gottesman,George Konidaris

Advances in reinforcement learning have led to its successful application in complex tasks with continuous state and action spaces. Despite these advances in practice, most theoretical work pertains to finite state and action spaces. We propose building a theoretical understanding of continuous state and action spaces by employing a geometric lens. Central to our work is the idea that the transition dynamics induce a low dimensional manifold of reachable states embedded in the high-dimensional nominal state space. We prove that, under certain conditions, the dimensionality of this manifold is at most the dimensionality of the action space plus one. This is the first result of its kind, linking the geometry of the state space to the dimensionality of the action space. We empirically corroborate this upper bound for four MuJoCo environments.We further demonstrate the applicability of our result by learning a policy in this low dimensional representation.   To do so we introduce an algorithm that learns a mapping to a low dimensional representation, as a narrow hidden layer of a deep neural network, in tandem with the policy using DDPG. Our experiments show that a policy learnt this way perform on par or better for four MuJoCo control suite tasks.

Malign Overfitting: Interpolation and Invariance are Fundamentally at Odds

Yoav Wald,Gal Yona,Uri Shalit,Yair Carmon

Learned classifiers should often possess certain invariance properties meant to encourage fairness, robustness, or out-of-distribution generalization.
However, multiple recent works empirically demonstrate that common invariance-inducing regularizers are ineffective in the over-parameterized regime, in which classifiers perfectly fit (i.e. interpolate) the training data. This suggests that the phenomenon of ``benign overfitting," in which models generalize well despite interpolating, might not favorably extend to settings in which robustness or fairness are desirable.

In this work, we provide a theoretical justification for these observations. We prove that---even in the simplest of settings---any interpolating learning rule (with an arbitrarily small margin) will not satisfy these invariance properties. We then propose and analyze an algorithm that---in the same setting---successfully learns a non-interpolating classifier that is provably invariant. We validate our theoretical observations on simulated data and the Waterbirds dataset.

Exploring and Exploiting Decision Boundary Dynamics for Adversarial Robustness

Yuancheng Xu,Yanchao Sun,Micah Goldblum,Tom Goldstein,Furong Huang

The robustness of a deep classifier can be characterized by its margins: the decision boundary's distances to natural data points. However, it is unclear whether existing robust training methods effectively increase the margin for each vulnerable point during training. To understand this, we propose a continuous-time framework for quantifying the relative speed of the decision boundary with respect to each individual point. Through visualizing the moving speed of the decision boundary under Adversarial Training, one of the most effective robust training algorithms, a surprising moving-behavior is revealed: the decision boundary move s away from some vulnerable points but simultaneously moves closer to others, decreasing their margins. To alleviate these conflicting dynamics of the decision boundary, we propose Dynamics-aware Robust Training (DyART), which encourages the decision boundary to engage in movement that prioritizes increasing smaller margins. In contrast to prior works, DyART directly operates on the margins rather than their indirect approximations, allowing for more targeted and effective robustness improvement. Experiments on the CIFAR-10 and Tiny-ImageNet datasets verify that DyART alleviates the conflicting dynamics of the decision boundary and obtains improved robustness under various perturbation sizes compared to the state-of-the-art defenses. Our code is available at https://github.com/Yuancheng-Xu/Dynamics-Aware-Robust-Training.

****

Countering the Attack-Defense Complexity Gap for Robust Classifiers

Samuele Marro,Michele Lombardi

We consider the decision version of defending and attacking Machine Learning classifiers. We provide a rationale for the well-known difficulties in building robust models: in particular we prove that, under broad assumptions, attacking a polynomial-time classifier is NP-complete, while training a polynomial-time model that is robust on even a single input is Σ_2^P-complete. We also provide more general bounds for non-polynomial classifiers. We then show how such a complexity gap can be sidestepped by introducing Counter-Attack (CA), a system that computes on-the-fly robustness certificates for a given input up to an arbitrary distance bound ε. We also prove that, even when attacked with perturbations of magnitude $\varepsilon^\prime > \varepsilon$, CA still provides computational robustness: specifically, while computing a certificate is NP-complete, attacking the system beyond its intended robustness is Σ_2^P-complete. Since the exact form of CA can still be computationally expensive, we introduce a relaxation of this method, which we empirically show to be reliable at identifying non-robust inputs. As part of our work, we introduce UG100, a new dataset obtained by applying a provably optimal attack to six limited-scale networks (three for MNIST and three for CIFAR10), each trained in three different manners.

Evaluating Counterfactual Explainers

Diego Velazquez,Pau Rodriguez,Alexandre Lacoste,Issam H. Laradji,Xavier Roca,Jordi Gonzàlez

Explainability methods have been widely used to provide insight into the decisions made by statistical models, thus facilitating their adoption in various domains within the industry. Counterfactual explanation methods aim to improve our understanding of a model by perturbing samples in a way that would alter its response in an unexpected manner. This information is helpful for users and for machine learning practitioners to understand and improve their models. Given the value provided by counterfactual explanations, there is a growing interest in the research community to investigate and propose new methods. However, we identify two issues that could hinder the progress in this field. (1) Existing metrics do not accurately reflect the value of an explainability method for the users. (2) Comparisons between methods are usually performed with datasets like CelebA, where images are annotated with attributes that do not fully describe them and with subjective attributes such as ``Attractive''. In this work, we address these problems by proposing an evaluation method with a principled metric to evaluate and compare different counterfactual explanation methods. The evaluation method is based on a synthetic dataset where images are fully described by their annotated attributes. As a result, we are able to perform a fair comparison of multiple explainability methods in the recent literature, obtaining insights about their performance. We make the code public for the benefit of the research community.

SMART: Sentences as Basic Units for Text Evaluation

Reinald Kim Amplayo,Peter J Liu,Yao Zhao,Shashi Narayan

Widely used evaluation metrics for text generation either do not work well with longer texts or fail to evaluate all aspects of text quality. In this paper, we introduce a new metric called SMART to mitigate such limitations. Specifically, we treat sentences as basic units of matching instead of tokens, and use a sentence matching function to soft-match candidate and reference sentences. Candidate sentences are also compared to sentences in the source documents to allow grounding (e.g., factuality) evaluation. Our results show that system-level correlations of our proposed metric with a model-based matching function outperforms all competing metrics on the SummEval summarization meta-evaluation dataset, while the same metric with a string-based matching function is competitive with current model-based metrics. The latter does not use any neural model, which is useful during model development phases where resources can be limited and fast evaluation is required. SMART also outperforms all factuality evaluation metrics on the TRUE benchmark. Finally, we also conducted extensive analyses showing that our proposed metrics work well with longer summaries and are less biased towards specific models.

A Reinforcement Learning Approach to Estimating Long-term Treatment Effects

Ziyang Tang,Yiheng Duan,Stephanie Zhang,Lihong Li

Randomized experiments (a.k.a. A/B tests) are a powerful tool for estimating treatment effects, to inform decisions making in business, healthcare and other applications. In many problems, the treatment has a lasting effect that evolves over time. A limitation with randomized experiments is that they do not easily extend to measure long-term effects, since running long experiments is time-consuming and expensive. In this paper, we take a reinforcement learning (RL) approach that estimates the average reward in a Markov process. Motivated by real-world scenarios where the observed state transition is nonstationary, we develop a new algorithm for a class of nonstationary problems, and demonstrate promising results in two synthetic datasets and one online store dataset.

Sample-Efficient Reinforcement Learning by Breaking the Replay Ratio Barrier

Pierluca D'Oro,Max Schwarzer,Evgenii Nikishin,Pierre-Luc Bacon,Marc G Bellemare,Aaron Courville

Increasing the replay ratio, the number of updates of an agent's parameters per environment interaction, is an appealing strategy for improving the sample efficiency of deep reinforcement learning algorithms. In this work, we show that fully or partially resetting the parameters of deep reinforcement learning agents causes better replay ratio scaling capabilities to emerge. We push the limits of the sample efficiency of carefully-modified algorithms by training them using an order of magnitude more updates than usual, significantly improving their performance in the Atari 100k and DeepMind Control Suite benchmarks. We then provide an analysis of the design choices required for favorable replay ratio scaling to be possible and discuss inherent limits and tradeoffs.

****

Tier Balancing: Towards Dynamic Fairness over Underlying Causal Factors

Zeyu Tang,Yatong Chen,Yang Liu,Kun Zhang

The pursuit of long-term fairness involves the interplay between decision-making and the underlying data generating process. In this paper, through causal modeling with a directed acyclic graph (DAG) on the decision-distribution interplay, we investigate the possibility of achieving long-term fairness from a dynamic perspective. We propose Tier Balancing, a technically more challenging but more natural notion to achieve in the context of long-term, dynamic fairness analysis. Different from previous fairness notions that are defined purely on observed variables, our notion goes one step further, capturing behind-the-scenes situation changes on the unobserved latent causal factors that directly carry out the influence from the current decision to the future data distribution. Under the specified dynamics, we prove that in general one cannot achieve the long-term fairness goal only through one-step interventions. Furthermore, in the effort of approaching long-term fairness, we consider the mission of "getting closer to" the long-term fairness goal and present possibility and impossibility results accordingly.

Anamnesic Neural Differential Equations with Orthogonal Polynomial Projections
Edward De Brouwer,Rahul G Krishnan
Neural ordinary differential equations (Neural ODEs) are an effective framework for learning dynamical systems from irregularly sampled time series data. These models provide a continuous-time latent representation of the underlying dynamical system where new observations at arbitrary time points can be used to update the latent representation of the dynamical system. Existing parameterizations for the dynamics functions of Neural ODEs limit the ability of the model to retain global information about the time series; specifically, a piece-wise integration of the latent process between observations can result in a loss of memory on the dynamic patterns of previously observed data points. We propose PolyODE, a Neural ODE that models the latent continuous-time process as a projection onto a basis of orthogonal polynomials. This formulation enforces long-range memory and preserves a global representation of the underlying dynamical system. Our construction is backed by favourable theoretical guarantees and in a series of experiments, we demonstrate that it outperforms previous works in the reconstruction of past and future data, and in downstream prediction tasks.

Neural Design for Genetic Perturbation Experiments
Aldo Pacchiano,Drausin Wulsin,Robert A Barton,Luis Voloch
The problem of how to genetically modify cells in order to maximize a certain cellular phenotype has taken center stage in drug development over the last few years (with, for example, genetically edited CAR-T, CAR-NK, and CAR-NKT cells entering cancer clinical trials). Exhausting the search space for all possible genetic edits (perturbations) or combinations thereof is infeasible due to cost and experimental limitations. This work provides a theoretically sound framework for iteratively exploring the space of perturbations in pooled batches in order to maximize a target phenotype under an experimental budget. Inspired by this application domain, we study the problem of batch query bandit optimization and introduce the Optimistic Arm Elimination (OAE) principle designed to find an almost optimal arm under different functional relationships between the queries (arms) and the outputs (rewards). We analyze the convergence properties of OAE by relating it to the Eluder dimension of the algorithm's function class and validate that OAE outperforms other strategies in finding optimal actions in experiments on simulated problems, public datasets well-studied in bandit contexts, and in genetic perturbation datasets when the regression model is a deep neural network. OAE also outperforms the benchmark algorithms in 3 of 4 datasets in the GeneDisco experimental planning challenge.

Conceptual SCAN: Learning With and About Rules
Nathan Scales,Nathanael Schärli,Abubakr Babiker,Yu-Han Liu,Mostafa Dehghani,Olivier Bousquet
The ability to learn from a mix of rules and examples and to reflect on the learned abstractions is an important aspect of human intelligence. At the same time, there is a lack of benchmarks that systematically test for this ability, which makes it hard to evaluate the degree to which it is present in state-of-the-art ML architectures. We introduce a method to systematically construct such benchmarks by using an example structure that allows us to explicitly provide and ask about rules that are relevant for the given task. We present a simple dataset that is constructed according to this method, and we use it to analyze the performance of a variety of T5-based machine learning models. We identify four challenge areas in this setup: maintaining consistency between learned rules and their application, scaling to larger rule sets, compositional generalization, and dealing with limited training data.

Have Missing Data? Make It Miss More! Imputing Tabular Data with Masked Autoencoding
Tianyu Du,Luca Melis,Ting Wang
We present ReMasker, a novel method for imputing missing values in tabular data by extending the masked autoencoding framework. In contrast to prior work, ReMas

ker is both {\em simple} -- besides the missing values (i.e., naturally masked), we randomly ``re-mask'' another set of values, optimize the autoencoder by reconstructing this re-masked set, and apply the trained model to predict the missing values; and {\em effective} -- with extensive evaluation on benchmark datasets, we show that ReMasker consistently outperforms state-of-the-art methods in terms of both imputation fidelity and utility under various missingness settings, while its performance advantage often increases with the ratio of missing data. We further explore theoretical justification for its effectiveness, showing that ReMasker tends to learn missingness-invariant representations of tabular data. Our findings indicate that masked modeling represents a promising direction for further research on tabular data imputation.

Invertible normalizing flow neural networks by JKO scheme
Chen Xu,Xiuyuan Cheng,Yao Xie

Normalizing flow is a class of deep generative models for efficient sampling and density estimation. In practice, the flow often appears as a chain of invertible neural network blocks. To facilitate training, past works have regularized flow trajectories and designed special network architectures. The current paper develops a neural ODE flow network inspired by the Jordan-Kinderleherer-Otto (JKO) scheme, which allows an efficient \textit{block-wise} training procedure: as the JKO scheme unfolds the dynamic of gradient flow, the proposed model naturally stacks residual network blocks one-by-one and reduces the memory load as well as the difficulty of training deep networks. We also develop an adaptive time-reparametrization of the flow network with a progressive refinement of the trajectory in probability space, which improves the optimization efficiency and model accuracy in practice.

On high-dimensional generative tasks for tabular data, JKO-Flow can process larger data batches and perform competitively as or better than continuous and discrete flow models, using 10X less number of iterations (e.g., batches) and significantly less time per iteration.

Unsupervised learning of features and object boundaries from local prediction
Heiko H. Schütt,Wei Ji Ma

A visual system has to learn both which features to extract from images and how to group locations into (proto-)objects. Those two aspects are usually dealt with separately, although predictability is discussed as a cue for both. To incorporate features and boundaries into the same model, we model a layer of feature maps with a pairwise Markov random field model in which each factor is paired with an additional binary variable, which switches the factor on or off. Using one of two contrastive learning objectives, we can learn both the features and the parameters of the Markov random field factors from images without further supervision signals. The features learned by shallow neural networks based on this loss are local averages, opponent colors, and Gabor-like stripe patterns. Furthermore, we can infer connectivity between locations by inferring the switch variables. Contours inferred from this connectivity perform quite well on the Berkeley segmentation database (BSDS500) without any training on contours. Thus, computing predictions across space aids both segmentation and feature learning, and models trained to optimize these predictions show similarities to the human visual system. We speculate that retinotopic visual cortex might implement such predictions over space through lateral connections.

Multi-Segmental Informational Coding for Self-Supervised Representation Learning
Chuang Niu,Ge Wang

Self-supervised representation learning aims to map high-dimensional data into a compact embedding space, where samples with similar semantics are close to each other. Currently, most representation learning methods maximize the cosine similarity or minimize the distance between different views from the same sample in an ℓ^2 normalized embedding space, and reduce the feature redundancy via a linear correlation constraint. In this study, we propose MUlti-Segmental Informational Coding (MUSIC) as a new embedding scheme for self-supervised representati on learning. MUSIC divides an embedding vector into multiple segments to represent different types of attributes, and each segment automatically learns a set of discrete and complementary attributes. MUSIC enables the estimation of the probability distribution over discrete attributes and thus the learning process can be directly guided by information measurements, reducing the feature redundancy beyond the linear correlation. Our theoretical analysis guarantees that MUSIC learns transform-invariant, non-trivial, diverse, and discriminative features. MUSIC does not require a special asymmetry design, a very high dimension of embedding features, or a deep projection head, making the training framework flexible and efficient. Extensive experiments demonstrate the superiority of MUSIC.

Rule-based policy regularization for reinforcement learning-based building control

Hsin Yu Liu,Bharathan Balaji,Rajesh Gupta,Dezhi Hong

Rule-based control (RBC) is widely adopted in buildings due to its stability and robustness. It resembles a behavior cloning methodology refined by human expertise. However, it is unlikely for RBC to exceed a reinforcement learning (RL) agent’s performance since it is challenging to ingest a large number of parameters during decision-making. In this paper, we explore how to incorporate rule-based control into reinforcement learning to learn a more robust policy in both online and offline settings with a unified approach. We start with state-of-the-art online and offline RL methods, TD3 and TD3+BC, then improve on them using a dynamically weighted actor loss function to selectively choose which policy should RL models learn from at each time step of training. With experiments across multiple tasks and various weather conditions in both deterministic and stochastic scenarios, we empirically demonstrate that our dynamically weighted rule-based incorporated control regularization (RUBICON) method outperforms representative baseline methods in offline settings by 40.7% in a reward settings consisting of the combination of thermal comfort and energy consumption and by 49.7% in online settings in building-RL environments.

Neural Graphical Models

Harsh Shrivastava,Urszula Chajewska

Graphs are ubiquitous and are often used to understand the dynamics of a system. Probabilistic Graphical Models comprising Bayesian and Markov networks, and Conditional Independence graphs are some of the popular graph representation techniques. They can model relationships between features (nodes) together with the underlying distribution. Although theoretically these models can represent very complex dependency functions, in practice often simplifying assumptions are made due to computational limitations associated with graph operations. This work introduces Neural Graphical Models (NGMs) which attempt to represent complex feature dependencies with reasonable computational costs. Specifically, given a graph of feature relationships and corresponding samples, we capture the dependency structure between the features along with their complex function representations by using neural networks as a multi-task learning framework. We provide efficient learning, inference and sampling algorithms for NGMs. Moreover, NGMs can fit generic graph structures including directed, undirected and mixed-edge graphs as well as support mixed input data types. We present empirical studies that show NGMs' capability to represent Gaussian graphical models, inference analysis of a lung cancer data and extract insights from a real world infant mortality data provided by CDC.

AUGMENTING ZERO-SHOT DENSE RETRIEVERS WITH PLUG-IN MIXTURE-OF-MEMORIES

Suyu Ge,Chenyan Xiong,Corby Louis Rosset,Arnold Overwijk,Jiawei Han,Paul N. Bennett

In this paper we improve the zero-shot generalization ability of language models via Mixture-Of-Memory Augmentation (MoMA), a mechanism that retrieves augmentation documents from multiple information corpora (“external memories”), with the option to “plug in” new memory at inference time. We develop a joint learning mechanism that trains the augmentation component with latent labels derived from t he end retrieval task, paired with hard negatives from the memory mixture. We instantiate the model in a zero-shot dense retrieval setting by augmenting a strong T5-based retriever with MoMA. Our model, MoMA-DR, obtains strong zero-shot retrieval accuracy on the eighteen tasks included in the standard BEIR benchmark. It outperforms other dense retrieval models of similar scales and achieves comparable accuracy with systems that seek generalization from increased scales in encoder models or vector indices. Our analysis illustrates the necessity of augmenting with mixture-of-memory for robust generalization, the benefits of joint learning, and how MoMA-DR utilizes the plug-in memory at inference time without changing its parameters. We plan to open source our code.

Efficient Discrete Multi Marginal Optimal Transport Regularization

Ronak Mehta,Jeffery Kline,Vishnu Suresh Lokhande,Glenn Fung,Vikas Singh

Optimal transport has emerged as a powerful tool for a variety of problems in machine learning, and it is frequently used to enforce distributional constraints. In this context, existing methods often use either a Wasserstein metric, or else they apply concurrent barycenter approaches when more than two distributions are considered. In this paper, we leverage multi-marginal optimal transport (MMOT), where we take advantage of a procedure that computes a generalized earth mover's distance as a sub-routine. We show that not only is our algorithm computationally more efficient compared to other barycentric-based distance methods, but it has the additional advantage that gradients used for backpropagation can be efficiently computed during the forward pass computation itself, which leads to substantially faster model training. We provide technical details about this new regularization term and its properties, and we present experimental demonstrations of faster runtimes when compared to standard Wasserstein-style methods. Finally, on a range of experiments designed to assess effectiveness at enforcing fairness, we demonstrate our method compares well with alternatives.

AutoTransfer: AutoML with Knowledge Transfer - An Application to Graph Neural Networks

Kaidi Cao,Jiaxuan You,Jiaju Liu,Jure Leskovec

AutoML has demonstrated remarkable success in finding an effective neural architecture for a given machine learning task defined by a specific dataset and an evaluation metric. However, most present AutoML techniques consider each task independently from scratch, which requires exploring many architectures, leading to high computational cost. Here we propose AutoTransfer, an AutoML solution that improves search efficiency by transferring the prior architectural design knowledge to the novel task of interest. Our key innovation includes a task-model bank that captures the model performance over a diverse set of GNN architectures and tasks, and a computationally efficient task embedding that can accurately measure the similarity among different tasks. Based on the task-model bank and the task embeddings, we estimate the design priors of desirable models of the novel task, by aggregating a similarity-weighted sum of the top-K design distributions on tasks that are similar to the task of interest. The computed design priors can be used with any AutoML search algorithm. We evaluate AutoTransfer on six datasets in the graph machine learning domain. Experiments demonstrate that (i) our proposed task embedding can be computed efficiently, and that tasks with similar embeddings have similar best-performing architectures; (ii) AutoTransfer significantly improves search efficiency with the transferred design priors, reducing the number of explored architectures by an order of magnitude. Finally, we release GNN-Bank-101, a large-scale dataset of detailed GNN training information of 120,000 task-model combinations to facilitate and inspire future research.

Meta-learning from demonstrations improves compositional generalization

Sam Spilsbury,Alexander Ilin

We study the problem of compositional generalization of language-instructed agents in gSCAN. gSCAN is a popular benchmark which requires an agent to generalize to instructions containing novel combinations of words, which are not seen in the training data. We propose to improve the agent’s generalization capabilities w ith an architecture inspired by the Meta-Sequence-to-Sequence learning approach (Lake, 2019). The agent receives as a context a few examples of pairs of instructions and action trajectories in a given instance of the environment (a support set) and it is tasked to predict an action sequence for a query instruction for the same environment instance. The context is generated by an oracle and the instructions come from the same distribution as seen in the training data. In each training episode, we also shuffle the indices of the actions and the words of the instructions to make the agent figure out the relations between the actions and the words from the context. Our predictive model has the standard transformer architecture. We show that the proposed architecture can significantly improve the generalization capabilities of the agent on one of the most difficult gSCAN splits: the ``adverb-to-verb” split H.

Deep Dependency Networks for Action Classification in Video

Shivvrat Arya,Yu Xiang,Vibhav Giridhar Gogate

We propose a simple approach which combines the strengths of probabilistic graphical models and deep learning architectures for solving the multi-label action classification task in videos. At a high level, given a video clip, the goal in this task is to infer the set of activities, defined as verb-noun pairs, that are performed in the clip. First, we show that the performance of previous approaches that combine Markov Random Fields with neural networks can be modestly improved by leveraging more powerful methods such as iterative join graph propagation, ℓ-1 regularization based structure learning and integer linear programming. Then we propose a new modeling framework called deep dependency network which augments a dependency network, a model that is easy to train and learns more accurate dependencies but is limited to Gibbs sampling for inference, to the output layer of a neural network. We show that despite its simplicity, joint learning this new architecture yields significant improvements in performance over the baseline neural network. In particular, our experimental evaluation on three video datasets: Charades, Textually Annotated Cooking Scenes (TaCOS), and Wetlab shows that deep dependency networks are almost always superior to pure neural architectures that do not use dependency networks.

Temporal Dependencies in Feature Importance for Time Series Prediction

Kin Kwan Leung,Clayton Rooke,Jonathan Smith,Saba Zuberi,Maksims Volkovs

Time series data introduces two key challenges for explainability methods: firstly, observations of the same feature over subsequent time steps are not independent, and secondly, the same feature can have varying importance to model predictions over time. In this paper, we propose Windowed Feature Importance in Time (WinIT), a feature removal based explainability approach to address these issues. Unlike existing feature removal explanation methods, WinIT explicitly accounts for the temporal dependence between different observations of the same feature in the construction of its importance score. Furthermore, WinIT captures the varying importance of a feature over time, by summarizing its importance over a window of past time steps. We conduct an extensive empirical study on synthetic and real-world data, compare against a wide range of leading explainability methods, and explore the impact of various evaluation strategies. Our results show that WinIT achieves significant gains over existing methods, with more consistent performance across different evaluation metrics.

Peaks2Image: Reconstructing fMRI Statistical Maps from Peaks

Raphaël Meudec,Jérôme Dockès,Demian Wassermann,Bertrand Thirion

Neuroscience is striving to overcome the lack of power due to the small sample size of standard studies. An important step forward has been the creation of large-scale public image repositories, such as NeuroVault. Such repositories enable comparing images across studies and automatically associating them with cognitive terms. Yet, this type of meta-analysis faces a major roadblock: the scarcity and inconsistency of image annotations and metadata. Another resource containing rich annotations is the neuroscientific literature. However it only yields a handful of brain-space coordinates per publication, those of the main activity peak s reported in each study. In this work, we propose Peaks2Image, a neuralnetwork approach to reconstructing continuous spatial representations of brain activity from peak activation tables. Using reconstructions of studies published in the neuroscientific literature, we train a decoder using tf-idf features as labels, leading to a much broader set of decoded terms than current image-based studies. We validate the decoder on 43,000 NeuroVault images, successfully decoding 58 out of 81 concepts in a zero-shot setting.

Bridging the Gap between Semi-supervised and Supervised Continual Learning via Data Programming

Pengyuan Lu,Seungwon Lee,Amanda Annette Watson,David Kent,Insup Lee,ERIC EATON,James Weimer

Semi-supervised continual learning (SSCL) has shown its utility in learning cumulative knowledge with partially labeled data per task. However, the state-of-the-art has yet to explicitly address how to reduce the performance gap between using partially labeled data and fully labeled. In response, we propose a general-purpose SSCL framework, namely DP-SSCL, that uses data programming (DP) to pseudo-label the unlabeled data per task, and then cascades both ground-truth-labeled and pseudo-labeled data to update a downstream supervised continual learning model. The framework includes a feedback loop that brings mutual benefits: On one hand, DP-SSCL inherits guaranteed pseudo-labeling quality from DP techniques to improve continual learning, approaching the performance of using fully supervised data. On the other hand, knowledge transfer from previous tasks facilitates training of the DP pseudo-labeler, taking advantage of cumulative information via self-teaching. Experiments show that (1) DP-SSCL bridges the performance gap, approaching the final accuracy and catastrophic forgetting as using fully labeled data, (2) DP-SSCL outperforms existing SSCL approaches at low cost, by up to 25% higher final accuracy and lower catastrophic forgetting on standard benchmarks, while reducing memory overhead from 100 MB level to 1 MB level at the same time complexity, and (3) DP-SSCL is flexible, maintaining steady performance supporting plug-and-play extensions for a variety of supervised continual learning models.

Characterizing the spectrum of the NTK via a power series expansion

Michael Murray,Hui Jin,Benjamin Bowman,Guido Montufar

Under mild conditions on the network initialization we derive a power series expansion for the Neural Tangent Kernel (NTK) of arbitrarily deep feedforward networks in the infinite width limit. We provide expressions for the coefficients of this power series which depend on both the Hermite coefficients of the activation function as well as the depth of the network. We observe faster decay of the Hermite coefficients leads to faster decay in the NTK coefficients and explore the role of depth. Using this series, first we relate the effective rank of the NTK to the effective rank of the input-data Gram. Second, for data drawn uniformly on the sphere we study the eigenvalues of the NTK, analyzing the impact of the choice of activation function. Finally, for generic data and activation functions with sufficiently fast Hermite coefficient decay, we derive an asymptotic upper bound on the spectrum of the NTK.

****

Unmasking the Lottery Ticket Hypothesis: What's Encoded in a Winning Ticket's Mask?

Mansheej Paul,Feng Chen,Brett W. Larsen,Jonathan Frankle,Surya Ganguli,Gintare Karolina Dziugaite

Modern deep learning involves training costly, highly overparameterized networks, thus motivating the search for sparser networks that require less compute and memory but can still be trained to the same accuracy as the full network (i.e. matching). Iterative magnitude pruning (IMP) is a state of the art algorithm that can find such highly sparse matching subnetworks, known as winning tickets. IMP operates by iterative cycles of training, masking a fraction of smallest magnitude weights, rewinding unmasked weights back to an early training point, and repeating. Despite its simplicity, the underlying principles for when and how IMP f inds winning tickets remain elusive. In particular, what useful information does an IMP mask found at the end of training convey to a rewound network near the beginning of training? How does SGD allow the network to extract this information? And why is iterative pruning needed, i.e. why can't we prune to very high sparsities in one shot? We develop answers to these questions in terms of the geometry of the error landscape. First, we find that—at higher sparsities—pairs of pruned networks at successive pruning iterations are connected by a linear path with zero error barrier if and only if they are matching. This indicates that masks found at the end of training convey to the rewind point the identity of an axial subspace that intersects a desired linearly connected mode of a matching sublevel set. Second, we show SGD can exploit this information due to a strong form of robustness: it can return to this mode despite strong perturbations early in training. Third, we show how the flatness of the error landscape at the end of training determines a limit on the fraction of weights that can be pruned at each iteration of IMP. This analysis yields a new quantitative link between IMP performance and the Hessian eigenspectrum. Finally, we show that the role of retraining in IMP is to find a network with new small weights to prune. Overall, these results make progress toward demystifying the existence of winning tickets by revealing the fundamental role of error landscape geometry in the algorithms used to find them.

A critical look at the evaluation of GNNs under heterophily: Are we really making progress?

Oleg Platonov,Denis Kuznedelev,Michael Diskin,Artem Babenko,Liudmila Prokhorenkova

Node classification is a classical graph representation learning task on which Graph Neural Networks (GNNs) have recently achieved strong results. However, it is often believed that standard GNNs only work well for homophilous graphs, i.e., graphs where edges tend to connect nodes of the same class. Graphs without this property are called heterophilous, and it is typically assumed that specialized methods are required to achieve strong performance on such graphs. In this work, we challenge this assumption. First, we show that the standard datasets used for evaluating heterophily-specific models have serious drawbacks, making results obtained by using them unreliable. The most significant of these drawbacks is the presence of a large number of duplicate nodes in the datasets Squirrel and Chameleon, which leads to train-test data leakage. We show that removing duplicate nodes strongly affects GNN performance on these datasets. Then, we propose a set of heterophilous graphs of varying properties that we believe can serve as a better benchmark for evaluating the performance of GNNs under heterophily. We show that standard GNNs achieve strong results on these heterophilous graphs, almost always outperforming specialized models. Our datasets and the code for reproducing our experiments are available at https://github.com/yandex-research/heterophilous-graphs

Dr.Spider: A Diagnostic Evaluation Benchmark towards Text-to-SQL Robustness

Shuaichen Chang,Jun Wang,Mingwen Dong,Lin Pan,Henghui Zhu,Alexander Hanbo Li,Wuwei Lan,Sheng Zhang,Jiarong Jiang,Joseph Lilien,Steve Ash,William Yang Wang,Zhiguo Wang,Vittorio Castelli,Patrick Ng,Bing Xiang

Neural text-to-SQL models have achieved remarkable performance in translating natural language questions into SQL queries. However, recent studies reveal that text-to-SQL models are vulnerable to task-specific perturbations. Previous curated robustness test sets usually focus on individual phenomena. In this paper, we propose a comprehensive robustness benchmark based on Spider, a cross-domain text-to-SQL benchmark, to diagnose the model robustness. We design 17 perturbations on databases, natural language questions, and SQL queries to measure the robustness from different angles. In order to collect more diversified natural question perturbations, we utilize large pretrained language models (PLMs) to simulate human behaviors in creating natural questions. We conduct a diagnostic study of the state-of-the-art models on the robustness set. Experimental results reveal that even the most robust model suffers from a 14.0% performance drop overall and a 50.7% performance drop on the most challenging perturbation. We also present a breakdown analysis regarding text-to-SQL model designs and provide insights for improving model robustness.

A Non-monotonic Self-terminating Language Model

Eugene Choi,Kyunghyun Cho,Cheolhyoung Lee

Recent large-scale neural autoregressive sequence models have shown impressive performances on a variety of natural language generation tasks. However, their generated sequences often exhibit degenerate properties such as non-termination, undesirable repetition, and premature termination, when generated with decoding algorithms such as greedy search, beam search, top-k sampling, and nucleus sampling. In this paper, we focus on the problem of non-terminating sequences resulting from an incomplete decoding algorithm. We first define an incomplete probable decoding algorithm which includes greedy search, top-k sampling, and nucleus sampling, beyond the incomplete decoding algorithm originally put forward by Welleck et al. (2020). We then propose a non-monotonic self-terminating language model, which significantly relaxes the constraint of monotonically increasing termination probability in the originally proposed self-terminating language model by Welleck et al. (2020), to address the issue of non-terminating sequences when using incomplete probable decoding algorithms. We prove that our proposed model prevents non-terminating sequences when using not only incomplete probable decoding algorithms but also beam search. We empirically validate our model on sequence completion tasks with various architectures.

uGLAD: A deep learning model to recover conditional independence graphs

Harsh Shrivastava,Urszula Chajewska,Robin Abraham,Xinshi Chen

Probabilistic Graphical Models are generative models of complex systems. They rely on conditional independence assumptions between variables to learn sparse representations which can be visualized in a form of a graph. Such models are used for domain exploration and structure discovery in poorly understood domains. This work introduces a novel technique to perform sparse graph recovery by optimizing deep unrolled networks. Assuming that the input data $X\in\mathbb{R}^{M\times D}$ comes from an underlying multivariate Gaussian distribution, we apply a deep model on X that outputs the precision matrix Θ. Then, the partial correlation matrix \mathrm{P} is calculated which can also be interpreted as providing a list of conditional independence assertions holding in the input distribution. Our model, \texttt{uGLAD}, builds upon and extends the state-of-the-art model \texttt{GLAD} to the unsupervised setting. The key benefits of our model are (1) \texttt{uGLAD} automatically optimizes sparsity-related regularization parameters leading to better performance than existing algorithms. (2) We introduce multi-task learning based `consensus' strategy for robust handling of missing data in an unsupervised setting. We evaluate performance on synthetic Gaussian, non-Gaussian data generated from Gene Regulatory Networks, and present case studies in anaerobic digestion and infant mortality.

****

Quantifying Memorization Across Neural Language Models

Nicholas Carlini,Daphne Ippolito,Matthew Jagielski,Katherine Lee,Florian Tramer,Chiyuan Zhang

Large language models (LMs) have been shown to memorize parts of their training data, and when prompted appropriately, they will emit the memorized training data verbatim. This is undesirable because memorization violates privacy (exposing user data), degrades utility (repeated easy-to-memorize text is often low quality), and hurts fairness (some texts are memorized over others).

We describe three log-linear relationships that quantify the degree to which LMs emit memorized training data. Memorization significantly grows as we increase (1) the capacity of a model, (2) the number of times an example has been duplicated, and (3) the number of tokens of context used to prompt the model. Surprisingly, we find the situation becomes complicated when generalizing these results across model families. On the whole, we find that memorization in LMs is more prevalent than previously believed and will likely get worse as models continues to scale, at least without active mitigations.

Powderworld: A Platform for Understanding Generalization via Rich Task Distributions

Kevin Frans,Phillip Isola

One of the grand challenges of reinforcement learning is the ability to generalize to new tasks. However, general agents require a set of rich, diverse tasks to train on. Designing a `foundation environment' for such tasks is tricky -- the ideal environment would support a range of emergent phenomena, an expressive task space, and fast runtime. To take a step towards addressing this research bottleneck, this work presents Powderworld, a lightweight yet expressive simulation environment running directly on the GPU. Within Powderworld, two motivating task distributions are presented, one for world-modelling and one for reinforcement learning. Each contains hand-designed test tasks to examine generalization. Experiments indicate that increasing the environment's complexity improves generalization for world models, yet causes reinforcement learning agents to struggle. Powderworld aims to support the study of generalization by providing a source of diverse tasks arising from the same core rules.

****

Federated Self-supervised Learning for Heterogeneous Clients

Disha Makhija,Nhat Ho,Joydeep Ghosh

Federated Learning has become an important learning paradigm due to its privacy and computational benefits. As the field advances, two key challenges that still remain to be addressed are: (1) system heterogeneity - variability in the compute and/or data resources present on each client, and (2) lack of labeled data in certain federated settings. Several recent developments have tried to overcome these challenges independently. In this work, we propose a unified and systematic framework, \emph{Heterogeneous Self-supervised Federated Learning} (Hetero-SSFL) for enabling self-supervised learning with federation on heterogeneous clients. The proposed framework allows collaborative representation learning across all the clients without imposing architectural constraints or requiring presence of labeled data. The key idea in Hetero-SSFL is to let each client train its unique self-supervised model and enable the joint learning across clients by aligning the lower dimensional representations on a common dataset. The entire training procedure could be viewed as self and peer-supervised as both the local training and the alignment procedures do not require presence of any labeled data. As in conventional self-supervised learning, the obtained client models are task independent and can be used for varied end-tasks.

We provide a convergence guarantee of the proposed framework for non-convex objectives in heterogeneous settings and also empirically demonstrate that our proposed approach outperforms the state of the art methods by a significant margin.

****

ContraSim -- A Similarity Measure Based on Contrastive Learning

Adir Rahamim,Yonatan Belinkov

Recent work has compared neural network representations via similarity-based analyses, shedding light on how different aspects (architecture, training data, etc.) affect models' internal representations. The quality of a similarity measure is typically evaluated by its success in assigning a high score to representations that are expected to be matched. However, existing similarity measures perform mediocrely on standard benchmarks. In this work, we develop a new similarity measure, dubbed ContraSim, based on contrastive learning. In contrast to common closed-form similarity measures, ContraSim learns a parameterized measure by using both similar and dissimilar examples. We perform an extensive experimental evaluation of our method, with both language and vision models, on the standard layer prediction benchmark and two new benchmarks that we develop: the multilingual benchmark and the image--caption benchmark. In all cases, ContraSim achieves much higher accuracy than previous similarity measures, even when presented with challenging examples.

****

Learning to Segment from Noisy Annotations: A Spatial Correction Approach

Jiachen Yao,Yikai Zhang,Songzhu Zheng,Mayank Goswami,Prateek Prasanna,Chao Chen

Noisy labels can significantly affect the performance of deep neural networks (DNNs). In medical image segmentation tasks, annotations are error-prone due to the high demand in annotation time and in the annotators' expertise. Existing methods mostly tackle label noise in classification tasks. Their independent-noise assumptions do not fit label noise in segmentation task. In this paper, we propose a novel noise model for segmentation problems that encodes spatial correlation and bias, which are prominent in segmentation annotations. Further, to mitigate such label noise, we propose a label correction method to recover true label progressively. We provide theoretical guarantees of the correctness of the proposed method. Experiments show that our approach outperforms current state-of-the-art methods on both synthetic and real-world noisy annotations.

****

Measuring Forgetting of Memorized Training Examples

Matthew Jagielski,Om Thakkar,Florian Tramer,Daphne Ippolito,Katherine Lee,Nicholas Carlini,Eric Wallace,Shuang Song,Abhradeep Guha Thakurta,Nicolas Papernot,Chiyuan Zhang

Machine learning models exhibit two seemingly contradictory phenomena: training data memorization and various forms of forgetting. In memorization, models overfit specific training examples and become susceptible to privacy attacks. In forgetting, examples which appeared early in training are forgotten by the end. In this work, we connect these phenomena.

We propose a technique to measure to what extent models ``forget'' the specifics of training examples, becoming less susceptible to privacy attacks on examples they have not seen recently.

We show that, while non-convexity can prevent forgetting from happening in the worst-case, standard image,speech, and language models empirically do forget examples over time.

We identify nondeterminism as a potential explanation, showing that deterministically trained models do not forget.

Our results suggest that examples seen early when training with extremely large datasets---for instance those examples used to pre-train a model---may observe privacy benefits at the expense of examples seen later.

****

Graduated Non-Convexity for Robust Self-Trained Language Understanding

Hongyin Luo,Yoon Kim,James R. Glass

Self-training has been proved an efficient strategy for unsupervised fine-tuning of language models using unlabeled data and model-generated pseudo-labels. However, the performance of self-trained models is unstable under different settings of training and evaluation data, influenced by both data distribution and pseudo-label accuracy. In this work, we propose an outlier robust self-training method based on graduated non-convexity (GNC) to mitigate the problem. We construct self-training as a non-convex optimization problem with outlier training examples. The models are self-trained with robust cost functions based according to Black-Rangarajan Duality. The algorithm learns slack variables as the loss weights for all training samples. The slack variables are used to calibrate the loss items during training to update the model parameters. The calibrated loss items lead to more robust self-trained models against different training and evaluation data and tasks. We conducted experiments on few-shot natural language understanding tasks with labeled and unlabeled data examples. Experiment results show that the proposed loss calibration method improves the performance and stability of self-training under different training tasks and data examples, and also benefits the robustness against adversarial evaluation corpora.

MaskViT: Masked Visual Pre-Training for Video Prediction

Agrim Gupta,Stephen Tian,Yunzhi Zhang,Jiajun Wu,Roberto Martín-Martín,Li Fei-Fei

The ability to predict future visual observations conditioned on past observations and motor commands can enable embodied agents to plan solutions to a variety of tasks in complex environments. This work shows that we can create good video prediction models by pre-training transformers via masked visual modeling. Our a pproach, named MaskViT, is based on two simple design decisions. First, for memory and training efficiency, we use two types of window attention: spatial and spatiotemporal. Second, during training, we mask a variable percentage of tokens instead of a fixed mask ratio. For inference, MaskViT generates all tokens via iterative refinement where we incrementally decrease the masking ratio following a mask scheduling function. On several datasets we demonstrate that MaskViT outperforms prior works in video prediction, is parameter efficient, and can generate high resolution videos ($256 \times $256). Further, we demonstrate the benefits of inference speedup (up to $512 \times$) due to iterative decoding by using MaskViT for planning on a real robot. Our work suggests that we can endow embodied agents with powerful predictive models by leveraging the general framework of masked visual modeling with minimal domain knowledge.

Text Summarization with Oracle Expectation
Yumo Xu,Mirella Lapata

Extractive summarization produces summaries by identifying and concatenating the most important sentences in a document. Since most summarization datasets do not come with gold labels indicating whether document sentences are summary-worthy, different labeling algorithms have been proposed to extrapolate oracle extracts for model training. In this work, we identify two flaws with the widely used greedy labeling approach: it delivers suboptimal and deterministic oracles. To alleviate both issues, we propose a simple yet effective labeling algorithm that creates soft, expectation-based sentence labels. We define a new learning objective for extractive summarization which incorporates learning signals from multiple oracle summaries and prove it is equivalent to estimating the oracle expectation for each document sentence. Without any architectural modifications, the proposed labeling scheme achieves superior performance on a variety of summarization benchmarks across domains and languages, in both supervised and zero-shot settings.

MERMADE: K-shot Robust Adaptive Mechanism Design via Model-Based Meta-Learning
Arundhati Banerjee,Soham Rajesh Phade,Stefano Ermon,Stephan Zheng

Mechanism design (MD) studies how rules and rewards shape the behavior of intelligent agents, e.g., in auctions or the economy. Simulations with AI agents are powerful tools for MD, but real-world agents may behave and learn differently than simulated agents under a given mechanism. Also, the mechanism designer may not fully observe an agent's learning strategy or rewards, and executing a mechanism may be costly, e.g., enforcing a tax might require extra labor. Hence, it is key to design robust adaptive mechanisms that generalize well to agents with unseen (learning) behavior, are few-shot adaptable, and are cost-efficient. Here, we introduce MERMADE, a model-based meta-learning framework to learn mechanisms that can quickly adapt when facing out-of-distribution agents with different learning strategies and reward functions. First, we show that meta-learning allows adapting to the theoretically known and appropriate Stackelberg equilibrium in a simple matrix game at meta-test time, with few interactions with the agent. Second, with bandit agents, we show empirically that our approach yields strong meta-test time performance against agents with various unseen explore-exploit behaviors. Finally, we outperform baselines that separately use either meta-learning or agent behavior modeling to learn a cost-effective mechanism that is K-shot adaptable with only partial information about the agents.

Continuous-time identification of dynamic state-space models by deep subspace encoding
Gerben I. Beintema,Maarten Schoukens,Roland Tóth

Continuous-time (CT) modeling has proven to provide improved sample efficiency and interpretability in learning the dynamical behavior of physical systems compared to discrete-time (DT) models. However, even with numerous recent developments, the CT nonlinear state-space (NL-SS) model identification problem remains to be solved in full, considering common experimental aspects such as the presence of external inputs, measurement noise, latent states, and general robustness. Th is paper presents a novel estimation method that addresses all these aspects and that can obtain state-of-the-art results on multiple benchmarks with compact fully connected neural networks capturing the CT dynamics. The proposed estimation method called the subspace encoder approach (SUBNET) ascertains these results by efficiently approximating the complete simulation loss by evaluating short simulations on subsections of the data, by using an encoder function to estimate the initial state for each subsection and a novel state-derivative normalization to ensure stability and good numerical conditioning of the training process. We prove that the use of subsections increases cost function smoothness together with the necessary requirements for the existence of the encoder function and we show that the proposed state-derivative normalization is essential for reliable estimation of CT NL-SS models.

Waveformer: Linear-Time Attention with Forward and Backward Wavelet Transform

Yufan Zhuang,Zihan Wang,Fangbo Tao,Jingbo Shang

We propose Waveformer that learns attention mechanism in the wavelet coefficient space, requires only linear time complexity, and enjoys universal approximating power. Specifically, we first apply forward wavelet transform to project the input sequences to multi-resolution orthogonal wavelet bases, then conduct nonlinear transformations (in this case, a random feature kernel) in the wavelet coefficient space, and finally reconstruct the representation in input space via backward wavelet transform. We note that other non-linear transformations may be used, hence we name the learning paradigm Wavelet transformatIon for Sequence lEarning (WISE). We emphasize the importance of backward reconstruction in the WISE paradigm — without it, one would be mixing information from both the input space and coefficient space through skip connections, which shall not be considered as mathematically sound. Compared with Fourier transform in recent works, wavelet transform is more efficient in time complexity and better captures local and positional information; we further support this through our ablation studies. Extensive experiments on seven long-range understanding datasets from the Long Range Arena benchmark and code understanding tasks demonstrate that (1) Waveformer achieves competitive and even better accuracy than a number of state-of-the-art Transformer variants and (2) WISE can boost accuracies of various attention approximation methods without increasing the time complexity. These together showcase the superiority of learning attention in a wavelet coefficient space over the input space.

SaMoE: Parameter Efficient MoE Language Models via Self-Adaptive Expert Combination

Minjia Zhang,Conglong Li,Xiaoxia Wu,Zhewei Yao,Yuxiong He

Recently, Mixture-of-Experts (MoE) has demonstrated success in scaling models to have large amounts of parameters without significant increases in computational cost. However, MoEs have been also reported to be parameter inefficient such that larger models do not always lead to better performance.

In this work, we study how to build parameter-efficient MoE models. Our analysis identifies that MoE layers exhibit poor gradient flow as the number of experts increases, leading to insufficient training of experts. To overcome this issue, we propose a new MoE architecture design (SaMoE), which improves the parameter efficiency of MoE models by learning a soft combination of a global set of expert layers for each MoE layer. Such a scheme enables substantial parameter savings on MoE while achieving comparable or better accuracy than the standard MoE training baseline. Extensive experiments on billion-scale GPT-3 style autoregressive MoE language models demonstrate that SaMoE significantly improves the parameter efficiency of MoE models by reducing up to 5.2X total parameters while obtaining superior pre-training and zero-shot generalization results as compared to baseline.

How to Train your HIPPO: State Space Models with Generalized Orthogonal Basis Projections

Albert Gu,Isys Johnson,Aman Timalsina,Atri Rudra,Christopher Re

Linear time-invariant state space models (SSM) are a classical model from engineering and statistics, that have recently been shown to be very promising in machine learning through the Structured State Space sequence model (S4). A core component of S4 involves initializing the SSM state matrix to a particular matrix called a HiPPO matrix, which was empirically important for S4's ability to handle long sequences. However, the specific matrix that S4 uses was actually derived in previous work for a particular *time-varying* dynamical system, and the use of this matrix as a *time-invariant* SSM had no known mathematical interpretation. Consequently, the theoretical mechanism by which S4 models long-range dependencies actually remains unexplained. We derive a more general and intuitive formulation of the HiPPO framework, which provides a simple mathematical interpretation of S4 as a decomposition onto exponentially-warped Legendre polynomials, explaining its ability to capture long dependencies. Our generalization introduces a theoretically rich class of SSMs that also lets us derive more intuitive S4 variants for other bases such as the Fourier basis, and explains other aspects of training S4, such as how to initialize the important timescale parameter. These insights improve S4's performance to 86% on the Long Range Arena benchmark, with 96% on the most difficult Path-X task.

Interpretable Debiasing of Vectorized Language Representations with Iterative Orthogonalization

Prince Osei Aboagye,Yan Zheng,Jack Shunn,Chin-Chia Michael Yeh,Junpeng Wang,Zhongfang Zhuang,Huiyuan Chen,Liang Wang,Wei Zhang,Jeff Phillips

We propose a new mechanism to augment a word vector embedding representation that offers improved bias removal while retaining the key information—resulting in improved interpretability of the representation. Rather than removing the information associated with a concept that may induce bias, our proposed method identifies two concept subspaces and makes them orthogonal. The resulting representation has these two concepts uncorrelated. Moreover, because they are orthogonal, one can simply apply a rotation on the basis of the representation so that the resulting subspace corresponds with coordinates. This explicit encoding of concepts to coordinates works because they have been made fully orthogonal, which previous approaches do not achieve. Furthermore, we show that this can be extended to multiple subspaces. As a result, one can choose a subset of concepts to be represented transparently and explicitly, while the others are retained in the mixed but extremely expressive format of the representation.

Unpacking Large Language Models with Conceptual Consistency

Pritish Sahu,Michael Cogswell,Yunye Gong,Ajay Divakaran

If a Large Language Model (LLM) answers “yes” to the question “Are mountains tall?” then does it know what a mountain is? Can you rely on it responding correctly or incorrectly to other questions about mountains? The success of Large Language Models (LLMs) indicates they are increasingly able to answer queries like these accurately, but that ability does not necessarily imply a general

understanding of concepts relevant to the anchor query. We propose conceptual consistency to measure a LLM’s understanding of relevant concepts. This novel metric measures how well a model can be characterized by finding out how consistent its responses to queries about conceptually relevant background knowledge

are. To compute it we extract background knowledge by traversing paths between concepts in a knowledge base and then try to predict the model’s response to the anchor query from the background knowledge. We investigate the performance of current LLMs in a commonsense reasoning setting using the CSQA dataset and the ConceptNet knowledge base. While conceptual consistency, like other metrics, does increase with the scale of the LLM used, we find that popular models do not necessarily have high conceptual consistency. Our analysis also shows significant variation in conceptual consistency across different kinds of relations, concepts, and prompts. This serves as a step toward building models that humans can apply a theory of mind to, and thus interact with intuitively.

LSTM-BASED-AUTO-BI-LSTM for Remaining Useful Life (RUL) Prediction: the first round of test results

Carlos Ferreira,Gil Gonçalves

The Remaining Useful Life (RUL) is one of the most critical indicators to detect a component’s failure before it effectively occurs. It can be predicted by historical data or direct data extraction by adopting model-based, data-driven, or hybrid methodologies. Data-driven methods have mainly used Machine Learning (ML) approaches, despite several studies still pointing out different challenges in this sense. For instance, traditional ML methods cannot extract features directly from time series depending, in some cases, on the prior knowledge of the system. In this context, this work proposes a DL-based approach called LSTM-based-AUTO-Bi-LSTM. It ensembles an LSTM-based autoencoder to automatically perform feature engineering (instead of manually) with Bidirectional Long Short-Term Memory (Bi-LSTM) to predict RUL. We have tested the model using the Turbofan Engine Degradation Simulation Dataset (FD001), an open dataset. It was generated from the Commercial Modular Aero-Propulsion System Simulation (C-MAPSS) from the Prognostics Center of Excellence (PcoE), from the National Aeronautics and Space Administration (NASA). The objective is to release the first round of analytical results and statistical visualisations of the model application, which will guide us in future improvements.

Recurrent Real-valued Neural Autoregressive Density Estimator for Online Density Estimation and Classification of Streaming Data

Tianyu Li,Bogdan Mazoure,Guillaume Rabusseau

In contrast with the traditional offline learning, where complete data accessibility is assumed, many modern applications involve processing data in a streaming fashion. This online learning setting raises various challenges, including concept drift, hardware memory constraints, etc. In this paper, we propose the Recurrent Real-valued Neural Autoregressive Density Estimator (RRNADE), a flexible density-based model for online classification and density estimation. RRNADE combines a neural Gaussian mixture density module with a recurrent module. This combination allows RRNADE to exploit possible sequential correlations in the streaming task, which are often ignored in the classical streaming setting where each input is assumed to be independent from the previous ones. We showcase the ability of RRNADE to adapt to concept drifts on synthetic density estimation tasks. We also apply RRNADE to online classification tasks on both real world and synthetic datasets and compare it with multiple density based as well as nondensity based online classification methods. In almost all of these tasks, RRNADE outperforms the other methods. Lastly, we conduct an ablation study demonstrating the complementary benefits of the density and the recurrent modules.

Out-of-Distribution Detection and Selective Generation for Conditional Language Models

Jie Ren,Jiaming Luo,Yao Zhao,Kundan Krishna,Mohammad Saleh,Balaji Lakshminarayanan,Peter J Liu

Machine learning algorithms typically assume independent and identically distributed samples in training and at test time (IID). Much work has shown that high-performing ML classifiers can degrade significantly and provide overly-confident, wrong classification predictions, particularly for out-of-distribution (OOD) inputs. Conditional language models (CLMs) are predominantly trained to classify the next token in an output sequence, and may suffer even worse degradation on OOD inputs as the prediction is done auto-regressively over many steps. Furthermore, the space of potential low-quality outputs is larger as arbitrary text can be generated and it is important to know when to trust the generated output. We present a highly accurate and lightweight OOD detection method for CLMs, and demonstrate its effectiveness on abstractive summarization and translation. We also show how our method can be used under the common and realistic setting of distri bution shift for selective generation (analogous to selective prediction for classification) of high-quality outputs, while automatically abstaining from low-quality ones, enabling safer deployment of generative language models.

Layer Grafted Pre-training: Bridging Contrastive Learning And Masked Image Modeling For Label-Efficient Representations

Ziyu Jiang,Yinpeng Chen,Mengchen Liu,Dongdong Chen,Xiyang Dai,Lu Yuan,Zicheng Liu,Zhangyang Wang

Recently, both Contrastive Learning (CL) and Mask Image Modeling (MIM) demonstrate that self-supervision is powerful to learn good representations. However, naively combining them is far from success. In this paper, we start by making the empirical observation that a naive joint optimization of CL and MIM losses leads to conflicting gradient directions - more severe as the layers go deeper. This motivates us to shift the paradigm from combining loss at the end, to choosing the proper learning method per network layer. Inspired by experimental observations, we find that MIM and CL are suitable to lower and higher layers, respectively. We hence propose to combine them in a surprisingly simple, ``sequential cascade'' fashion: early layers are first trained under one MIM loss, on top of which latter layers continue to be trained under another CL loss. The proposed Layer Grafted Pre-training learns good visual representations that demonstrate superior label efficiency in downstream applications, in particular yielding strong few-shot performance besides linear evaluation. For instance, on ImageNet-1k, Layer Grafted Pre-training yields 65.5% Top-1 accuracy in terms of 1% few-shot learning with ViT-B/16, which improves MIM and CL baselines by 14.4% and 2.1% with no bells and whistles. The code is available at https://github.com/VITA-Group/layerGraftedPretraining_ICLR23.git.

Structural Adversarial Objectives for Self-Supervised Representation Learning

Xiao Zhang,Michael Maire

Within the framework of generative adversarial networks (GANs), we propose objectives that task the discriminator with additional structural modeling responsibilities. In combination with an efficient smoothness regularizer imposed on the network, these objectives guide the discriminator to learn to extract informative representations, while maintaining a generator capable of sampling from the domain. Specifically, we influence the features produced by the discriminator at two levels of granularity. At coarse scale, we impose a Gaussian assumption encouraging smoothness and diversified representation, while at finer scale, we group features forming local clusters. Experiments demonstrate that augmenting GANs with these self-supervised objectives suffices to produce discriminators which, evaluated in terms of representation learning, compete with networks trained by state-of-the-art contrastive approaches. Furthermore, operating within the GAN framework frees our system from the reliance on data augmentation schemes that is prevalent across purely contrastive representation learning methods.

VIMA: General Robot Manipulation with Multimodal Prompts

Yunfan Jiang,Agrim Gupta,Zichen Zhang,Guanzhi Wang,Yongqiang Dou,Yanjun Chen,Li Fei-Fei,Anima Anandkumar,Yuke Zhu,Linxi Fan

Prompt-based learning has emerged as a successful paradigm in natural language processing, where a single general-purpose language model can be instructed to perform any task specified by input prompts. Yet task specification in robotics comes in various forms, such as imitating one-shot demonstrations, following language instructions, and reaching visual goals. They are often considered different tasks and tackled by specialized models. This work shows that we can express a wide spectrum of robot manipulation tasks with *multimodal prompts*, interleaving textual and visual tokens. We design a transformer-based generalist robot agent, VIMA, that processes these prompts and outputs motor actions autoregressively. To train and evaluate VIMA, we develop a new simulation benchmark with thousands of procedurally-generated tabletop tasks with multimodal prompts, 600K+ expert trajectories for imitation learning, and four levels of evaluation protocol fo r systematic generalization. VIMA achieves strong scalability in both model capacity and data size. It outperforms prior SOTA methods in the hardest zero-shot generalization setting by up to 2.9x task success rate given the same training data. With 10x less training data, VIMA still performs 2.7x better than the top competing approach. Video demos are available at https://iclr3081.github.io/.

Discovering Latent Knowledge in Language Models Without Supervision

Collin Burns,Haotian Ye,Dan Klein,Jacob Steinhardt

Existing techniques for training language models can be misaligned with the truth: if we train models with imitation learning, they may reproduce errors that humans make; if we train them to generate text that humans rate highly, they may output errors that human evaluators can't detect. We propose circumventing this issue by directly finding latent knowledge inside the internal activations of a language model in a purely unsupervised way. Specifically, we introduce a method for accurately answering yes-no questions given only unlabeled model activations. It works by finding a direction in activation space that satisfies logical consistency properties, such as that a statement and its negation have opposite truth values. We show that despite using no supervision and no model outputs, our method can recover diverse knowledge represented in large language models: across 6 models and 10 question-answering datasets, it outperforms zero-shot accuracy by 4\% on average. We also find that it cuts prompt sensitivity in half and continues to maintain high accuracy even when models are prompted to generate incorrect answers. Our results provide an initial step toward discovering what language models know, distinct from what they say, even when we don't have access to explicit ground truth labels.

****

ModReduce: A Multi-Knowledge Distillation Framework with Online Learning

Yahya Saad Abbas,Abdelhakim Walid Badawy,Mohamed Mahfouz Shahawy,Samah Hussien,Samah Ayman,Hesham Mohamed Eraqi,Cherif Salama

Deep neural networks have produced revolutionary results in many applications; however, the computational resources required to use such models are expensive in terms of processing power and memory space. Research has been conducted in the field of knowledge distillation, aiming to enhance the performance of smaller models. Knowledge distillation transfers knowledge from large networks into smaller ones. Literature defines three types of knowledge that can be transferred: response-based, relational-based, and feature-based.

To the best of our knowledge, only transferring one or two types of knowledge has been studied before, but transferring all three remains unexplored. In this paper, we propose ModReduce, a framework designed to transfer the three knowledge types in a unified manner using a combination of offline and online knowledge distillation. Moreover, an extensive experimental study on the effects of combining different knowledge types on student models’ generalization and overall performance has been performed. Our experiments showed that ModReduce outperforms state-of-the-art knowledge distillation methods in terms of Average Relative Improvement.

Defending against Reconstruction attacks using Rényi Differential Privacy

Pierre Stock,Igor Shilov,Ilya Mironov,Alexandre Sablayrolles

Reconstruction attacks allow an adversary to regenerate data samples of the training set using access to only a trained model. It has been recently shown that simple heuristics can reconstruct data samples from language models, making this threat scenario an important aspect of model release. Differential privacy is a known solution to such attacks, but is often used with a large privacy budget (epsilon > 8) which does not translate to meaningful guarantees. In this paper we show that, for a same mechanism, we can derive privacy guarantees for reconstruction attacks that are better than the traditional ones from the literature. In particular, we show that larger privacy budgets do not provably protect against membership inference, but can still protect extraction of rare secrets. We design a method to efficiently run reconstruction attacks with lazy sampling and empirically show that we can surface at-risk training samples from non-private langua

ge models. We show experimentally that our guarantees hold on real-life language models trained with differential privacy for difficult scenarios, including GPT-2 finetuned on Wikitext-103.

Diffusion Adversarial Representation Learning for Self-supervised Vessel Segmentation
Boah Kim,Yujin Oh,Jong Chul Ye
Vessel segmentation in medical images is one of the important tasks in the diagnosis of vascular diseases and therapy planning. Although learning-based segmentation approaches have been extensively studied, a large amount of ground-truth labels are required in supervised methods and confusing background structures make neural networks hard to segment vessels in an unsupervised manner. To address this, here we introduce a novel diffusion adversarial representation learning (DARL) model that leverages a denoising diffusion probabilistic model with adversarial learning, and apply it to vessel segmentation. In particular, for self-supervised vessel segmentation, DARL learns the background signal using a diffusion module, which lets a generation module effectively provide vessel representations. Also, by adversarial learning based on the proposed switchable spatially-adaptive denormalization, our model estimates synthetic fake vessel images as well as vessel segmentation masks, which further makes the model capture vessel-relevant semantic information. Once the proposed model is trained, the model generates segmentation masks in a single step and can be applied to general vascular structure segmentation of coronary angiography and retinal images. Experimental results on various datasets show that our method significantly outperforms existing unsupervised and self-supervised vessel segmentation methods.

Reconciling Security and Communication Efficiency in Federated Learning
Karthik Prasad,Sayan Ghosh,Graham Cormode,Ilya Mironov,Ashkan Yousefpour,Pierre Stock
Cross-device Federated Learning is an increasingly popular machine learning setting to train a model by leveraging a large population of client devices with high privacy and security guarantees. However, communication efficiency remains a major bottleneck when scaling federated learning to production environments, particularly due to bandwidth constraints during uplink communication. In this paper, we formalize and address the problem of compressing client-to-server model updates under the Secure Aggregation primitive, a core component of Federated Learning pipelines that allows the server to aggregate the client updates without accessing them individually. In particular, we adapt standard scalar quantization and pruning methods to Secure Aggregation and propose Secure Indexing, a variant of Secure Aggregation that supports quantization for extreme compression. We establish state-of-the-art results on LEAF benchmarks in a secure Federated Learning setup with up to 40x compression in uplink communication with no meaningful loss in utility compared to uncompressed baselines.
****

Semantic Image Manipulation with Background-guided Internal Learning
Zhongping Zhang,Huiwen He,Bryan A. Plummer,Zhenyu Liao,Huayan Wang
Image manipulation has attracted a lot of interest due to its wide range of applications. Prior work modifies images either from low-level manipulation, such as image inpainting or through manual edits via paintbrushes and scribbles, or from high-level manipulation, employing deep generative networks to output an image conditioned on high-level semantic input. In this study, we propose Semantic Image Manipulation with Background-guided Internal Learning (SIMBIL), which combines high-level and low-level manipulation. Specifically, users can edit an image at the semantic level by applying changes on the scene graph. Then our model manipulates the image at the pixel level according to the modified scene graph. There are two major advantages of our approach. First, high-level manipulation requires less manual effort from the user compared to manipulating raw image pixels. Second, our low-level internal learning approach is scalable to images of various sizes without reliance on external visual datasets for training. We outperform the state-of-the-art in a quantitative and qualitative evaluation on CLEVR and

Visual Genome datasets. Experiments show around 8 points improvement of SSIM (RoI) on CLEVR and around 25% improvement of user evaluation accuracy on Visual Genome, demonstrating the effectiveness of our approach.

Pretraining the Vision Transformer using self-supervised methods for vision based Deep Reinforcement Learning

Manuel Goulão,Arlindo L. Oliveira

The Vision Transformer architecture has shown to be competitive in the computer vision (CV) space where it has dethroned convolution-based networks in several benchmarks. Nevertheless, Convolutional Neural Networks (CNN) remain the preferential architecture for the representation module in Reinforcement Learning. In this work, we study pretraining a Vision Transformer using several state-of-the-art self-supervised methods and assess data-efficiency gains from this training framework. We propose a new self-supervised learning method called TOV-VICReg that extends VICReg to better capture temporal relations between observations by adding a temporal order verification task. Furthermore, we evaluate the resultant encoders with Atari games in a sample-efficiency regime. Our results show that the vision transformer, when pretrained with TOV-VICReg, outperforms the other self-supervised methods but still struggles to overcome a CNN. Nevertheless, we were able to outperform a CNN in two of the ten games where we perform a 100k steps evaluation. Ultimately, we believe that such approaches in Deep Reinforcement Learning (DRL) might be the key to achieving new levels of performance as seen in natural language processing and computer vision.

****

Noise Injection Node Regularization for Robust Learning

Noam Itzhak Levi,Itay Mimouni Bloch,Marat Freytsis,Tomer Volansky

We introduce Noise Injection Node Regularization (NINR), a method of injecting structured noise into Deep Neural Networks (DNN) during the training stage, resulting in an emergent regularizing effect. We present theoretical and empirical evidence for substantial improvement in robustness against various test data perturbations for feed-forward DNNs when trained under NINR. The novelty in our approach comes from the interplay of adaptive noise injection and initialization conditions such that noise is the dominant driver of dynamics at the start of training. As it simply requires the addition of external nodes without altering the existing network structure or optimization algorithms, this method can be easily incorporated into many standard problem specifications. We find improved stability against a number of data perturbations, including domain shifts, with the most dramatic improvement obtained for unstructured noise, where our technique outperforms other existing methods such as dropout or L_2 regularization, in some cases. We further show that desirable generalization properties on clean data are generally maintained.

****

Q-Ensemble for Offline RL: Don't Scale the Ensemble, Scale the Batch Size

Alexander Nikulin,Vladislav Kurenkov,Denis Tarasov,Dmitry Akimov,Sergey Kolesnikov

Training large neural networks is known to be time-consuming, where learning duration may stretch up to days or weeks. To address this problem, the approach of large-batch optimization was introduced, demonstrating that scaling mini-batch sizes with appropriate learning rate adjustments may speed up the training process by orders of magnitude. While long training time was not typically a major issue for model-free deep offline RL algorithms, recently introduced Q-ensemble methods achieving state-of-the-art performance made this issue more relevant, notably extending the training duration. In this work, we demonstrate how large-batch optimization, typically overlooked in deep offline RL community, can benefit this class of methods. We show that simply scaling the mini-batch size and naively adjusting the learning rate allows for (1) a reduced size of the Q-ensemble, (2) stronger penalization of out-of-distribution actions, and (3) improved convergence time, effectively shortening training durations by 2.5x times on average.

****

Efficient Edge Inference by Selective Query

Anil Kag,Igor Fedorov,Aditya Gangrade,Paul Whatmough,Venkatesh Saligrama

Edge devices provide inference on predictive tasks to many end-users. However, deploying deep neural networks that achieve state-of-the-art accuracy on these devices is infeasible due to edge resource constraints. Nevertheless, cloud-only processing, the de-facto standard, is also problematic, since uploading large amounts of data imposes severe communication bottlenecks. We propose a novel end-to-end hybrid learning framework that allows the edge to selectively query only those hard examples that the cloud can classify correctly. Our framework optimizes over neural architectures and trains edge predictors and routing models so that the overall accuracy remains high while minimizing the overall latency. Training a hybrid learner is difficult since we lack annotations of hard edge-examples. We introduce a novel proxy supervision in this context and show that our method adapts seamlessly and near optimally across different latency regimes. On the ImageNet dataset, our proposed method deployed on a micro-controller unit exhibits 25% reduction in latency compared to cloud-only processing while suffering no excess loss.

****

Learning Intuitive Policies Using Action Features

Mingwei Ma,Jizhou Liu,Samuel Sokota,Max Kleiman-Weiner,Jakob Nicolaus Foerster

An unaddressed challenge in multi-agent coordination is to enable AI agents to exploit the semantic relationships between the features of actions and the features of observations. Humans take advantage of these relationships in highly intuitive ways. For instance, in the absence of a shared language, we might point to the object we desire or hold up our fingers to indicate how many objects we want. To address this challenge, we investigate the effect of network architecture on the propensity of learning algorithms to exploit these semantic relationships. Across a procedurally generated coordination task, we find that attention-based architectures that jointly process a featurized representation of observations and actions have a better inductive bias for zero-shot coordination. Through fine-grained evaluation and scenario analysis, we show that the resulting policies are human-interpretable. Moreover, such agents coordinate with people without training on any human data.

****

Differentially Private L_2-Heavy Hitters in the Sliding Window Model

Jeremiah Blocki,Seunghoon Lee,Tamalika Mukherjee,Samson Zhou

The data management of large companies often prioritize more recent data, as a source of higher accuracy prediction than outdated data. For example, the Facebook data policy retains user search histories for 6 months while the Google data retention policy states that browser information may be stored for up to 9 months. These policies are captured by the sliding window model, in which only the most recent W statistics form the underlying dataset. In this paper, we consider the problem of privately releasing the L_2-heavy hitters in the sliding window model, which include L_p-heavy hitters for $p\le 2$ and in some sense are the strongest possible guarantees that can be achieved using polylogarithmic space, but cannot be handled by existing techniques due to the sub-additivity of the L_2 norm. Moreover, existing non-private sliding window algorithms use the smooth histogram framework, which has high sensitivity. To overcome these barriers, we introduce the first differentially private algorithm for L_2-heavy hitters in the sliding window model by initiating a number of L_2-heavy hitter algorithms across the stream with significantly lower threshold. Similarly, we augment the algorithms with an approximate frequency tracking algorithm with significantly higher accuracy. We then use smooth sensitivity and statistical distance arguments to show that we can add noise proportional to an estimation of the L_2 norm. To the best of our knowledge, our techniques are the first to privately release statistics that are related to a sub-additive function in the sliding window model, and may be of independent interest to future differentially private algorithmic design in the sliding window model.

****

Scaling Convex Neural Networks with Burer-Monteiro Factorization

Arda Sahiner,Tolga Ergen,Batu Ozturkler,John M. Pauly,Morteza Mardani,Mert Pilan

ci
Recently, it has been demonstrated that a wide variety of (non) linear two-layer neural networks (such as two-layer perceptrons, convolutional networks, and self-attention) can be posed as equivalent convex optimization problems, with an induced regularizer which encourages low rank. However, this regularizer becomes prohibitively expensive to compute at moderate scales, impeding training convex neural networks. To this end, we propose applying the Burer-Monteiro factorization to convex neural networks, which for the first time enables a Burer-Monteiro perspective on neural networks with non-linearities. This factorization leads to an equivalent yet computationally tractable non-convex alternative with no spurious local minima. We develop a novel relative optimality bound of stationary points of the Burer-Monteiro factorization, thereby providing verifiable conditions under which any stationary point is a global optimum. Further, for the first time, we show that linear self-attention with sufficiently many heads has no spurious local minima. Our experiments demonstrate the utility and implications of the novel relative optimality bound for stationary points of the Burer-Monteiro factorization.

Human-level Atari 200x faster
Steven Kapturowski,Víctor Campos,Ray Jiang,Nemanja Rakicevic,Hado van Hasselt,Charles Blundell,Adria Puigdomenech Badia
The task of building general agents that perform well over a wide range of tasks has been an important goal in reinforcement learning since its inception. The problem has been subject of research of a large body of work, with performance frequently measured by observing scores over the wide range of environments contained in the Atari 57 benchmark. Agent57 was the first agent to surpass the human benchmark on all 57 games, but this came at the cost of poor data-efficiency, requiring nearly 80 billion frames of experience to achieve. Taking Agent57 as a starting point, we employ a diverse set of strategies to achieve a 200-fold reduction of experience needed to outperform the human baseline, within our novel agent MEME. We investigate a range of instabilities and bottlenecks we encountered while reducing the data regime, and propose effective solutions to build a more robust and efficient agent. We also demonstrate competitive performance with high-performing methods such as Muesli and MuZero. Our contributions aim to achieve faster propagation of learning signals related to rare events, stabilize learning under differing value scales, improve the neural network architecture, and make updates more robust under a rapidly-changing policy.

Wide Graph Neural Network
Jiaqi Sun,Lin Zhang,Guangyi Chen,Kun Zhang,Peng XU,Yujiu Yang
Usually, graph neural networks (GNNs) suffer from several problems, e.g., over-smoothing (in the spatial domain), poor flexibility (in the spectral domain), and low performance on heterophily (in both domains). In this paper, we provide a new GNN framework, called Wide Graph Neural Networks (WGNN) to solve these problems. It is motivated by our proposed unified view of GNNs from the perspective of dictionary learning. In light of this view, we formulate the graph learning in GNNs as learning representations from the dictionaries, where the fixed graph information is regarded as the dictionary and the trainable parameters are representations. Then, the dictionaries of spatial GNNs encode the adjacency matrix multiplication, while spectral ones sum its polynomials. Differently, WGNN directly concatenates all polynomials as the dictionary, where each polynomial is a sub-dictionary. Beyond polynomials, WGNN allows sub-dictionaries with an arbitrary size, for instance, the principal components of the adjacency matrix. This wide concatenation structure enjoys the great capability of avoiding over-smoothing and promoting flexibility, while the supplement of principal components can significantly improve the representation of heterophilic graphs. We provide a detailed theoretical analysis and conduct extensive experiments on eight datasets to demonstrate the superiority of the proposed WGNN.

Taming the Long Tail of Deep Probabilistic Forecasting

Mayank Sharan,Jedrzej Kozerawski,Rose Yu

Deep probabilistic forecasting is gaining attention in numerous applications from weather prognosis, through electricity consumption estimation, to autonomous vehicle trajectory prediction. However, existing approaches focus on improvements on average metrics without addressing the long tailed distribution of errors. In this work, we observe long tail behavior in the error distribution of state-of-the-art deep learning methods for probabilistic forecasting. We present two loss augmentation methods to reduce tailedness: Pareto Loss and Kurtosis Loss. Both methods are related to the concept of moments, which measures the shape of a distribution. Kurtosis Loss is based on a symmetric measure, the fourth moment. Pareto Loss is based on an asymmetric measure of right tailedness and models loss using a Generalized Pareto Distribution (GPD). We demonstrate the performance of our methods on several real-world datasets, including time series and spatiotemporal trajectories, achieving significant improvements on tail error metrics, while maintaining and even improving upon average error metrics.

Approximate Conditional Coverage via Neural Model Approximations

Allen Schmaltz,Danielle Rasooly

We propose a new approach for constructing prediction sets for Transformer networks via the strong signals for prediction reliability from KNN-based approximations. This enables a data-driven partitioning of the high-dimensional feature space and a new Inductive Venn Predictor for calibration, the Venn-ADMIT Predictor. Our approach more closely obtains approximate conditional coverage than recent work proposing adaptive and localized conformal score functions for deep networks. We analyze coverage on several representative natural language processing classification tasks, including class-imbalanced and distribution-shifted settings.

AUTOJOIN: EFFICIENT ADVERSARIAL TRAINING FOR ROBUST MANEUVERING VIA DENOISING AUTOEN- CODER AND JOINT LEARNING

Taylor Michael Villarreal,Bibek Poudel,Ryan Wickman,Yu Shen,Weizi Li

As a result of increasingly adopted machine learning algorithms and ubiquitous sensors, many ‘perception-to-control’ systems are developed and deployed. For these systems to be trustworthy, we need to improve their robustness with adversarial training being one approach. We propose a gradient-free adversarial training technique, called AutoJoin, which is a very simple yet effective and efficient approach to produce robust models for imaged-based maneuvering. Compared to other SOTA methods with testing on over 5M perturbed and clean images, AutoJoin achieves significant performance increases up to the 40% range under gradient-free perturbations while improving on clean performance up to 300%. Regarding efficiency, AutoJoin demonstrates strong advantages over other SOTA techniques by saving up to 83% time per training epoch and 90% training data. Although not the focus of AutoJoin, it even demonstrates superb ability in defending gradient-based attacks. The core idea of AutoJoin is to use a decoder attachment to the original regression model creating a denoising autoencoder within the architecture. This architecture allows the tasks ‘maneuvering’ and ‘denoising sensor input’ to be jointly learnt and reinforce each other’s performance.

Private Data Stream Analysis for Universal Symmetric Norm Estimation

Vladimir Braverman,Joel Manning,Steven Wu,Samson Zhou

We study how to release summary statistics on a data stream subject to the constraint of differential privacy. In particular, we focus on releasing the family of \emph{symmetric norms}, which are invariant under sign-flips and coordinate-wise permutations on an input data stream and include L_p norms, k-support norms, top-k norms, and the box norm as special cases. Although it may be possible to design and analyze a separate mechanism for each symmetric norm, we propose a general parametrizable framework that differentially privately releases a number of sufficient statistics from which the approximation of all symmetric norms can be simultaneously computed. Our framework partitions the coordinates of the underlying frequency vector into different levels based on their magnitude and releases approximate frequencies for the ``heavy'' coordinates in important leve

ls and releases approximate level sizes for the ``light'' coordinates in important levels. Surprisingly, our mechanism allows for the release of an \emph{arbitrary} number of symmetric norm approximations without any overhead or additional loss in privacy. Moreover, our mechanism permits $(1+\alpha)$-approximation to each of the symmetric norms and can be implemented using sublinear space in the streaming model for many regimes of the accuracy and privacy parameters.

StarGraph: Knowledge Representation Learning based on Incomplete Two-hop Subgraph
Hongzhu Li,Xiangrui Gao,Linhui Feng,Yafeng Deng,Yuhui Yin
Conventional representation learning algorithms for knowledge graphs (KG) map each entity to a unique embedding vector, ignoring the rich information contained in the neighborhood. We propose a method named StarGraph, which gives a novel way to utilize the neighborhood information for large-scale knowledge graphs to obtain entity representations. An incomplete two-hop neighborhood subgraph for each target node is at first generated, then processed by a modified self-attention network to obtain the entity representation, which is used to replace the entity embedding in conventional methods. We achieved SOTA performance on ogbl-wikikg2 and got competitive results on fb15k-237. The experimental results proves that StarGraph is efficient in parameters, and the improvement made on ogbl-wikikg2 demonstrates its great effectiveness of representation learning on large-scale knowledge graphs.

Temporal Domain Generalization with Drift-Aware Dynamic Neural Networks
Guangji Bai,Chen Ling,Liang Zhao
Temporal domain generalization is a promising yet extremely challenging area where the goal is to learn models under temporally changing data distributions and generalize to unseen data distributions following the trends of the change. The advancement of this area is challenged by: 1) characterizing data distribution drift and its impacts on models, 2) expressiveness in tracking the model dynamics, and 3) theoretical guarantee on the performance. To address them, we propose a Temporal Domain Generalization with Drift-Aware Dynamic Neural Network (DRAIN) framework. Specifically, we formulate the problem into a Bayesian framework that jointly models the relation between data and model dynamics. We then build a recurrent graph generation scenario to characterize the dynamic graph-structured neural networks learned across different time points. It captures the temporal drift of model parameters and data distributions and can predict models in the future without the presence of future data. In addition, we explore theoretical guarantees of the model performance under the challenging temporal DG setting and provide theoretical analysis, including uncertainty and generalization error. Finally, extensive experiments on several real-world benchmarks with temporal drift demonstrate the proposed method’s effectiveness and efficiency.
****
Incompatibility Clustering as a Defense Against Backdoor Poisoning Attacks
Charles Jin,Melinda Sun,Martin Rinard
We propose a novel clustering mechanism based on an incompatibility property between subsets of data that emerges during model training. This mechanism partitions the dataset into subsets that generalize only to themselves, i.e., training on one subset does not improve performance on the other subsets. Leveraging the interaction between the dataset and the training process, our clustering mechanism partitions datasets into clusters that are defined by—and therefore meaningful to—the objective of the training process.

We apply our clustering mechanism to defend against data poisoning attacks, in which the attacker injects malicious poisoned data into the training dataset to affect the trained model's output. Our evaluation focuses on backdoor attacks against deep neural networks trained to perform image classification using the GTSRB and CIFAR-10 datasets. Our results show that (1) these attacks produce poisoned datasets in which the poisoned and clean data are incompatible and (2) our technique successfully identifies (and removes) the poisoned data. In an end-to-end evaluation, our defense reduces the attack success rate to below 1% on 134 out of 165 scenarios, with only a 2% drop in clean accuracy on CIFAR-10 and a negligible drop in clean accuracy on GTSRB.

Enforcing Hard Constraints with Soft Barriers: Safe Reinforcement Learning in Unknown Stochastic Environments

Yixuan Wang,Simon Sinong Zhan,Ruochen Jiao,Zhilu Wang,Wanxin Jin,Zhuoran Yang,Zhaoran Wang,Chao Huang,Qi Zhu

It is quite challenging to ensure the safety of reinforcement learning (RL) agents in an unknown and stochastic environment under hard constraints that require the system state not to reach certain specified unsafe regions. Many popular safe RL methods such as those based on the Constrained Markov Decision Process (CMDP) paradigm formulate safety violations in a cost function and try to constrain the expectation of cumulative cost under a threshold. However, it is often difficult to effectively capture and enforce hard reachability-based safety constraints indirectly with such constraints on safety violation cost. In this work, we leverage the notion of barrier function to explicitly encode the hard safety constraints, and given that the environment is unknown, relax them to our design of \emph{generative-model-based soft barrier functions}. Based on such soft barriers, we propose a safe RL approach that can jointly learn the environment and optimize the control policy, while effectively avoiding the unsafe regions with safety probability optimization.

Experiments on a set of examples demonstrate that our approach can effectively enforce hard safety constraints and significantly outperform CMDP-based baseline methods in system safe rate measured via simulations.

Integrating Episodic and Global Novelty Bonuses for Efficient Exploration

Mikael Henaff,Minqi Jiang,Roberta Raileanu

Exploration in environments which differ across episodes has received increasing attention in recent years. Current methods use some combination of global novelty bonuses, computed using the agent's entire training experience, and episodic novelty bonuses, computed using only experience from the current episode. However, the use of these two types of bonuses has been ad-hoc and poorly understood. In this work, we first shed light on the behavior these two kinds of bonuses on hard exploration tasks through easily interpretable examples. We find that the two types of bonuses succeed in different settings, with episodic bonuses being most effective when there is little shared structure between environments and global bonuses being effective when more structure is shared. We also find that combining the two bonuses leads to more robust behavior across both of these settings. Motivated by these findings, we then investigate different algorithmic choices for defining and combining function approximation-based global and episodic bonuses. This results in a new algorithm which sets a new state of the art across 18 tasks from the MiniHack suite used in prior work. Our code is public at \url{web-link}.

A Unified Approach to Reinforcement Learning, Quantal Response Equilibria, and Two-Player Zero-Sum Games

Samuel Sokota,Ryan D'Orazio,J Zico Kolter,Nicolas Loizou,Marc Lanctot,Ioannis Mitliagkas,Noam Brown,Christian Kroer

This work studies an algorithm, which we call magnetic mirror descent, that is inspired by mirror descent and the non-Euclidean proximal gradient algorithm. Our contribution is demonstrating the virtues of magnetic mirror descent as both an equilibrium solver and as an approach to reinforcement learning in two-player zero-sum games. These virtues include: 1) Being the first quantal response equilibria solver to achieve linear convergence for extensive-form games with first order feedback; 2) Being the first standard reinforcement learning algorithm to achieve empirically competitive results with CFR in tabular settings; 3) Achieving favorable performance in 3x3 Dark Hex and Phantom Tic-Tac-Toe as a self-play deep reinforcement learning algorithm.

Dynamics-aware Skill Generation from Behaviourally Diverse Demonstrations
Shibei Zhu,Rituraj Kaushik,Samuel Kaski,Ville Kyrki
Learning from demonstrations (LfD) provides a data-efficient way for a robot to learn a task by observing humans performing the task, without the need for an explicit reward function. However, in many real-world scenarios (e.g., driving a car) humans often perform the same task in different ways, motivated not only by the primary objective of the task (e.g., reaching the destination safely) but also by their individual preferences (e.g., different driving behaviours), leading to a multi-modal distribution of demonstrations. In this work, we consider an LfD problem, where the reward function for the main objective of the task is known to the learning agent; however, the individual preferences leading to the variations in the demonstrations are unknown. We show that current LfD approaches learn policies that either track a single mode or the mean of the demonstration distribution. In contrast, we propose an algorithm to learn a diverse set of policies to perform the task, capturing the different modes in the demonstrations due to the diverse preferences of the individuals. We show that we can build a parameterised solution space that captures different behaviour patterns from the demonstrations. Then, a set of policies can be generated in solution space that generate a diverse range of behaviours that go beyond the provided demonstrations.

DiP-GNN: Discriminative Pre-Training of Graph Neural Networks
Simiao Zuo,Haoming Jiang,Qingyu Yin,Xianfeng Tang,Bing Yin,Tuo Zhao
Graph neural network (GNN) pre-training methods have been proposed to enhance the power of GNNs. Specifically, a GNN is first pre-trained on a large-scale unlabeled graph and then fine-tuned on a separate small labeled graph for downstream applications, such as node classification. One popular pre-training method is to mask out a proportion of the edges, and a GNN is trained to recover them. However, such a generative method suffers from graph mismatch. That is, the masked graph input to the GNN deviates from the original graph. To alleviate this issue, we propose DiP-GNN (Discriminative Pre-training of Graph Neural Networks). Specifically, we train a generator to recover identities of the masked edges, and simultaneously, we train a discriminator to distinguish the generated edges from the original graph's edges. The discriminator is subsequently used for downstream fine-tuning. In our pre-training framework, the graph seen by the discriminator better matches the original graph because the generator can recover a proportion of the masked edges. Extensive experiments on large-scale homogeneous and heterogeneous graphs demonstrate the effectiveness of the proposed framework. Our code will be publicly available.

Learning to Act through Activation Function Optimization in Random Networks
Joachim Winther Pedersen,Sebastian Risi
Biological neural networks are characterised by a high degree of neural diversity, a trait that artificial neural networks (ANNs) generally lack.
Additionally, learning in ANNs is typically synonymous with only modifying the strengths of connection weights.
However, there is much evidence from neuroscience that different classes of neurons each have crucial roles in the information processing done by the network. In nature, each neuron is a dynamical system that is a powerful information processor in its own right. In this paper we ask the question, how well can ANNs learn to perform reinforcement learning tasks only through the optimization of neural activation functions, without any weight optimization?
We demonstrate the viability of the method and show that the neural parameters are expressive enough to allow learning three different continuous control tasks without weight optimization.
These results open up for more possibilities for synergies between synaptic and neural optimization in ANNs in the future.

Safer Reinforcement Learning with Counterexample-guided Offline Training
Xiaotong Ji,Antonio Filieri
Safe reinforcement learning (RL) aims at addressing the limitation of reinforcem

ent learning in safety-critical scenarios, where failures during learning may incur high costs. Several methods exist to incorporate external knowledge or to use proximal sensor data to limit the exploration of unsafe states. However, dealing with (partially) unknown environments and dynamics, where an agent must discover safety threats during exploration, remains challenging. In this paper, we propose a method to abstract hybrid continuous-discrete systems into compact surrogate models representing the safety-relevant knowledge acquired by the agent at any time during exploration. We exploit probabilistic counterexamples generation to synthesise minimal, partial simulation environments from the surrogate model where the agent can train offline to produce heuristic strategies to minimise the risk of visiting unsafe states during subsequent online exploration. We demonstrate our method's effectiveness in increasing the agent's exploration safety on a selection of OpenAI Gym benchmarks.
****
Pitfalls of Gaussians as a noise distribution in NCE
Holden Lee,Chirag Pabbaraju,Anish Prasad Sevekari,Andrej Risteski
Noise Contrastive Estimation (NCE) is a popular approach for learning probability density functions parameterized up to a constant of proportionality. The main idea is to design a classification problem for distinguishing training data from samples from an (easy-to-sample) noise distribution q, in a manner that avoids having to calculate a partition function. It is well-known that the choice of q can severely impact the computational and statistical efficiency of NCE. In practice, a common choice for q is a Gaussian which matches the mean and covariance of the data.

In this paper, we show that such a choice can result in an exponentially bad (in the ambient dimension) conditioning of the Hessian of the loss - even for very simple data distributions. As a consequence, both the statistical and algorithmic complexity for such a choice of q will be problematic in practice - suggesting that more complex noise distributions are essential to the success of NCE.
****
Scaling Laws for a Multi-Agent Reinforcement Learning Model
Oren Neumann,Claudius Gros
The recent observation of neural power-law scaling relations has made a significant impact in the field of deep learning. A substantial amount of attention has been dedicated as a consequence to the description of scaling laws, although mostly for supervised learning and only to a reduced extent for reinforcement learning frameworks. In this paper we present an extensive study of performance scaling for a cornerstone reinforcement learning algorithm, AlphaZero. On the basis of a relationship between Elo rating, playing strength and power-law scaling, we train AlphaZero agents on the games Connect Four and Pentago and analyze their performance. We find that player strength scales as a power law in neural network parameter count when not bottlenecked by available compute, and as a power of compute when training optimally sized agents. We observe nearly identical scaling exponents for both games. Combining the two observed scaling laws we obtain a power law relating optimal size to compute similar to the ones observed for language models. We find that the predicted scaling of optimal neural network size fits our data for both games. This scaling law implies that previously published state-of-the-art game-playing models are significantly smaller than their optimal size, given the respective compute budgets. We also show that large AlphaZero models are more sample efficient, performing better than smaller models with the same amount of training data.
****
Risk Control for Online Learning Models
Shai Feldman,Liran Ringel,Stephen Bates,Yaniv Romano
To provide rigorous uncertainty quantification for online learning models, we develop a framework for constructing uncertainty sets that provably control risk---such as coverage of confidence intervals, false negative rate, or F1 score---in the online setting. This extends conformal prediction to apply to a larger class of online learning problems. Our method guarantees risk control at any user-sp

ecified level even when the underlying data distribution shifts drastically, even adversarially, over time in an unknown fashion.
The technique we propose is highly flexible as it can be applied with any base online learning algorithm (e.g., a deep neural network trained online), requiring minimal implementation effort and essentially zero additional computational cost.
We further extend our approach to control multiple risks simultaneously, so the prediction sets we generate are valid for all given risks.
To demonstrate the utility of our method, we conduct experiments on real-world tabular time-series data sets showing that the proposed method rigorously controls various natural risks.
Furthermore, we show how to construct valid intervals for an online image-depth estimation problem that previous sequential calibration schemes cannot handle.

Federated Learning with Openset Noisy Labels
Zonglin Di,Zhaowei Zhu,Xin Eric Wang,Yang Liu
Federated learning is a learning paradigm that allows the central server to learn from different data sources while keeping the data private at local. Without controlling and monitoring the local data collection process, it is highly likely that the locally available training labels are noisy, just as in a centralized data collection effort. Moreover, different clients may hold samples within different label spaces. The noisy label space is likely to be different from the unobservable clean label space, resulting in openset noisy labels. In this work, we study the challenge of federated learning from clients with openset noisy labels. We observe that many existing solutions, e.g., loss correction, in the noisy label literature cannot achieve their originally claimed effect in local training. A central contribution of this work is to propose an approach that communicates globally randomly selected ``contrastive labels" among clients to prevent local models from memorizing the openset noise patterns individually. Randomized label generations are applied during label sharing to facilitate access to the contrastive labels while ensuring differential privacy (DP). Both the DP guarantee and the effectiveness of our approach are theoretically guaranteed. Compared with several baseline methods, our solution shows its efficiency in several public benchmarks and real-world datasets under different noise ratios and noise models.

Perfectly Secure Steganography Using Minimum Entropy Coupling
Christian Schroeder de Witt,Samuel Sokota,J Zico Kolter,Jakob Nicolaus Foerster,Martin Strohmeier
Steganography is the practice of encoding secret information into innocuous content in such a manner that an adversarial third party would not realize that there is hidden meaning. While this problem has classically been studied in security literature, recent advances in generative models have led to a shared interest among security and machine learning researchers in developing scalable steganography techniques. In this work, we show that a steganography procedure is perfectly secure under Cachin (1998)'s information theoretic-model of steganography if and only if it is induced by a coupling. Furthermore, we show that, among perfectly secure procedures, a procedure is maximally efficient if and only if it is induced by a minimum entropy coupling. These insights yield what are, to the best of our knowledge, the first steganography algorithms to achieve perfect security guarantees with non-trivial efficiency; additionally, these algorithms are highly scalable. To provide empirical validation, we compare a minimum entropy coupling-based approach to three modern baselines---arithmetic coding, Meteor, and adaptive dynamic grouping---using GPT-2, WaveRNN, and Image Transformer as communication channels. We find that the minimum entropy coupling-based approach achieves superior encoding efficiency, despite its stronger security constraints. In aggregate, these results suggest that it may be natural to view information-theoretic steganography through the lens of minimum entropy coupling.

The power of choices in decision tree learning

Guy Blanc,Jane Lange,Chirag Pabbaraju,Li-Yang Tan

We propose a simple and natural generalization of standard and empirically successful decision tree learning algorithms such as ID3, C4.5, and CART.   These classic algorithms, which have been central to machine learning for decades, are greedy in nature: they grow a decision tree by iteratively splitting on the "best" attribute. We augment these algorithms with an additional greediness parameter k and our resulting algorithm, Top-k, considers the k best attributes as possible splits instead of just the single best attribute.

We demonstrate, theoretically and empirically, the power of this simple generalization. We first prove a sharp greediness hierarchy theorem showing that for every $k\in \mathbb{N}$, Top-$(k+1)$ can be much more powerful than Top-k: there are data distributions for which the former achieves accuracy $1-\epsilon$, whereas the latter only achieves accuracy $\frac{1}{2}+\epsilon$. We then show, through extensive experiments, that Top-k compares favorably with the two main approaches to decision tree learning: classic greedy algorithms and more recent "optimal decision tree" algorithms. On one hand, Top-k consistently enjoys significant accuracy gains over the greedy algorithms across a wide range of benchmarks, at the cost of only a mild training slowdown. On the other hand, Top-k is markedly more scalable than optimal decision tree algorithms, and is able to handle dataset and feature set sizes that remain beyond the reach of these algorithms.

Taken together, our results highlight the potential practical impact of the power of choices in decision tree learning.

****

Identifiability of Label Noise Transition Matrix

Yang Liu,Hao Cheng,Kun Zhang

The noise transition matrix plays a central role in the problem of learning with noisy labels. Among many other reasons, a large number of existing solutions rely on access to it. Identifying and estimating the transition matrix without ground truth labels is a critical and challenging task. When label noise transition depends on each instance, the problem of identifying the instance-dependent noise transition matrix becomes substantially more challenging. Despite recent works proposing solutions for learning from instance-dependent noisy labels, the field lacks a unified understanding of when such a problem remains identifiable. The goal of this paper is to characterize the identifiability of the label noise transition matrix. Building on Kruskal's identifiability results, we show the necessity of multiple noisy labels in identifying the noise transition matrix for the generic case at the instance level. We further instantiate the results to relate to the successes of the state-of-the-art solutions and how additional assumptions alleviated the requirement of multiple noisy labels. Our result also reveals that disentangled features are helpful in the above identification task and we provide empirical evidence.

Learning from Others: Similarity-based Regularization for Mitigating Artifacts

Reda Igbaria,Yonatan Belinkov

Common methods for mitigating spurious correlations in natural language understanding (NLU) usually operate in the output space, encouraging a main model to behave differently from a bias model by down-weighing examples where the bias model is confident.

While improving out of distribution (OOD) performance, it was recently observed that the internal representations of the presumably debiased models are actually more, rather than less biased.

We propose SimgReg, a new method for debiasing internal model components via similarity-based regularization, in representation space: We encourage the model to learn representations that are either similar to an unbiased model or different from a biased model. We experiment with three NLU tasks and different kinds of biases.

We find that SimReg improves OOD performance, with little in-distribution degrad ation. Moreover, the representations learned by SimReg are less biased than in other methods.

Calibrating Transformers via Sparse Gaussian Processes
Wenlong Chen,Yingzhen Li
Transformer models have achieved profound success in prediction tasks in a wide range of applications in natural language processing, speech recognition and computer vision. Extending Transformer’s success to safety-critical domains requires calibrated uncertainty estimation which remains under-explored. To address this, we propose Sparse Gaussian Process attention (SGPA), which performs Bayesian inference directly in the output space of multi-head attention blocks (MHAs) in transformer to calibrate its uncertainty. It replaces the scaled dot-product operation with a valid symmetric kernel and uses sparse Gaussian processes (SGP) techniques to approximate the posterior processes of MHA outputs. Empirically, on a suite of prediction tasks on text, images and graphs, SGPA-based Transformers achieve competitive predictive accuracy, while noticeably improving both in-distribution calibration and out-of-distribution robustness and detection.

****

Model Transferability with Responsive Decision Subjects
Yang Liu,Yatong Chen,Zeyu Tang,Kun Zhang
This paper studies model transferability when human decision subjects respond to a deployed machine learning model. In our setting, an agent or a user corresponds to a sample (X,Y) drawn from a distribution $\mathcal{D}$ and will face a model h and its classification result $h(X)$. Agents can modify X to adapt to h, which will incur a distribution shift on (X,Y). Therefore, when training h, the learner will need to consider the subsequently ``induced" distribution when the output model is deployed. Our formulation is motivated by applications where the deployed machine learning models interact with human agents, and will ultimately face \emph{responsive} and interactive data distributions. We formalize the discussions of the transferability of a model by studying how the model trained on the available source distribution (data) would translate to the performance on the induced domain. We provide both upper bounds for the performance gap due to the induced domain shift, as well as lower bound for the trade-offs that a classifier has to suffer on either the source training distribution or the induced target distribution. We provide further instantiated analysis for two popular domain adaptation settings with covariate shift and target shift.

****

Red PANDA: Disambiguating Image Anomaly Detection by Removing Nuisance Factors
Niv Cohen,Jonathan Kahana,Yedid Hoshen
Anomaly detection methods strive to discover patterns that differ from the norm in a meaningful way. This goal is ambiguous as different human operators may find different attributes meaningful. An image differing from the norm by an attribute such as pose may be considered anomalous by some operators while others may consider the attribute irrelevant. Breaking from previous research, we present a new anomaly detection method that allows operators to exclude an attribute when detecting anomalies. Our approach aims to learn representations which do not contain information regarding such nuisance attributes. Anomaly scoring is performed using a density-based approach. Importantly, our approach does not require specifying the attributes where anomalies could appear, which is typically impossible in anomaly detection, but only attributes to ignore. An empirical investigation is presented verifying the effectiveness of our approach.

****

Abstracting Imperfect Information Away from Two-Player Zero-Sum Games
Samuel Sokota,Ryan D'Orazio,Chun Kai Ling,David J Wu,J Zico Kolter,Noam Brown
In their seminal work, Nayyar et al. (2013) showed that imperfect information can be abstracted away from common-payoff games by having players publicly announce their policies as they play. This insight underpins sound solvers and decision-time planning algorithms for common-payoff games. Unfortunately, a naive application of the same insight to two-player zero-sum games fails because Nash equili

bria of the game with public policy announcements may not correspond to Nash equilibria of the original game. As a consequence, existing sound decision-time planning algorithms require complicated additional mechanisms that have unappealing properties. The main contribution of this work is showing that certain regularized equilibria do not possess the aforementioned non-correspondence problem---thus, computing them can be treated as perfect information problems. This result yields a simplified framework for decision-time planning in two-player zero-sum games, void of the unappealing properties that plague existing decision-time planning algorithms.

Is Attention All That NeRF Needs?

Mukund Varma T,Peihao Wang,Xuxi Chen,Tianlong Chen,Subhashini Venugopalan,Zhangyang Wang

We present Generalizable NeRF Transformer (GNT), a transformer-based architecture that reconstructs Neural Radiance Fields (NeRFs) and learns to render novel views on the fly from source views. While prior works on NeRFs optimize a scene representation by inverting a handcrafted rendering equation, GNT achieves neural representation and rendering that generalizes across scenes using transformers at two stages. (1) The view transformer leverages multi-view geometry as an inductive bias for attention-based scene representation, and predicts coordinate-aligned features by aggregating information from epipolar lines on the neighboring views. (2) The ray transformer renders novel views using attention to decode the features from the view transformer along the sampled points during ray marching. Our experiments demonstrate that when optimized on a single scene, GNT can successfully reconstruct NeRF without an explicit rendering formula due to the learned ray renderer. When trained on multiple scenes, GNT consistently achieves state-of-the-art performance when transferring to unseen scenes and outperform all other methods by ~10% on average. Our analysis of the learned attention maps to infer depth and occlusion indicate that attention enables learning a physically-grounded rendering. Our results show the promise of transformers as a universal modeling tool for graphics. Please refer to our project page for video results: https://vita-group.github.io/GNT/

Stochastic No-regret Learning for General Games with Variance Reduction

Yichi Zhou,Fang Kong,Shuai Li

We show that a stochastic version of optimistic mirror descent (OMD), a variant of mirror descent with recency bias, converges fast in general games. More specifically, with our algorithm, the individual regret of each player vanishes at a speed of $O(1/T^{3/4})$ and the sum of all players' regret vanishes at a speed of $O(1/T)$, which is an improvement upon the $O(1/\sqrt{T})$ convergence rate of prior stochastic algorithms, where T is the number of interaction rounds. Due to the advantage of stochastic methods in the computational cost, we significantly improve the time complexity over the deterministic algorithms to approximate coarse correlated equilibrium. To achieve lower time complexity, we equip the stochastic version of OMD in \cite{alacaoglu2021stochastic} with a novel low-variance Monte-Carlo estimator. Our algorithm extends previous works \cite{alacaoglu2021stochastic,carmon2019variance} from two-player zero-sum games to general games.

The Dark Side of AutoML: Towards Architectural Backdoor Search

Ren Pang,Changjiang Li,Zhaohan Xi,Shouling Ji,Ting Wang

This paper asks the intriguing question: is it possible to exploit neural architecture search (NAS) as a new attack vector to launch previously improbable attacks? Specifically, we present EVAS, a new attack that leverages NAS to find neural architectures with inherent backdoors and exploits such vulnerability using input-aware triggers. Compared with existing attacks, EVAS demonstrates many interesting properties: (i) it does not require polluting training data or perturbing model parameters; (ii) it is agnostic to downstream fine-tuning or even re-training from scratch; (iii) it naturally evades defenses that rely on inspecting model parameters or training data. With extensive evaluation on benchmark datasets

, we show that EVAS features high evasiveness, transferability, and robustness, thereby expanding the adversary's design spectrum. We further characterize the mechanisms underlying EVAS, which are possibly explainable by architecture-level ``shortcuts'' that recognize trigger patterns. This work showcases that NAS can be exploited in a harmful way to find architectures with inherent backdoor vulnerability. The code is available at https://github.com/ain-soph/nas_backdoor.

Generalization and Estimation Error Bounds for Model-based Neural Networks

Avner Shultzman,Eyar Azar,Miguel R. D. Rodrigues,Yonina C. Eldar

Model-based neural networks provide unparalleled performance for various tasks, such as sparse coding and compressed sensing problems. Due to the strong connection with the sensing model, these networks are interpretable and inherit prior structure of the problem. In practice, model-based neural networks exhibit higher generalization capability compared to ReLU neural networks. However, this phenomenon was not addressed theoretically. Here, we leverage complexity measures including the global and local Rademacher complexities, in order to provide upper bounds on the generalization and estimation errors of model-based networks. We show that the generalization abilities of model-based networks for sparse recovery outperform those of regular ReLU networks, and derive practical design rules that allow to construct model-based networks with guaranteed high generalization. We demonstrate through a series of experiments that our theoretical insights shed light on a few behaviours experienced in practice, including the fact that ISTA and ADMM networks exhibit higher generalization abilities (especially for small number of training samples), compared to ReLU networks.

Isometric Representations in Neural Networks Improve Robustness

Kosio Beshkov,Jonas Verhellen,Mikkel Elle Lepperød

Artificial and biological agents are unable to learn given completely random and unstructured data. The structure of data is encoded in the distance or similarity relationships between data points. In the context of neural networks, the neuronal activity within a layer forms a representation reflecting the transformation that the layer implements on its inputs. In order to utilize the structure in the data in a truthful manner, such representations should reflect the input distances and thus be continuous and isometric. Supporting this statement, recent findings in neuroscience propose that generalization and robustness are tied to neural representations being continuously differentiable. However, in machine learning, most algorithms lack robustness and are generally thought to rely on aspects of the data that differ from those that humans use, as is commonly seen in adversarial attacks.

During cross-entropy classification, the metric and structural properties of network representations are usually broken both between and within classes. This side effect from training can lead to instabilities under perturbations near locations where such structure is not preserved. One of the standard solutions to obtain robustness is to train specifically by introducing perturbations in the training data. This leads to networks that are particularly robust to specific training perturbations but not necessarily to general perturbations. While adding ad hoc regularization terms to improve robustness has become common practice, to our knowledge, forcing representations to preserve the metric structure of the input data as a stabilising mechanism has not yet been introduced.

In this work, we train neural networks to perform classification while simultaneously maintaining the metric structure within each class, leading to continuous and isometric within-class representations. We show that such network representations turn out to be a beneficial component for making accurate and robust inferences about the world. By stacking layers with this property we provide the community with an network architecture that facilitates hierarchical manipulation of internal neural representations. Finally, we verify that our isometric regularization term improves the robustness to adversarial attacks on MNIST.

TAN without a burn: Scaling laws of DP-SGD
Tom Sander,Pierre Stock,Alexandre Sablayrolles

Differentially Private methods for training Deep Neural Networks (DNNs) have progressed recently, in particular with the use of massive batches and aggregated data augmentations for a large number of steps. These techniques require much more compute than their non-private counterparts, shifting the traditional privacy-accuracy trade-off to a privacy-accuracy-compute trade-off and making hyper-parameter search virtually impossible for realistic scenarios. In this work, we decouple privacy analysis and experimental behavior of noisy training to explore the trade-off with minimal computational requirements. We first use the tools of Rényi Differential Privacy (RDP) to show that the privacy budget, when not overcharged, only depends on the total amount of noise (TAN) injected throughout training. We then derive scaling laws for training models with DP-SGD to optimize hyper-parameters with more than a $100\times$ reduction in computational budget. We apply the proposed method on CIFAR-10 and ImageNet and, in particular, strongly improve the state-of-the-art on ImageNet with a $+9$ points gain in accuracy for a privacy budget $\varepsilon=8$.

****

A sampling framework for value-based reinforcement learning
Frank Shih,Faming Liang

Value-based algorithms have achieved great successes in solving Reinforcement Learning problems via minimizing the mean squared Bellman error (MSBE). Temporal-difference (TD) algorithms such as Q-learning and SARSA often use stochastic gradient descent based optimization approaches to estimate the value function parameters, but fail to quantify their uncertainties. In our work, under the Kalman filtering paradigm, we establish a novel and scalable sampling framework based on stochastic gradient Markov chain Monte Carlo, which allows us to efficiently generate samples from the posterior distribution of deep neural network parameters. For TD-learning with both linear and nonlinear function approximation, we prove that the proposed algorithm converges to a stationary distribution, which allows us to measure uncertainties of the value function and its parameters.

The Curse of Low Task Diversity: On the Failure of Transfer Learning to Outperform MAML and their Empirical Equivalence
Brando Miranda,Patrick Yu,Yu-Xiong Wang,Oluwasanmi O Koyejo

Recently, it has been observed that a transfer learning solution might be all we need to solve many few-shot learning benchmarks -- thus raising important questions about when and how meta-learning algorithms should be deployed.
In this paper, we seek to clarify these questions by
1. proposing a novel metric -- the {\it diversity coefficient} -- to measure the diversity of tasks in a few-shot learning benchmark and
2. by comparing MAML and transfer learning under fair conditions (same architecture, same optimizer and all models trained to convergence).
Using the diversity coefficient, we show that the popular MiniImagenet and Cifar-fs few-shot learning benchmarks have low diversity.
This novel insight contextualizes claims that transfer learning solutions are better than meta-learned solutions in the regime of low diversity under a fair comparison.
Specifically, we empirically find that a low diversity coefficient correlates with a high similarity between transfer learning and Model-Agnostic Meta-Learning (MAML) learned solutions in terms of accuracy at meta-test time and classification layer similarity (using feature based distance metrics like SVCCA, PWCCA, CKA, and OPD).
To further support our claim, we find this meta-test accuracy holds even as the model size changes.
Therefore, we conclude that in the low diversity regime, MAML and transfer learning have equivalent meta-test performance when both are compared fairly.
We also hope our work inspires more thoughtful constructions and quantitative evaluations of meta-learning benchmarks in the future.

Bi-Stride Multi-Scale Graph Neural Network for Mesh-Based Physical Simulation

Yadi Cao,Menglei Chai,Minchen Li,Chenfanfu Jiang

Learning physical systems on unstructured meshes by flat Graph neural networks (GNNs) faces the challenge of modeling the long-range interactions due to the scaling complexity w.r.t. the number of nodes, limiting the generalization under mesh refinement. On regular grids, the convolutional neural networks (CNNs) with a U-net structure can resolve this challenge by efficient stride, pooling, and upsampling operations. Nonetheless, these tools are much less developed for graph neural networks (GNNs), especially when GNNs are employed for learning large-scale mesh-based physics. The challenges arise from the highly irregular meshes and the lack of effective ways to construct the multi-level structure without losing connectivity. Inspired by the bipartite graph determination algorithm, we introduce Bi-Stride Multi-Scale Graph Neural Network (BSMS-GNN) by proposing \textit{bi-stride} as a simple pooling strategy for building the multi-level GNN. \textit{Bi-stride} pools nodes by striding every other BFS frontier; it 1) works robustly on any challenging mesh in the wild, 2) avoids using a mesh generator at coarser levels, 3) avoids the spatial proximity for building coarser levels, and 4) uses non-parametrized aggregating/returning instead of MLPs during pooling and unpooling. Experiments show that our framework significantly outperforms the state-of-the-art method's computational efficiency in representative physics-based simulation cases.

Spatially Resolved Temporal Networks: Online Unsupervised Representation Learning of High Frequency Time Series

Faris Faried Gulamali,Ashwin Shreekant Sawant,Ira Hofer,Matt Levin,Karandeep Singh,Benjamin S Glicksberg,Girish N Nadkarni

Univariate high-frequency time series are dominant data sources for many medical, economic and environmental applications. In many of these domains, the time series are tied to real-time changes in state. In the intensive care unit, for example, changes in an electrocardiogram signal can indicate a heart attack, and intracranial pressure waveforms can indicate whether a patient is developing decreased blood perfusion to the brain. However, most representation learning to resolve states is conducted in an offline, batch-dependent manner. In high frequency time-series, high intra-state and inter-sample variability makes offline, batch-dependent learning a relatively difficult task. Hence, we propose Spatial Resolved Temporal Networks (SpaRTeN), a novel composite deep learning model for online, unsupervised representation learning through a spatially constrained latent space. We simultaneously train two distinct blocks: a recurrent neural network ensemble f_R that captures states in high frequency time series, and a spatial block f_S that spatially resolves state changes from the predictions generated by f_R. The spatial block f_S identifies the block in f_R that best fits the current state of the time series, and the training procedure for f_R optimizes that block. This procedure corresponds to a minimax framework. When f_S and f_R are deep neural networks, the entire system can be trained via back-propagation. Finally, we demonstrate the application of this framework to online forecasting and interpretable, zero-shot clustering. We compare and demonstrate that SpaRTeN outperforms spectral clustering and a Gaussian mixture model.

ChordMixer: A Scalable Neural Attention Model for Sequences with Different Length

Ruslan Khalitov,Tong Yu,Lei Cheng,Zhirong Yang

Sequential data naturally have different lengths in many domains, with some very long sequences. As an important modeling tool, neural attention should capture long-range interaction in such sequences. However, most existing neural attention models admit only short sequences, or they have to employ chunking or padding to enforce a constant input length. Here we propose a simple neural network building block called ChordMixer which can model the attention for long sequences with variable lengths. Each ChordMixer block consists of a position-wise rotation layer without learnable parameters and an element-wise MLP layer. Repeatedly applying such blocks forms an effective network backbone that mixes the input signa ls towards the learning targets. We have tested ChordMixer on the synthetic adding problem, long document classification, and DNA sequence-based taxonomy classification. The experiment results show that our method substantially outperforms other neural attention models.

Boosting Adversarial Transferability using Dynamic Cues

Muzammal Naseer,Ahmad Mahmood,Salman Khan,Fahad Khan

The transferability of adversarial perturbations between image models has been extensively studied. In this case, an attack is generated from a known surrogate \eg, the ImageNet trained model, and transferred to change the decision of an unknown (black-box) model trained on an image dataset. However, attacks generated from image models do not capture the dynamic nature of a moving object or a changing scene due to a lack of temporal cues within image models. This leads to reduced transferability of adversarial attacks from representation-enriched \emph{image} models such as Supervised Vision Transformers (ViTs), Self-supervised ViTs (\eg, DINO), and Vision-language models (\eg, CLIP) to black-box \emph{video} models. In this work, we induce dynamic cues within the image models without sacrificing their original performance on images. To this end, we optimize \emph{temporal prompts} through frozen image models to capture motion dynamics. Our temporal prompts are the result of a learnable transformation that allows optimizing for temporal gradients during an adversarial attack to fool the motion dynamics. Specifically, we introduce spatial (image) and temporal (video) cues within the same source model through task-specific prompts. Attacking such prompts maximizes the adversarial transferability from image-to-video and image-to-image models using the attacks designed for image models. As an example, an iterative attack launched from image model Deit-B with temporal prompts reduces generalization (top1 \% accuracy) of a video model by 35\% on Kinetics-400. Our approach also improves adversarial transferability to image models by 9\% on ImageNet w.r.t the current state-of-the-art approach. Our attack results indicate that the attacker does not need specialized architectures, \eg, divided space-time attention, 3D convolutions, or multi-view convolution networks for different data modalities. Image models are effective surrogates to optimize an adversarial attack to fool black-box models in a changing environment over time. Code is available at \url{https://bit.ly/3Xd9gRQ}

Static Prediction of Runtime Errors by Learning to Execute Programs with External Resource Descriptions

David Bieber,Rishab Goel,Dan Zheng,Hugo Larochelle,Daniel Tarlow

The execution behavior of a program often depends on external resources, such as program inputs or file contents, and so the program cannot be run in isolation. Nevertheless, software developers benefit from fast iteration loops where automated tools identify errors as early as possible, even before programs can be compiled and run. This presents an interesting machine learning challenge: can we predict runtime errors in a "static" setting, where program execution is not possible? Here, we introduce a competitive programming dataset and task for predicting runtime errors, which we show is difficult for generic models like Transformers. We approach this task by developing an interpreter-inspired architecture with an inductive bias towards mimicking program executions, which models exception handling and "learns to execute" descriptions of external resources. Surprisingly, we show that the model can also predict the locations of errors, despite being trained only on labels indicating error presence or absence and kind. In total, we present a practical and difficult-yet-approachable challenge problem related to learning program execution behavior and we demonstrate promising new capabilities of interpreter-inspired machine learning models for code.

Matching receptor to odorant with protein language and graph neural networks

Matej Hladiš,Maxence Lalis,Sebastien Fiorucci,Jérémie Topin

Odor perception in mammals is triggered by interactions between volatile organic compounds and a subset of hundreds of proteins called olfactory receptors (ORs). Molecules activate these receptors in a complex combinatorial coding allowing mammals to discriminate a vast number of chemical stimuli. Recently, ORs have gained attention as new therapeutic targets following the discovery of their involvement in other physiological processes and diseases. To date, predicting molecule-induced activation for ORs is highly challenging since 43% of ORs have no identified active compound. In this work, we combine [CLS] token from protBERT with a molecular graph and propose a tailored GNN architecture incorporating inductive biases from the protein-molecule binding. We abstract the biological process of protein-molecule activation as the injection of a molecule into a protein-specific environment. On a newly gathered dataset of 46 700 OR-molecule pairs, this model outperforms state-of-the-art models on drug-target interaction prediction as well as standard GNN baselines. Moreover, by incorporating non-bonded interactions the model is able to work with mixtures of compounds. Finally, our predictions reveal a similar activation pattern for molecules within a given odor family, which is in agreement with the theory of combinatorial coding in olfaction.

****

How does overparametrization affect performance on minority groups?

Subha Maity,Saptarshi Roy,Songkai Xue,Mikhail Yurochkin,Yuekai Sun

The benefits of overparameterization for the overall performance of modern machine learning (ML) models are well known. However, the effect of overparameterization at a more granular level of data subgroups is less understood. Recent empirical studies demonstrate encouraging results: (i) when groups are not known, overparameterized models trained with empirical risk minimization (ERM) perform better on minority groups; (ii) when groups are known, ERM on data subsampled to equalize group sizes yields state-of-the-art worst-group-accuracy in the overparameterized regime. In this paper, we complement these empirical studies with a theoretical investigation of the risk of overparameterized random feature models on minority groups. In a setting in which the regression functions for the majority and minority groups are different, we show that overparameterization always improves minority group performance.

Federated Training of Dual Encoding Models on Small Non-IID Client Datasets

Raviteja Vemulapalli,Warren Richard Morningstar,Philip Andrew Mansfield,Hubert Eichner,Karan Singhal,Arash Afkanpour,Bradley Green

Dual encoding models that encode a pair of inputs are widely used for representation learning. Many approaches train dual encoding models by maximizing agreement between pairs of encodings on centralized training data. However, in many scenarios, datasets are inherently decentralized across many clients (user devices or organizations) due to privacy concerns, motivating federated learning. In this work, we focus on federated training of dual encoding models on decentralized data composed of many small, non-IID (independent and identically distributed) client datasets. We show that existing approaches that work well in centralized settings perform poorly when naively adapted to this setting using federated averaging. We observe that, we can simulate large-batch loss computation on individual clients for loss functions that are based on encoding statistics. Based on this insight, we propose a novel federated training approach, Distributed Cross Correlation Optimization (DCCO), which trains dual encoding models using encoding statistics aggregated across clients, without sharing individual data samples. Our experimental results on two datasets demonstrate that the proposed DCCO approach outperforms federated variants of existing approaches by a large margin.

Offline Policy Comparison with Confidence: Benchmarks and Baselines

Anurag Koul,Mariano Phielipp,Alan Fern

Decision makers often wish to use offline historical data to compare sequential-action policies at various world states. Importantly, computational tools should produce confidence values for such offline policy comparison (OPC) to account for statistical variance and limited data coverage. Nevertheless, there is little work that directly evaluates the quality of confidence values for OPC. In this work, we address this issue by creating benchmarks for OPC with Confidence (OPCC), derived by adding sets of policy comparison queries to datasets from offline reinforcement learning. In addition, we present an empirical evaluation of the "risk versus coverage" trade-off for a class of model-based baselines. In particular, the baselines learn ensembles of dynamics models, which are used in various ways to produce simulations for answering queries with confidence values. While our results suggest advantages for certain baseline variations, there appears to be significant room for improvement in future work.

****

SGDA with shuffling: faster convergence for nonconvex-P■ minimax optimization
Hanseul Cho,Chulhee Yun

Stochastic gradient descent-ascent (SGDA) is one of the main workhorses for solving finite-sum minimax optimization problems. Most practical implementations of SGDA randomly reshuffle components and sequentially use them (i.e., without-replacement sampling); however, there are few theoretical results on this approach for minimax algorithms, especially outside the easier-to-analyze (strongly-)monotone setups. To narrow this gap, we study the convergence bounds of SGDA with random reshuffling (SGDA-RR) for smooth nonconvex-nonconcave objectives with Polyak-{\L}ojasiewicz (P{\L}) geometry. We analyze both simultaneous and alternating SGDA-RR for nonconvex-P{\L} and primal-P{\L}-P{\L} objectives, and obtain convergence rates faster than with-replacement SGDA. Our rates extend to mini-batch SGDA-RR, recovering known rates for full-batch gradient descent-ascent (GDA). Lastly, we present a comprehensive lower bound for GDA with an arbitrary step-size ratio, which matches the full-batch upper bound for the primal-P{\L}-P{\L} case.

NTFields: Neural Time Fields for Physics-Informed Robot Motion Planning
Ruiqi Ni,Ahmed H Qureshi

Neural Motion Planners (NMPs) have emerged as a promising tool for solving robot navigation tasks in complex environments. However, these methods often require expert data for learning, which limits their application to scenarios where data generation is time-consuming. Recent developments have also led to physics-informed deep neural models capable of representing complex dynamical Partial Differential Equations (PDEs). Inspired by these developments, we propose Neural Time Fields (NTFields) for robot motion planning in cluttered scenarios. Our framework represents a wave propagation model generating continuous arrival time to find path solutions informed by a nonlinear first-order PDE called Eikonal Equation. We evaluate our method in various cluttered 3D environments, including the Gibson dataset, and demonstrate its ability to solve motion planning problems for 4-DOF and 6-DOF robot manipulators where the traditional grid-based Eikonal planners often face the curse of dimensionality. Furthermore, the results show that our method exhibits high success rates and significantly lower computational times than the state-of-the-art methods, including NMPs that require training data from classical planners.

MOAT: Alternating Mobile Convolution and Attention Brings Strong Vision Models
Chenglin Yang,Siyuan Qiao,Qihang Yu,Xiaoding Yuan,Yukun Zhu,Alan Yuille,Hartwig Adam,Liang-Chieh Chen

This paper presents MOAT, a family of neural networks that build on top of MObile convolution (i.e., inverted residual blocks) and ATtention. Unlike the current works that stack separate mobile convolution and transformer blocks, we effectively merge them into a MOAT block. Starting with a standard Transformer block, we replace its multi-layer perceptron with a mobile convolution block, and further reorder it before the self-attention operation. The mobile convolution block not only enhances the network representation capacity, but also produces better downsampled features. Our conceptually simple MOAT networks are surprisingly effective, achieving 89.1% / 81.5% top-1 accuracy on ImageNet-1K / ImageNet-1K-V2 with ImageNet-22K pretraining. Additionally, MOAT can be seamlessly applied to downstream tasks that require large resolution inputs by simply converting the global attention to window attention. Thanks to the mobile convolution that effectively exchanges local information between pixels (and thus cross-windows), MOAT does not need the extra window-shifting mechanism. As a result, on COCO object detection, MOAT achieves 59.2% AP$^{\text{box}}$ with 227M model parameters (single

-scale inference, and hard NMS), and on ADE20K semantic segmentation, MOAT attains 57.6% mIoU with 496M model parameters (single-scale inference). Finally, the tiny-MOAT family, obtained by simply reducing the channel sizes, also surprisingly outperforms several mobile-specific transformer-based models on ImageNet. The tiny-MOAT family is also benchmarked on downstream tasks, serving as a baseline for the community. We hope our simple yet effective MOAT will inspire more seamless integration of convolution and self-attention. Code is publicly available.

Part-Based Models Improve Adversarial Robustness
Chawin Sitawarin,Kornrapat Pongmala,Yizheng Chen,Nicholas Carlini,David Wagner
We show that combining human prior knowledge with end-to-end learning can improve the robustness of deep neural networks by introducing a part-based model for object classification. We believe that the richer form of annotation helps guide neural networks to learn more robust features without requiring more samples or larger models. Our model combines a part segmentation model with a tiny classifier and is trained end-to-end to simultaneously segment objects into parts and then classify the segmented object. Empirically, our part-based models achieve both higher accuracy and higher adversarial robustness than a ResNet-50 baseline on all three datasets. For instance, the clean accuracy of our part models is up to 15 percentage points higher than the baseline's, given the same level of robustness. Our experiments indicate that these models also reduce texture bias and yield better robustness against common corruptions and spurious correlations. The code is publicly available at https://github.com/chawins/adv-part-model.
****

PGrad: Learning Principal Gradients For Domain Generalization
Zhe Wang,Jake Grigsby,Yanjun Qi
Machine learning models fail to perform when facing out-of-distribution (OOD) domains, a challenging task known as domain generalization (DG). In this work, we develop a novel DG training strategy, we call PGrad, to learn a robust gradient direction, improving models' generalization ability on unseen domains. The proposed gradient aggregates the principal directions of a sampled roll-out optimization trajectory that measures the training dynamics across all training domains. PGrad gradient design forces the DG training to ignore domain-dependent noise signals and updates all training domains with a robust direction covering main components of parameter dynamics. We further improve PGrad via bijection-based computational refinement and directional plus length-based calibrations. Our theoretical proof connects PGrad to the spectral analysis of Hessian in training neural networks. Experiments on DomainBed and WILDS benchmarks demonstrate that our approach effectively enables robust DG optimization and leads to smoothly decreased loss curves. Empirically, PGrad achieves competitive results across seven datasets, demonstrating its efficacy across both synthetic and real-world distributional shifts.

Learning Efficient Models From Few Labels By Distillation From Multiple Tasks
Kenneth Borup,Cheng Perng Phoo,Bharath Hariharan
We address the challenge of getting efficient yet accurate recognition systems that can be trained with limited labels. Many specialized applications of computer vision (e.g. analyzing X-rays or satellite images) have severe resource constraints both during training and inference. While transfer learning is an effective solution for training on small labeled datasets it still often requires a large base model for fine-tuning. In this paper we present a weighted multi-source distillation method; we distill multiple (diverse) source models trained on different domains, weighted by their relevance for the target task, into a single efficient model using limited labeled data. When the goal is accurate recognition under computational constraints, our approach outperforms both transfer learning from strong ImageNet initializations as well as state-of-the-art semi-supervised techniques such as FixMatch. When averaged over 8 diverse target tasks our method outperform the baselines by 5.6%-points and 4.5%-points, respectively.
****

Extremely Simple Activation Shaping for Out-of-Distribution Detection

Andrija Djurisic,Nebojsa Bozanic,Arjun Ashok,Rosanne Liu

The separation between training and deployment of machine learning models implies that not all scenarios encountered in deployment can be anticipated during training, and therefore relying solely on advancements in training has its limits. Out-of-distribution (OOD) detection is an important area that stress-tests a model’s ability to handle unseen situations: Do models know when they don’t know? Existing OOD detection methods either incur extra training steps, additional data or make nontrivial modifications to the trained network. In contrast, in this work, we propose an extremely simple, post-hoc, on-the-fly activation shaping method, ASH, where a large portion (e.g. 90%) of a sample’s activation at a late layer is removed, and the rest (e.g. 10%) simplified or lightly adjusted. The shaping is applied at inference time, and does not require any statistics calculated from training data. Experiments show that such a simple treatment enhances in-distribution and out- of-distribution sample distinction so as to allow state-of-the-art OOD detection on ImageNet, and does not noticeably deteriorate the in-distribution accuracy. Video, animation and code can be found at: https://andrijazz.github.io/ash.

ZiCo: Zero-shot NAS via inverse Coefficient of Variation on Gradients

Guihong Li,Yuedong Yang,Kartikeya Bhardwaj,Radu Marculescu

Neural Architecture Search (NAS) is widely used to automatically obtain the neural network with the best performance among a large number of candidate architectures. To reduce the search time, zero-shot NAS aims at designing training-free proxies that can predict the test performance of a given architecture. However, as shown recently, none of the zero-shot proxies proposed to date can actually work consistently better than a naive proxy, namely, the number of network parameters (#Params). To improve this state of affairs, as the main theoretical contribution, we first reveal how some specific gradient properties across different samples impact the convergence rate and generalization capacity of neural networks. Based on this theoretical analysis, we propose a new zero-shot proxy, ZiCo, the first proxy that works consistently better than #Params. We demonstrate that ZiCo works better than State-Of-The-Art (SOTA) proxies on several popular NAS-Benchmarks (NASBench101, NATSBench-SSS/TSS, TransNASBench-101) for multiple applications (e.g., image classification/reconstruction and pixel-level prediction). Finally, we demonstrate that the optimal architectures found via ZiCo are as competitive as the ones found by one-shot and multi-shot NAS methods, but with much less search time. For example, ZiCo-based NAS can find optimal architectures with 78.1%, 79.4%, and 80.4% test accuracy under inference budgets of 450M, 600M, and 1000M FLOPs, respectively, on ImageNet within 0.4 GPU days. Our code is available at https://github.com/SLDGroup/ZiCo.

****

Statistical Guarantees for Consensus Clustering

Zhixin Zhou,Gautam Dudeja,Arash A Amini

Consider the problem of clustering n objects. One can apply multiple algorithms to produce N potentially different clustersings of the same objects, that is, partitions of the n objects into K groups. Even a single randomized algorithm can output different clusterings. This often happens when one samples from the posterior of a Bayesian model, or runs multiple MCMC chains from random initializations. A natural task is then to form a consensus among these different clusterings. The challenge in an unsupervised setting is that the optimal matching between clusters of different inputs is unknown. We model this problem as finding a barycenter (also known as Fr\'{e}chet mean) relative to the misclassification rate. We show that by lifting the problem to the space of association matrices, one can derive aggregation algorithms that circumvent the knowledge of the optimal matchings. We analyze the statistical performance of aggregation algorithms under a stochastic label perturbation model, and show that a K-means type algorithm followed by a local refinement step can achieve near optimal performance, with a rate that decays exponentially fast in N. Numerical experiments show t he effectiveness of the proposed methods.

****

Perceive, Ground, Reason, and Act: A Benchmark for General-purpose Visual Representation

Jiangyong Huang,William Yicheng Zhu,Baoxiong Jia,Zan Wang,Xiaojian Ma,Qing Li,Siyuan Huang

Current computer vision models, unlike the human visual system, cannot yet achieve general-purpose visual understanding. Existing efforts at general vision models are limited to a narrow range of tasks and offer no overarching framework to perform visual tasks holistically. We present a new comprehensive benchmark, General-purpose Visual Understanding Evaluation (G-VUE), covering the full spectrum of visual cognitive abilities with four disjoint functional domains — Perceive, Ground, Reason, and Act. The four domains are embodied in 11 carefully curated tasks, from 3D reconstruction to visual reasoning and manipulation. Along with the benchmark, we provide a general encoder-decoder framework for the tasks in G-VUE, to accommodate arbitrary visual representations on all 11 tasks. With our benchmark and framework, we evaluate 7 typical visual representations and observe that (1) transformer and more data empirically lead to more general-purpose, (2) language plays a significant role in learning versatile visual representation, and (3) correlations indicate a subtle constituent among tasks despite the distinctions, which could be evidence of general-purpose. We argue that instead of pursuing general-purpose vision models by end-to-end multi-task training, it is more reasonable to evaluate and investigate representations, which helps digest emerging pre-trained vision models and hopefully shed light on general intelligence.

****

Expressive Monotonic Neural Networks

Niklas Nolte,Ouail Kitouni,Mike Williams

The monotonic dependence of the outputs of a neural network on some of its inputs is a crucial inductive bias in many scenarios where domain knowledge dictates such behavior. This is especially important for interpretability and fairness considerations. In a broader context, scenarios in which monotonicity is important can be found in finance, medicine, physics, and other disciplines. It is thus desirable to build neural network architectures that implement this inductive bias provably. In this work, we propose a weight-constrained architecture with a single residual connection to achieve exact monotonic dependence in any subset of the inputs. The weight constraint scheme directly controls the Lipschitz constant of the neural network and thus provides the additional benefit of robustness. Compared to currently existing techniques used for monotonicity, our method is simpler in implementation and in theory foundations, has negligible computational overhead, is guaranteed to produce monotonic dependence, and is highly expressive. We show how the algorithm is used to train powerful, robust, and interpretable discriminators that achieve competitive performance compared to current state-of-the-art methods across various benchmarks, from social applications to the classification of the decays of subatomic particles produced at the CERN Large Hadron Collider.

****

Active Image Indexing

Pierre Fernandez,Matthijs Douze,Herve Jegou,Teddy Furon

Image copy detection and retrieval from large databases leverage two components. First, a neural network maps an image to a vector representation, that is relatively robust to various transformations of the image. Second, an efficient but approximate similarity search algorithm trades scalability (size and speed) against quality of the search, thereby introducing a source of error.

This paper improves the robustness of image copy detection with active indexing, that optimizes the interplay of these two components. We reduce the quantization loss of a given image representation by making imperceptible changes to the image before its release. The loss is back-propagated through the deep neural network back to the image, under perceptual constraints. These modifications make the image more retrievable.

Our experiments show that the retrieval and copy detection of activated images is significantly improved. For instance, activation improves by $+40\%$ the Recall1@1 on various image transformations, and for several popular indexing structures based on product quantization and locality sensitivity hashing.

****

Towards Explaining Distribution Shifts

Sean Kulinski,David I. Inouye

Distribution shift can have fundamental consequences such as signaling a change in the operating environment or significantly reducing the accuracy of downstream models. Thus, understanding such distribution shifts is critical for examining and hopefully mitigating the effect of such a shift. Most prior work has focused on merely detecting if a shift has occurred and assumes any detected shift can be understood and handled appropriately by a human operator. We hope to aid in these manual mitigation tasks by explaining the distribution shift using interpretable transportation maps from the original distribution to the shifted one. We derive our interpretable mappings from a relaxation of the optimal transport problem, where the candidate mappings are restricted to belong to a set of interpretable mappings. We then use quintessential examples of distribution shift in simulated and real-world cases to showcase how our explanatory mappings provide a better balance between detail and interpretability than the de facto standard mean shift explanation by both visual inspection and our PercentExplained metric.

****

Perturbation Analysis of Neural Collapse

Tom Tirer,Haoxiang Huang,Jonathan Niles-Weed

Training deep neural networks for classification often includes minimizing the training loss beyond the zero training error point. In this phase of training, a “neural collapse” behavior has been observed: the variability of features (outputs of the penultimate layer) of within-class samples decreases and the mean features of different classes approach a certain tight frame structure. Recent works analyze this behavior via idealized unconstrained features models where all the minimizers exhibit exact collapse. However, with practical networks and datasets, the features typically do not reach exact collapse, e.g., because deep layers cannot arbitrarily modify intermediate features that are far from being collapsed. In this paper, we propose a richer model that can capture this phenomenon by forcing the features to stay in the vicinity of a predefined features matrix (e.g., intermediate features). We explore the model in the small vicinity case via perturbation analysis and establish results that cannot be obtained by the previously studied models. For example, we prove reduction in the within-class variability of the optimized features compared to the predefined input features (via analyzing gradient flow on the “central-path” with minimal assumptions), analyze the minimizers in the near-collapse regime, and provide insights on the effect of regularization hyperparameters on the closeness to collapse. We support our theory with experiments in practical deep learning settings.

Learning Simultaneous Navigation and Construction in Grid Worlds

Wenyu Han,Haoran Wu,Eisuke Hirota,Alexander Gao,Lerrel Pinto,Ludovic Righetti,Chen Feng

We propose to study a new learning task, mobile construction, to enable an agent to build designed structures in 1/2/3D grid worlds while navigating in the same evolving environments. Unlike existing robot learning tasks such as visual navigation and object manipulation, this task is challenging because of the interdependence between accurate localization and strategic construction planning. In pursuit of generic and adaptive solutions to this partially observable Markov decision process (POMDP) based on deep reinforcement learning (RL), we design
a Deep Recurrent Q-Network (DRQN) with explicit recurrent position estimation in this dynamic grid world. Our extensive experiments show that pre-training this position estimation module before Q-learning can significantly improve the construction performance measured by the intersection-over-union score, achieving the best results in our benchmark of various baselines including model-free and model-based RL, a handcrafted SLAM-based policy, and human players. Our code is ava

ilable at: https://ai4ce.github.io/SNAC/.

Learning to CROSS exchange to solve min-max vehicle routing problems

Minjun Kim,Junyoung Park,Jinkyoo Park

CROSS exchange (CE), a meta-heuristic that solves various vehicle routing problems (VRPs), improves the solutions of VRPs by swapping the sub-tours of the vehicles. Inspired by CE, we propose Neuro CE (NCE), a fundamental operator of \textit{learned} meta-heuristic, to solve various min-max VRPs while overcoming the limitations of CE, i.e., the expensive $\mathcal{O}(n^4)$ search cost. NCE employs graph neural network to predict the cost-decrements (i.e., results of CE searches) and utilizes the predicted cost-decrements to guide the selection of sub-tours for swapping, while reducing the search cost to $\mathcal{O}(n^2)$. As the learning objective of NCE is to predict the cost-decrement, the training can be simply done in a supervised fashion, whose training samples can be easily collected. Despite the simplicity of NCE, numerical results show that the NCE trained with min-max flexible multi-depot VRP (min-max FMDVRP) outperforms the meta-heuristic baselines. More importantly, it significantly outperforms the neural baselines when solving distinctive special cases of min-max FMDVRP (e.g., min-max MDVRP, min-max mTSP, min-max CVRP) without additional training.

PandA: Unsupervised Learning of Parts and Appearances in the Feature Maps of GANs

James Oldfield,Christos Tzelepis,Yannis Panagakis,Mihalis Nicolaou,Ioannis Patras

Recent advances in the understanding of Generative Adversarial Networks (GANs) have led to remarkable progress in visual editing and synthesis tasks, capitalizing on the rich semantics that are embedded in the latent spaces of pre-trained GANs. However, existing methods are often tailored to specific GAN architectures and are limited to either discovering global semantic directions that do not facilitate localized control, or require some form of supervision through manually provided regions or segmentation masks. In this light, we present an architecture-agnostic approach that jointly discovers factors representing spatial parts and their appearances in an entirely unsupervised fashion. These factors are obtained by applying a semi-nonnegative tensor factorization on the feature maps, which in turn enables context-aware local image editing with pixel-level control. In addition, we show that the discovered appearance factors correspond to saliency maps that localize concepts of interest, without using any labels. Experiments on a wide range of GAN architectures and datasets show that, in comparison to the state of the art, our method is far more efficient in terms of training time and, most importantly, provides much more accurate localized control. Our code is available at: https://github.com/james-oldfield/PandA.

Compositional Law Parsing with Latent Random Functions

Fan Shi,Bin Li,Xiangyang Xue

Human cognition has compositionality. We understand a scene by decomposing the scene into different concepts (e.g., shape and position of an object) and learning the respective laws of these concepts, which may be either natural (e.g., laws of motion) or man-made (e.g., laws of a game). The automatic parsing of these laws indicates the model's ability to understand the scene, which makes law parsing play a central role in many visual tasks. This paper proposes a deep latent variable model for Compositional LAw Parsing (CLAP), which achieves the human-like compositionality ability through an encoding-decoding architecture to represent concepts in the scene as latent variables. CLAP employs concept-specific latent random functions instantiated with Neural Processes to capture the law of concepts. Our experimental results demonstrate that CLAP outperforms the baseline methods in multiple visual tasks such as intuitive physics, abstract visual reasoning, and scene representation. The law manipulation experiments illustrate CLAP's interpretability by modifying specific latent random functions on samples. For example, CLAP learns the laws of position-changing and appearance constancy from the moving balls in a scene, making it possible to exchange laws between sampl es or compose existing laws into novel laws.

Pink Noise Is All You Need: Colored Noise Exploration in Deep Reinforcement Learning

Onno Eberhard,Jakob Hollenstein,Cristina Pinneri,Georg Martius

In off-policy deep reinforcement learning with continuous action spaces, exploration is often implemented by injecting action noise into the action selection process. Popular algorithms based on stochastic policies, such as SAC or MPO, inject white noise by sampling actions from uncorrelated Gaussian distributions. In many tasks, however, white noise does not provide sufficient exploration, and temporally correlated noise is used instead. A common choice is Ornstein-Uhlenbeck (OU) noise, which is closely related to Brownian motion (red noise). Both red noise and white noise belong to the broad family of colored noise. In this work, we perform a comprehensive experimental evaluation on MPO and SAC to explore the effectiveness of other colors of noise as action noise. We find that pink noise, which is halfway between white and red noise, significantly outperforms white noise, OU noise, and other alternatives on a wide range of environments. Thus, we recommend it as the default choice for action noise in continuous control.

LilNetX: Lightweight Networks with EXtreme Model Compression and Structured Sparsification

Sharath Girish,Kamal Gupta,Saurabh Singh,Abhinav Shrivastava

We introduce LilNetX, an end-to-end trainable technique for neural networks that enables learning models with specified accuracy-rate-computation trade-off. Prior works approach these problems one at a time and often require post-processing or multistage training which become less practical and do not scale very well for large datasets or architectures. Our method constructs a joint training objective that penalizes the self information of network parameters in a latent representation space to encourage small model size while also introducing priors to increase structured sparsity in the parameter space to reduce computation. When compared with existing state-of-the-art model compression methods, we achieve up to 50% smaller model size and 98% model sparsity on ResNet-20 on the CIFAR-10 dataset as well as 37% smaller model size and 71% structured sparsity on ResNet-50 trained on ImageNet while retaining the same accuracy as those methods. We show that the resulting sparsity can improve the inference time of the models by almost 1.8 times the dense ResNet-50 baseline model. Code is available at https://github.com/Sharath-girish/LilNetX.

First-order Context-based Adaptation for Generalizing to New Dynamical Systems

Junyoung Park,Federico Berto,Arec Jamgochian,Mykel Kochenderfer,Jinkyoo Park

In this paper, we propose FOCA (First-Order Context-based Adaptation), a learning framework to model sets of systems governed by common but unknown laws that differentiate themselves by their context. Inspired by classical modeling-and-identification approaches, FOCA learns to represent the common law through shared parameters and relies on online optimization to compute system-specific context. Due to the online optimization-based context inference, the training of FOCA involves a bi-level optimization problem. To train FOCA efficiently, we utilize an exponential moving average (EMA)-based method that allows for fast training using only first-order derivatives. We test FOCA on polynomial regression and time-series prediction tasks composed of three ODEs and one PDE, empirically finding it outperforms baselines.

****

CBP-QSNN: Spiking Neural Networks Quantized Using Constrained Backpropagation

Donghyung Yoo,Doo Seok Jeong

Spiking Neural Networks (SNNs) support sparse event-based data processing at high power efficiency when implemented in event-based neuromorphic processors. However, the limited on-chip memory capacity of neuromorphic processors strictly delimits the depth and width of SNNs implemented. A direct solution is the use of q uantized SNNs (QSNNs) in place of SNNs with FP32 weights. To this end, we propose a method to quantize the weights using constrained backpropagation (CBP) with the Lagrangian function (conventional loss function plus well-defined weight-constraint functions) as an objective function. This work utilizes CBP as a post-training algorithm for deep SNNs pre-trained using various state-of-the-art methods including direct training (TSSL-BP, STBP, and surrogate gradient) and DNN-to-SNN conversion (SNN-Calibration), validating CBP as a general framework for QSNNs. CBP-QSNNs highlight their high accuracy insomuch as the degradation of accuracy on CIFAR-10, DVS128 Gesture, and CIFAR10-DVS in the worst case is less than 1\%. Particularly, CBP-QSNNs for SNN-Calibration-pretrained SNNs on CIFAR-100 highlight an unexpected large increase in accuracy by 3.72\% while using small weight-memory (3.5\% of the FP32 case).

Leveraging the Third Dimension in Contrastive Learning

Sumukh K Aithal,Anirudh Goyal,Alex Lamb,Yoshua Bengio,Michael Curtis Mozer

Self-Supervised Learning (SSL) methods operate on unlabeled data to learn robust representations useful for downstream tasks. Most SSL methods rely on augmentations obtained by transforming the 2D image pixel map. These augmentations ignore the fact that biological vision takes place in an immersive three-dimensional, temporally contiguous environment, and that low-level biological vision relies heavily on depth cues. Using a signal provided by a pretrained state-of-the-art RGB-to-depth model (the Depth Prediction Transformer, Ranftl et al., 2021), we explore two distinct approaches to incorporating depth signals into the SSL framework. First, we evaluate contrastive learning using an RGB+depth input representation. Second, we use the depth signal to generate novel views from slightly different camera positions, thereby producing a 3D augmentation for contrastive learning. We evaluate these two approaches on three different SSL methods---BYOL, SimSiam, and SwAV---using ImageNette (10 class subset of ImageNet) and ImageNet-100. We find that both approaches to incorporating depth signals improve the robustness and generalization of the baseline SSL methods, though the first approach (with depth-channel concatenation) is superior.

STaSy: Score-based Tabular data Synthesis

Jayoung Kim,Chaejeong Lee,Noseong Park

Tabular data synthesis is a long-standing research topic in machine learning. Many different methods have been proposed over the past decades, ranging from statistical methods to deep generative methods. However, it has not always been successful due to the complicated nature of real-world tabular data. In this paper, we present a new model named $\textbf{S}$core-based $\textbf{Ta}$bular data $\textbf{Sy}$nthesis ($\texttt{STaSy}$) and its training strategy based on the paradigm of score-based generative modeling. Despite the fact that score-based generative models have resolved many issues in generative models, there still exists room for improvement in tabular data synthesis. Our proposed training strategy includes a self-paced learning technique and a fine-tuning strategy, which further increases the sampling quality and diversity by stabilizing the denoising score matching training. Furthermore, we also conduct rigorous experimental studies in terms of the generative task trilemma: sampling quality, diversity, and time. In our experiments with 15 benchmark tabular datasets and 7 baselines, our method outperforms existing methods in terms of task-dependant evaluations and diversity.

REDUCING OVERSMOOTHING IN GRAPH NEURAL NETWORKS BY CHANGING THE ACTIVATION FUNCTION

Dimitrios Kelesis,Dimitrios Vogiatzis,Georgios Katsimpras,Dimitris Fotakis,Georgios Paliouras

The performance of Graph Neural Networks (GNNs) deteriorates as the depth of the network increases. That performance drop is mainly attributed to oversmoothing, which leads to similar node representations through repeated graph convolutions. We show that in deep GNNs the activation function plays a crucial role in over smoothing. We explain theoretically why this is the case and propose a simple modification to the slope of ReLU to reduce oversmoothing. The proposed approach enables deep architectures without the need to change the network architecture or to add residual connections. We verify the theoretical results experimentally and further show that deep networks, which do not suffer from oversmoothing are beneficial in the presence of the “cold start” problem, i.e. when there is no feature information about unlabeled nodes.

Visual Prompt Tuning For Test-time Domain Adaptation

Yunhe Gao,Xingjian Shi,Yi Zhu,Hao Wang,Zhiqiang Tang,Xiong Zhou,Mu Li,Dimitris N. Metaxas

Models should have the ability to adapt to unseen data during test-time to avoid performance drops caused by inevitable distribution shifts in real-world deployment scenarios. In this work, we tackle the practical yet challenging test-time adaptation (TTA) problem, where a model adapts to the target domain without accessing the source data. We propose a simple recipe called data-efficient prompt tuning (DePT) with two key ingredients. First, DePT plugs visual prompts into the vision Transformer and only tunes these source-initialized prompts during adaptation. We find such parameter-efficient finetuning can efficiently adapt the model representation to the target domain without overfitting to the noise in the learning objective. Second, DePT bootstraps the source representation to the target domain by memory bank-based online pseudo labeling. A hierarchical self-supervised regularization specially designed for prompts is jointly optimized to alleviate error accumulation during self-training. With much fewer tunable parameters, DePT demonstrates not only state-of-the-art performance on major adaptation benchmarks, but also superior data efficiency, i.e., adaptation with only 1\% or 10\% data without much performance degradation compared to 100\% data. In addition, DePT is also versatile to be extended to online or multi-source TTA settings.

Mitigating Dataset Bias by Using Per-Sample Gradient

Sumyeong Ahn,Seongyoon Kim,Se-Young Yun

The performance of deep neural networks is strongly influenced by the training dataset setup. In particular, when attributes with a strong correlation with the target attribute are present, the trained model can provide unintended prejudgments and show significant inference errors (i.e., the dataset bias problem). Various methods have been proposed to mitigate dataset bias, and their emphasis is on weakly correlated samples, called bias-conflicting samples. These methods are based on explicit bias labels provided by humans. However, such methods require human costs. Recently, several studies have sought to reduce human intervention by utilizing the output space values of neural networks, such as feature space, logits, loss, or accuracy. However, these output space values may be insufficient for the model to understand the bias attributes well. In this study, we propose a debiasing algorithm leveraging gradient called Per-sample Gradient-based Debiasing (PGD). PGD is comprised of three steps: (1) training a model on uniform batch sampling, (2) setting the importance of each sample in proportion to the norm of the sample gradient, and (3) training the model using importance-batch sampling, whose probability is obtained in step (2). Compared with existing baselines for various datasets, the proposed method showed state-of-the-art accuracy for the classification task. Furthermore, we describe theoretical understandings of how PGD can mitigate dataset bias.

CAMA: A New Framework for Safe Multi-Agent Reinforcement Learning Using Constraint Augmentation

Ziyan Wang,Yali Du,Aivar Sootla,Haitham Bou Ammar,Jun Wang

With the widespread application of multi-agent reinforcement learning (MARL) in real-life settings, the ability to meet safety constraints has become an urgent problem to solve. For example, it is necessary to avoid collisions to reach a common goal in controlling multiple drones. We address this problem by introducing the Constraint Augmented Multi-Agent framework --- CAMA. CAMA can serve as a plug-and-play module to the popular MARL algorithms, including centralized training, decentralized execution and independent learning frameworks. In our approach, we represent the safety constraint as the sum of discounted safety costs bounded by the predefined value, which we call the safety budget. Experiments demonstrate that CAMA can converge quickly to a high degree of constraint satisfaction and surpasses other state-of-the-art safety counterpart algorithms in both cooperative and competitive settings.

CWATR: Generating Richer Captions with Object Attributes

Enes Muvahhid ■ahin,Gözde BOZDA■I AKAR

Image captioning is a popular yet challenging task which is at the intersection of Computer Vision and Natural Language Processing. Recently, transformer-based unified Vision and Language models advanced the state-of-the-art further on image captioning. However, there are still fundamental problems in these models. Even though the generated captions by these models are grammatically correct and describe the input image fairly good, they might overlook important details in the image. In this paper, we demonstrate these problems in a state-of-the-art baseline image captioning method and analyze the reasoning behind these problems. We propose a novel approach, named CWATR (Captioning With ATtRibutes), to integrate object attributes to the generated captions in order to obtain richer and more detailed captions. Our analyses demonstrate that the proposed approach generates richer and more visually grounded captions by integrating attributes of the objects in the scene to the generated captions successfully.

Internal Purity: A Differential Entropy based Internal Validation Index for Clustering Validation

Bin Cao,Chen Yang,Kaibo He,JING FAN

In an effective process of cluster analysis, it is indispensable to validate the goodness of different partitions after clustering. Existing internal validation indices are implemented based on distance, variance and model-selection. The indices based on distance or variance cannnot catpure the real ``density" of the cluster and the time complexity for distance based indices is usually too high to be applied for large datasets. Moreover, the indices based on model-selection tend to overestimate the number of cluster in clustering validation. Therefore, we propose a novel internal validation index based on the differential entropy, named \textit{internal purity} (IP). The proposed IP index can effectively measure the purity of a cluster without using the external cluster information, and successfully overcome the drawbacks of existing internal indices. Based on six powerful deep pre-trained models and without further fine-tuning using the experimental datasets, we use four different clustering algorithms to compare our index with thirteen other well-known internal indices on five text and five image datasets. The results show that, for 60 test cases in total, our IP index can return the optimal clustering results in 43 cases while the second best index can merely report the optimal partition in 17 cases, which demonstrates the significant superiority of our IP index when validating the goodness of the clustering results. Moreover, theoretical analysis for the effectiveness and efficiency of the proposed index are also provided.

Task Regularized Hybrid Knowledge Distillation For Continual Object Detection

Jinming Zhang,Mengxue Kang,Jinpeng Zhang,Zhe Ma,Shan Yu

Knowledge distillation has been used to overcome catastrophic forgetting in Continual Object Detection(COD) task. Previous works mainly focus on combining different distillation methods, including feature, classification, location and relation, into a mixed scheme to solve this problem. In this paper, we propose a task regularized hybrid knowledge distillation method for COD task. First, we propose an image-level hybrid knowledge representation by combining instance-level hard and soft knowledge to use teacher knowledge critically. Second, we propose a task-based regularization distillation loss by taking account of loss and category differences to make continual learning more balance between old and new tasks.

We find that, under appropriate knowledge selection and transfer strategies, using only classification distillation can also relieve knowledge forgetting effectively. Extensive experiments conducted on MS COCO2017 demonstrate that our method achieves state-of-the-art results under various scenarios. We get an absolute improvement of 27.98 at $RelGap$ under the most difficult five-task scenario. Code is in attachment and will be available on github.

Efficient Model Updates for Approximate Unlearning of Graph-Structured Data
Eli Chien,Chao Pan,Olgica Milenkovic
With the adoption of recent laws ensuring the ``right to be forgotten'', the problem of machine unlearning has become of significant importance. This is particularly the case for graph-structured data, and learning tools specialized for such data, including graph neural networks (GNNs). This work introduces the first known approach for \emph{approximate graph unlearning} with provable theoretical guarantees. The challenges in addressing the problem are two-fold. First, there exist multiple different types of unlearning requests that need to be considered, including node feature, edge and node unlearning. Second, to establish provable performance guarantees, one needs to carefully evaluate the process of feature mixing during propagation. We focus on analyzing Simple Graph Convolutions (SGC) and their generalized PageRank (GPR) extensions, thereby laying the theoretical foundations for unlearning GNNs. Empirical evaluations of six benchmark datasets demonstrate excellent performance/complexity/privacy trade-offs of our approach compared to complete retraining and general methods that do not leverage graph information. For example, unlearning 200 out of 1208 training nodes of the Cora dataset only leads to a 0.1% loss in test accuracy, but offers a 4-fold speed-up compared to complete retraining with a $(\epsilon,\delta)=(1,10^{-4})$ ``privacy cost''. We also exhibit a 12% increase in test accuracy for the same dataset when compared to unlearning methods that do not leverage graph information, with comparable time complexity and the same privacy guarantee.

****

Risk-aware Bayesian RL for Cautious Exploration
Rohan Mitta,Hosein Hasanbeig,Daniel Kroening,Alessandro Abate
This paper addresses the problem of maintaining safety during training in Reinforcement Learning (RL), such that the safety constraint violations are bounded at any point during learning. Whilst enforcing safety during training might limit the agent's exploration, we propose a new architecture that handles the trade-off between efficient progress in exploration and safety maintenance.
As the agent's exploration progresses, we update Dirichlet-Categorical models of the transition probabilities of the Markov decision process that describes the agent's behavior within the environment by means of Bayesian inference. We then propose a way to approximate moments of the agent's belief about the risk associated with the agent's behavior originating from local action selection. We demonstrate that this approach can be easily coupled with RL, we provide rigorous theoretical guarantees, and we present experimental results to showcase the performance of the overall architecture.

Change Detection for bi-temporal images classification based on Siamese Variational AutoEncoder and Transfer Learning
Chouikhi Farah,Ali Ben Abbes,Imed Riadh Farah
Siamese structures empower Deep Learning (DL) models to increase their efficiency by learning how to extract the relevant temporal features from the input data. In this paper, a Siamese Variational Auto-Encoder (VAE) model based on transfer learning (TL) is applied for change detection (CD) using bi-temporal images. The introduced method is trained in a supervised strategy for classification tasks. Firstly, the suggested generative method utilizes two VAEs to extract features from bi-temporal images. Subsequently, concatenates them into a feature vector. To get a classification map of the source scene, the classifier receives this vector and the ground truth data as input. The source model is fine-tuned to be applied to the target scene with less ground truth data using a TL strategy. Experiments were carried out in two study areas in the arid regions of southern Tun

isia. The obtained results reveal that the proposed method outperformed the Siamese Convolution Neural Network (SCNN) by achieving an accuracy of more than 98%, in the source scene, and increased the accuracy in the target scene by 1.25% by applying the TL strategy.

Learning Top-k Classification with Label Ranking

Bin Cao,Kai Wang,JING FAN,Jianwei Yin

Class confusability and multi-label nature of examples inevitably arise in classification tasks with the increasing number of classes, which poses a huge challenge to classification. To mitigate this problem, top-k classification is proposed, where the classifier is allowed to predict k label candidates and the prediction result is considered correct as long as the ground truth label is included in the k labels. However, existing top-k classification methods neglect the ranking of the ground truth label among the predicted k labels, which has high application value. In this paper, we propose a novel three-stage approach to learn top-k classification with label ranking. We first propose an ensemble based relabeling method and relabel the training data with k labels, which is used to train the top-k classifier. We then propose a novel top-k classification loss function that aims to improve the ranking of the ground truth label. Finally, we have conducted extensive experiments on four text datasets and four image datasets, and the experimental results show that our method could significantly improve the performance of existing methods.

Populating memory in Continual Learning with Consistency Aware Sampling

Julio Hurtado,Alain Raymond,Vladimir Araujo,Vincenzo Lomonaco,Alvaro Soto,Davide Bacciu

Continual Learning (CL) methods aim to mitigate Catastrophic Forgetting (CF), where knowledge from previously learned tasks is often lost in favor of the new one. Among those algorithms, some have shown the relevance of keeping a rehearsal buffer with previously seen examples, referred to as $memory$. Yet, despite their popularity, limited research has been done to understand which elements are more beneficial to store in memory. It is common for this memory to be populated through random sampling, with little guiding principles that may aid in retaining prior knowledge. In this paper, and consistent with previous work, we found that some storage policies behave similarly given a certain memory size or compute budget, but when these constraints are relevant, results differ considerably. Based on these insights, we propose CAWS (Consistency AWare Sampling), an original storage policy that leverages a learning consistency score (C-Score) to populate the memory with elements that are $easy$ to $learn$ and $representative$ of previous tasks. Because of the impracticality of directly using the C-Score in CL, we propose more feasible and efficient proxies to calculate the score that yield state-of-the-art results on CIFAR-100 and Tiny Imagenet.

A Unified Algebraic Perspective on Lipschitz Neural Networks

Alexandre Araujo,Aaron J Havens,Blaise Delattre,Alexandre Allauzen,Bin Hu

Important research efforts have focused on the design and training of neural networks with a controlled Lipschitz constant. The goal is to increase and sometimes guarantee the robustness against adversarial attacks. Recent promising techniques draw inspirations from different backgrounds to design 1-Lipschitz neural networks, just to name a few: convex potential layers derive from the discretization of continuous dynamical systems, Almost-Orthogonal-Layer proposes a tailored method for matrix rescaling. However, it is today important to consider the recent and promising contributions in the field under a common theoretical lens to better design new and improved layers. This paper introduces a novel algebraic perspective unifying various types of 1-Lipschitz neural networks, including the ones previously mentioned, along with methods based on orthogonality and spectral methods. Interestingly, we show that many existing techniques can be derived and generalized via finding analytical solutions of a common semidefinite programming (SDP) condition. We also prove that AOL biases the scaled weight to the ones which are close to the set of orthogonal matrices in a certain mathematical ma nner. Moreover, our algebraic condition, combined with the Gershgorin circle theorem, readily leads to new and diverse parameterizations for 1-Lipschitz network layers. Our approach, called SDP-based Lipschitz Layers (SLL), allows us to design non-trivial yet efficient generalization of convex potential layers. Finally, the comprehensive set of experiments on image classification shows that SLLs outperform previous approaches on certified robust accuracy. Code is available at https://github.com/araujoalexandre/Lipschitz-SLL-Networks.

AudioGen: Textually Guided Audio Generation
Felix Kreuk,Gabriel Synnaeve,Adam Polyak,Uriel Singer,Alexandre Défossez,Jade Copet,Devi Parikh,Yaniv Taigman,Yossi Adi

In this work, we tackle the problem of generating audio samples conditioned on descriptive text captions. We propose AudioGen, an auto-regressive generative model, operating on a learnt discrete audio representation, that generates audio samples conditioned on text inputs. The task of text-to-audio generation poses multiple challenges. Due to the way audio travels through a medium, differentiating ``objects'' can be a difficult task (e.g., separating multiple people simultaneously speaking). This is further complicated by real-world recording conditions (e.g., background noise, reverberation, etc.). Scarce text annotations impose another constraint, limiting the ability to scale models. Finally, modeling high fidelity audio requires one to operate over extremely long sequences. To alleviate the aforementioned challenges we propose an augmentation technique that mixes different audio samples, driving the model to internally learn to separate multiple sources. We curated 10 datasets containing different types of audio and text annotations to handle the scarcity of text-audio data points. For faster inference, we explore the use of multi-stream modeling, allowing the use of shorter sequences while maintaining a similar bitrate and perceptual quality. Finally, we apply classifier-free guidance to improve adherence to text. Comparing to the evaluated baselines, AudioGen outperforms over both objective and subjective metrics. We further conduct an ablation study to gauge the effects of pre-trained text and audio components.

Faster Reinforcement Learning with Value Target Lower Bounding
Le Zhao,Wei Xu

We show that an arbitrary lower bound of the maximum achievable value can be used to improve the Bellman value target during value learning. In the tabular case, value learning using the lower bounded Bellman operator converges to the same optimal value as using the original Bellman operator, at a potentially faster speed. In practice, discounted episodic return in episodic tasks and n-step bootstrapped return in continuing tasks can serve as lower bounds to improve the value target. We experiment on Atari games, FetchEnv tasks and a challenging physically simulated car push and reach task. We see large gains in sample efficiency as well as converged performance over common baselines such as TD3, SAC and Hindsight Experience Replay (HER) in most tasks, and observe a reliable and competitive performance against the stronger n-step methods such as td-lambda, Retrace and optimality tightening. Prior works have already successfully applied a special case of lower bounding (using episodic return), but are limited to a small number of episodic tasks. To the best of our knowledge, we are the first to propose the general method of value target lower bounding (with possibly bootstrapped return), to demonstrate its optimality in theory, and effectiveness in a wide range of tasks over many strong baselines.

Hebbian and Gradient-based Plasticity Enables Robust Memory and Rapid Learning in RNNs
Yu Duan,Zhongfan Jia,Qian Li,Yi Zhong,Kaisheng Ma

Rapidly learning from ongoing experiences and remembering past events with a flexible memory system are two core capacities of biological intelligence. While the underlying neural mechanisms are not fully understood, various evidence supports that synaptic plasticity plays a critical role in memory formation and fast learning. Inspired by these results, we equip Recurrent Neural Networks (RNNs) wi

th plasticity rules to enable them to adapt their parameters according to ongoing experiences. In addition to the traditional local Hebbian plasticity, we propose a global, gradient-based plasticity rule, which allows the model to evolve towards its self-determined target. Our models show promising results on sequential and associative memory tasks, illustrating their ability to robustly form and retain memories. In the meantime, these models can cope with many challenging few-shot learning problems. Comparing different plasticity rules under the same framework shows that Hebbian plasticity is well-suited for several memory and associative learning tasks; however, it is outperformed by gradient-based plasticity on few-shot regression tasks which require the model to infer the underlying mapping.

Towards Minimax Optimal Reward-free Reinforcement Learning in Linear MDPs
Pihe Hu,Yu Chen,Longbo Huang

We study reward-free reinforcement learning with linear function approximation for episodic Markov decision processes (MDPs). In this setting, an agent first interacts with the environment without accessing the reward function in the exploration phase. In the subsequent planning phase, it is given a reward function and asked to output an ϵ-optimal policy. We propose a novel algorithm LSVI-RFE under the linear MDP setting, where the transition probability and reward functions are linear in a feature mapping. We prove an $\widetilde{O}(H^{4} d^{2}/\epsilon^2)$ sample complexity upper bound for LSVI-RFE, where H is the episode length and d is the feature dimension. We also establish a sample complexity lower bound of $\Omega(H^{3} d^{2}/\epsilon^2)$. To the best of our knowledge, LSVI-RFE is the first computationally efficient algorithm that achieves the minimax optimal sample complexity in linear MDP settings up to an H and logarithmic factors. Our LSVI-RFE algorithm is based on a novel variance-aware exploration mechanism to avoid overly-conservative exploration in prior works. Our sharp bound relies on the decoupling of UCB bonuses during two phases, and a Bernstein-type self-normalized bound, which remove the extra dependency of sample complexity on H and d, respectively.

Context and History Aware Other-Shaping
Akbir Khan,Newton Kwan,Timon Willi,Chris Lu,Andrea Tacchetti,Jakob Nicolaus Foerster

Cooperation failures, in which self-interested agents converge to collectively worst-case outcomes, are a common failure mode of Multi-Agent Reinforcement Learning (MARL) methods. Methods such as Model-Free Opponent Shaping (MFOS) and The Good Shepherd address this issue by shaping their co-player’s learning into mutual cooperation. However, these methods fail to capture important co-player learning dynamics or do not scale to co-players parameterised by deep neural networks. To address these issues, we propose Context and History Aware Other-Shaping (CHAOS). A CHAOS agent is a meta-learner parameterised by a recurrent neural network that learns to shape its co-player over multiple trials. CHAOS considers both the context (inter-episode information), and history (intra-episode information) to shape co-players successfully. CHAOS also successfully scales to shaping co-players parameterised by deep neural networks. In a set of experiments, we show that CHAOS achieves state-of-the-art shaping in matrix games. We provide extensive ablations, motivating the importance of both context and history. CHAOS also successfully shapes on a complex grid-worldbased game, demonstrating CHAOS’s scalability empirically. Finally, we provide empirical evidence that, counterintuitively, the widely-used Coin Game environment does not require history to learn shaping because states are often indicative of past actions. This suggests that the Coin Game is, in contrast to common understanding, unsuitable for investigating shaping in high-dimensional, multi-step environments.

ReD-GCN: Revisit the Depth of Graph Convolutional Network
Yuchen Yan,Yuzhong Chen,Mahashweta Das,Hao Yang,Hanghang Tong

Finding the proper depth d of a GNN that provides strong representation power has drawn significant attention, yet nonetheless largely remains an open probl em for the graph learning community. Although noteworthy progress has been made, the depth or the number of layers of a corresponding GCN is realized by a series of graph convolution operations, which naturally makes d a positive integer ($d \in \mathbb{N}+$). An interesting question is whether breaking the constraint of $\mathbb{N}+$ by making d a real number ($d \in \mathbb{R}$) can bring new insights into graph learning mechanisms. In this work, by redefining GCN's depth d as a trainable parameter continuously adjustable within $(-\infty,+\infty)$, we open a new door of controlling its expressiveness on graph signal processing to model graph homophily/heterophily (nodes with similar/dissimilar labels/attributes tend to inter-connect). A simple and powerful GCN model ReD-GCN, is proposed to retain the simplicity of GCN and meanwhile automatically search for the optimal d without the prior knowledge regarding whether the input graph is homophilic or heterophilic. Negative-valued d intrinsically enables high-pass frequency filtering functionality for graph heterophily. Variants extending the model flexibility/scalability are also developed. The theoretical feasibility of having a real-valued depth with explainable physical meanings is ensured via eigen-decomposition of the graph Laplacian and a properly designed transformation function from the perspective of functional calculus. Extensive experiments demonstrate the superiority of ReD-GCN on node classification tasks for a variety of graphs. Furthermore, by introducing the concept of eigengraph, a novel graph augmentation method is obtained: the optimal d effectively generates a new topology through a properly weighted combination of eigengraphs, which dramatically boosts the performance even for a vanilla GCN.

The Influence of Learning Rule on Representation Dynamics in Wide Neural Networks

Blake Bordelon,Cengiz Pehlevan

It is unclear how changing the learning rule of a deep neural network alters its learning dynamics and representations. To gain insight into the relationship between learned features, function approximation, and the learning rule, we analyze infinite-width deep networks trained with gradient descent (GD) and biologically-plausible alternatives including feedback alignment (FA), direct feedback alignment (DFA), and error modulated Hebbian learning (Hebb), as well as gated linear networks (GLN). We show that, for each of these learning rules, the evolution of the output function at infinite width is governed by a time varying effective neural tangent kernel (eNTK). In the lazy training limit, this eNTK is static and does not evolve, while in the rich mean-field regime this kernel's evolution can be determined self-consistently with dynamical mean field theory (DMFT). This DMFT enables comparisons of the feature and prediction dynamics induced by each of these learning rules. In the lazy limit, we find that DFA and Hebb can only learn using the last layer features, while full FA can utilize earlier layers with a scale determined by the initial correlation between feedforward and feedback weight matrices. In the rich regime, DFA and FA utilize a temporally evolving and depth-dependent NTK. Counterintuitively, we find that FA networks trained in the rich regime exhibit more feature learning if initialized with smaller correlation between the forward and backward pass weights. GLNs admit a very simple formula for their lazy limit kernel and preserve conditional Gaussianity of their preactivations under gating functions. Error modulated Hebb rules show very small task-relevant alignment of their kernels and perform most task relevant learning in the last layer.

Multiple Modes for Continual Learning

Siddhartha Datta,Nigel Shadbolt

Adapting model parameters to incoming streams of data is a crucial factor to deep learning scalability. Interestingly, prior continual learning strategies in online settings inadvertently anchor their updated parameters to a local parameter subspace to remember old tasks, else drift away from the subspace and forget. From this observation, we formulate a trade-off between constructing multiple parameter modes and allocating tasks per mode. Mode-Optimized Task Allocation (MOTA), our contributed adaptation strategy, trains multiple modes in parallel, then

optimizes task allocation per mode. We empirically demonstrate improvements over baseline continual learning strategies and across varying distribution shifts, namely sub-population, domain, and task shift.

A Theory of Equivalence-Preserving Program Embeddings
Logan Weber,Jesse Michel,Alex Renda,Saman Amarasinghe,Michael Carbin
Program embeddings are used to solve tasks such as \textit{code clone detection} and \textit{semantic labeling}. Solutions to these \textit{semantic tasks} should be invariant to semantics-preserving program transformations. When a program embedding function satisfies this invariance, we call it an \textit{equivalence-preserving program embedding function}. We say a programming language can be \textit{tractably embedded} when we can construct an equivalence-preserving program embedding function that executes in polynomial time in program/input length and produces program embeddings that are proportional to the input length. Determining whether a programming language can be tractably embedded is the \textit{equivalence-preserving program embedding problem}. We formalize this problem and theoretically characterize when programming languages can be tractably embedded. To validate our theoretical results, we use the BERT-Tiny model to learn an equivalence-preserving program embedding function for a programming language that can be tractably embedded and show the model fails to construct an equivalence-preserving program embedding function for a similar language that is intractable to embed.

On the Data-Efficiency with Contrastive Image Transformation in Reinforcement Learning
Sicong Liu,Xi Sheryl Zhang,Yushuo Li,Yifan Zhang,Jian Cheng
Data-efficiency has always been an essential issue in pixel-based reinforcement learning (RL). As the agent not only learns decision-making but also meaningful representations from images. The line of reinforcement learning with data augmentation shows significant improvements in sample-efficiency. However, it is challenging to guarantee the optimality invariant transformation, that is, the augmented data are readily recognized as a completely different state by the agent. In the end, we propose a contrastive invariant transformation (CoIT), a simple yet promising learnable data augmentation combined with standard model-free algorithms to improve sample-efficiency. Concretely, the differentiable CoIT leverages original samples with augmented samples and hastens the state encoder for a contrastive invariant embedding. We evaluate our approach on DeepMind Control Suite and Atari100K. Empirical results verify advances using CoIT, enabling it to outperform the new state-of-the-art on various tasks. Source code is available at https://github.com/mooricAnna/CoIT.
****
Energy-based Out-of-Distribution Detection for Graph Neural Networks
Qitian Wu,Yiting Chen,Chenxiao Yang,Junchi Yan
Representation learning on semi-structured data, e.g., graphs, has become a central problem in deep learning community as relational structures are pervasive in real situations and induce data inter-dependence that hinders trivial adaptation of existing approaches in other domains where the inputs are assumed to be i.i.d. sampled. However, current models in this regime mostly focus on improving testing performance of in-distribution data and largely ignores the potential risk w.r.t. out-of-distribution (OOD) testing samples that may cause negative outcome if the model is overconfident in prediction on them. In this paper, we identify a provably effective OOD discriminator based on an energy function directly extracted from a graph neural network trained with standard supervised classification loss. This paves a way for a simple and efficient OOD detection model for GNN-based semi-supervised learning on graphs, which we call GNN-Safe. It also has nice theoretical properties that guarantee an overall distinguishable margin between the detection scores for in-distribution and OOD samples, which, more critically, can be further strengthened by a non-learning-based structured propagation scheme. Extensive experiments over five real-world datasets validate the pract

ical efficacy of the proposed model for detecting various OOD instances that are inter-connected in a graph with up to 17.0% improvement on average AUROC over competitive peer models and without sacrificing in-distribution testing accuracy.

Theoretical Characterization of Neural Network Generalization with Group Imbalance

Hongkang Li,Shuai Zhang,Meng Wang,Yihua Zhang,Pin-Yu Chen,Sijia Liu

Group imbalance has been a known problem in empirical risk minimization (ERM), where the achieved high \textit{average} accuracy could be accompanied by low accuracy in a \textit{minority} group. Despite various algorithmic efforts to improve the minority group accuracy, a theoretical study of the generalization performance of ERM on individual groups remains elusive. By formulating the group imbalance problem with the Gaussian Mixture Model, this paper quantifies the impact of individual groups on the sample complexity, the convergence rate, and the average and group-level testing performance. Although our theoretical framework is centered on binary classification using a one-hidden-layer neural network, to the best of our knowledge, we provide the first theoretical analysis of the group-level generalization of ERM in addition to the commonly studied average generalization performance. Sample insights of our theoretical results include that when all group-level co-variance is in the medium regime and all mean are close to zero, the learning performance is most desirable in the sense of a small sample complexity, a fast training rate, and a high average and group-level testing accuracy. Moreover, we show that increasing the fraction of the minority group in the training data does not necessarily improve the generalization performance of the minority group. Our theoretical results are validated on both synthetic and empirical datasets such as CelebA and CIFAR-10 in image classification.

Formal Interpretability with Merlin-Arthur Classifiers

Stephan Waeldchen,Kartikey Sharma,Max Zimmer,Berkant Turan,Sebastian Pokutta

We propose a new type of multi-agent interactive classifier that provides, for the first time, provable interpretability guarantees even for complex agents such as neural networks.   In our setting, which is inspired by the Merlin-Arthur protocol from Interactive Proof Systems, two agents cooperate to provide a classification: the prover selects a small set of features as a certificate and presents it to the verifier who decides the class. A second, adversarial prover ensures the truthfulness of the system and allows us to connect the game-theoretic equilibrium between the provers and the verifier to guarantees on the exchanged features. We define completeness and soundness metrics to provide a lower bound on the mutual information between the features and the class. Our experiments demonstrate good agreement between theory and practice using neural network classifiers, and we show how our setup practically prevents manipulation.

****

Quasi-optimal Reinforcement Learning with Continuous Actions

Yuhan Li,Wenzhuo Zhou,Ruoqing Zhu

Many real-world applications of reinforcement learning (RL) require making decisions in continuous action environments. In particular, determining the optimal dose level plays a vital role in developing medical treatment regimes. One challenge in adapting existing RL algorithms to medical applications, however, is that the popular infinite support stochastic policies, e.g., Gaussian policy, may assign riskily high dosages and harm patients seriously. Hence, it is important to induce a policy class whose support only contains near-optimal actions, and shrink the action-searching area for effectiveness and reliability. To achieve this, we develop a novel quasi-optimal learning algorithm, which can be easily optimized in off-policy settings with guaranteed convergence under general function approximations. Theoretically, we analyze the consistency, sample complexity, adaptability, and convergence of the proposed algorithm. We evaluate our algorithm with comprehensive simulated experiments and a dose suggestion real application to Ohio Type 1 diabetes dataset.

Generalization Bounds for Federated Learning: Fast Rates, Unparticipating Client s and Unbounded Losses

Xiaolin Hu,Shaojie Li,Yong Liu

In {federated learning}, the underlying data distributions may be different across clients. This paper provides a theoretical analysis of generalization error of {federated learning}, which captures both heterogeneity and relatedness of the distributions. In particular, we assume that the heterogeneous distributions are sampled from a meta-distribution. In this two-level distribution framework, we characterize the generalization error not only for clients participating in the training but also for unparticipating clients. We first show that the generalization error for unparticipating clients can be bounded by participating generalization error and participating gap caused by clients' sampling. We further establish fast learning bounds of order $\mathcal{O}(\frac{1}{mn} + \frac{1}{m})$ for unparticipating clients, where m is the number of clients and n is the sample size at each client. To our knowledge, the obtained fast bounds are state-of-the-art in the two-level distribution framework. Moreover, previous theoretical results mostly require the loss function to be bounded. We derive convergence bounds of order $\mathcal{O}(\frac{1}{\sqrt{mn}} + \frac{1}{\sqrt{m}})$ under unbounded assumptions, including sub-exponential and sub-Weibull losses.

Contrastive Unsupervised Learning of World Model with Invariant Causal Features

Rudra P. K. Poudel,Harit Pandya,Roberto Cipolla

In this paper we present a world model, which learns the causal features using invariance principle. We use contrastive unsupervised learning to learn the invariant causal features, which enforces invariance across augmentations of irrelevant parts or styles of the observation. Since the world model based reinforcement learning methods optimize representation learning and policy of the agent independently, contrastive loss collapses due to lack of supervisory signal to the representation learning module. We propose depth reconstruction as an auxiliary task to explicitly enforce the invariance and data augmentation as style intervention on the RGB space to mitigate this issue. Our design help us to leverage state-of-the-art unsupervised representation learning method to learn the world model with invariant causal features, which outperforms current state-of-the-art model-based as well as model-free reinforcement learning methods on out-of-distribution point navigation tasks on Gibson and iGibson dataset at 100k and 500k interaction step benchmarks. Further experiments on DeepMind control suite even without depth reconstruction, our proposed model performs on par with the state-of-the-art counterpart models.

GOING BEYOND 1-WL EXPRESSIVE POWER WITH 1-LAYER GRAPH NEURAL NETWORKS

Tianjun Yao,Yingxu Wang,Shangsong Liang

Graph neural networks have become the \textit{de facto} standard for representational learning in graphs, and have achieved SOTA in many graph-related tasks such as node classification, graph classification and link prediction. However, it has been shown that the expressive power is equivalent maximally to Weisfeiler-Lehman Test. Recently, there is a line of work aiming to enhance the expressive power of graph neural networks. In this work, we propose a more generalized variant of neural Weisfeiler-Lehman test to enhance structural representation for each node in a graph to uplift the expressive power of any graph neural network. It is shown theoretically our method is strictly more powerful than 1\&2-WL test. The Numerical experiments also demonstrate that our proposed method outperforms the standard GNNs on almost all the benchmark datasets by a large margin in most cases with significantly lower running time and memory consumption compared with other more powerful GNNs.

System Identification as a Reinforcement Learning Problem

Jose Antonio Martin H.,Oscar Fernández Vicente,Sergio Perez,Anas Belfadil,Cristina Ibanez-Llano,Freddy Perozo,Jose Javier Valle,Javier Arechalde Pelaz

System identification, also known as learning forward models, transfer functions, system dynamics, etc., has a long tradition both in science and engineering in different fields. Particularly, it is a recurring theme in Reinforcement Learni ng research, where forward models approximate the state transition function of a Markov Decision Process by learning a mapping function from current state and action to the next state. This problem is commonly defined as a Supervised Learning problem in a direct way. This common approach faces several difficulties due to the inherent complexities of the dynamics to learn, for example, delayed effects, high non-linearity, non-stationarity, partial observability and, more important, error accumulation when using bootstrapped predictions (predictions based on past predictions), over large time horizons. Here we explore the use of Reinforcement Learning in this problem. We elaborate on why and how this problem fits naturally and sound as a Reinforcement Learning problem, and present some experimental results that demonstrate RL is a promising technique to solve these kind of problems.

When to Trust Aggregated Gradients: Addressing Negative Client Sampling in Federated Learning

Wenkai Yang,Yankai Lin,Guangxiang Zhao,Peng Li,Jie Zhou,Xu Sun

Federated Learning has become a widely-used framework which allows learning a global model on decentralized local datasets under the condition of protecting local data privacy. However, federated learning faces severe optimization difficulty when training samples are not independently and identically distributed (non-i.i.d.). In this paper, we point out that the client sampling practice plays a decisive role in the aforementioned optimization difficulty. We find that the negative client sampling will cause the merged data distribution of currently sampled clients heavily inconsistent with that of all available clients, and further make the aggregated gradient unreliable. To address this issue, we propose a novel learning rate adaptation mechanism to adaptively adjust the server learning rate for the aggregated gradient in each round, according to the consistency between the merged data distribution of currently sampled clients and that of all available clients. Specifically, we make theoretical deductions to find a meaningful and robust indicator that is positively related to the optimal server learning rate and can effectively reflect the merged data distribution of sampled clients, and we utilize it for the server learning rate adaptation. Extensive experiments on multiple image and text classification tasks validate the great effectiveness of our method.

More ConvNets in the 2020s: Scaling up Kernels Beyond 51x51 using Sparsity

Shiwei Liu,Tianlong Chen,Xiaohan Chen,Xuxi Chen,Qiao Xiao,Boqian Wu,Tommi Kärkkäinen,Mykola Pechenizkiy,Decebal Constantin Mocanu,Zhangyang Wang

Transformers have quickly shined in the computer vision world since the emergence of Vision Transformers (ViTs). The dominant role of convolutional neural networks (CNNs) seems to be challenged by increasingly effective transformer-based models. Very recently, a couple of advanced convolutional models strike back with large kernels motivated by the local-window attention mechanism, showing appealing performance and efficiency. While one of them, i.e. RepLKNet, impressively manages to scale the kernel size to 31x31 with improved performance, the performance starts to saturate as the kernel size continues growing, compared to the scaling trend of advanced ViTs such as Swin Transformer. In this paper, we explore the possibility of training extreme convolutions larger than 31x31 and test whether the performance gap can be eliminated by strategically enlarging convolutions. This study ends up with a recipe for applying extremely large kernels from the perspective of sparsity, which can smoothly scale up kernels to 61x61 with better performance. Built on this recipe, we propose Sparse Large Kernel Network (SLaK), a pure CNN architecture equipped with sparse factorized 51x51 kernels that can perform on par with or better than state-of-the-art hierarchical Transformers and modern ConvNet architectures like ConvNeXt and RepLKNet, on ImageNet classification as well as a wide range of downstream tasks including semantic segmentation on ADE20K, object detection on PASCAL VOC 2007, and object detection/segmentation on MS COCO. Codes are available at https://github.com/VITA-Group/SLaK.

Few-shot Cross-domain Image Generation via Inference-time Latent-code Learning

Arnab Kumar Mondal,Piyush Tiwary,Parag Singla,Prathosh AP

In this work, our objective is to adapt a Deep generative model trained on a large-scale source dataset to multiple target domains with scarce data. Specifically, we focus on adapting a pre-trained Generative Adversarial Network (GAN) to a target domain without re-training the generator. Our method draws the motivation from the fact that out-of-distribution samples can be `embedded' onto the latent space of a pre-trained source-GAN. We propose to train a small latent-generation network during the inference stage, each time a batch of target samples is to be generated. These target latent codes are fed to the source-generator to obtain novel target samples. Despite using the same small set of target samples and the source generator, multiple independent training episodes of the latent-generation network results in the diversity of the generated target samples. Our method, albeit simple, can be used to generate data from multiple target distributions using a generator trained on a single source distribution. We demonstrate the efficacy of our surprisingly simple method in generating multiple target datasets with only a single source generator and a few target samples.

RLx2: Training a Sparse Deep Reinforcement Learning Model from Scratch

Yiqin Tan,Pihe Hu,Ling Pan,Jiatai Huang,Longbo Huang

Training deep reinforcement learning (DRL) models usually requires high computation costs. Therefore, compressing DRL models possesses immense potential for training acceleration and model deployment. However, existing methods that generate small models mainly adopt the knowledge distillation-based approach by iteratively training a dense network. As a result, the training process still demands massive computing resources. Indeed, sparse training from scratch in DRL has not been well explored and is particularly challenging due to non-stationarity in bootstrap training. In this work, we propose a novel sparse DRL training framework, “the Rigged Reinforcement Learning Lottery” (RLx2), which builds upon gradient-based topology evolution and is capable of training a sparse DRL model based entirely on a sparse network. Specifically, RLx2 introduces a novel multi-step TD target mechanism with a dynamic-capacity replay buffer to achieve robust value learning and efficient topology exploration in sparse models. It also reaches state-of-the-art sparse training performance in several tasks, showing $7.5\times$-$20\times$ model compression with less than 3% performance degradation and up to $20\times$ and $50\times$ FLOPs reduction for training and inference, respectively.

****

Rethinking Positive Sampling for Contrastive Learning with Kernel

Benoit Dufumier,Carlo Alberto Barbano,Robin Louiset,Edouard Duchesnay,Pietro Gori

Data augmentation is a crucial component in unsupervised contrastive learning (CL). It determines how positive samples are defined and, ultimately, the quality of the representation. Even if efforts have been made to find efficient augmentations for ImageNet, CL underperforms compared to supervised methods and it is still an open problem in other applications, such as medical imaging, or in datasets with easy-to-learn but irrelevant imaging features. In this work, we propose a new way to define positive samples using kernel theory along with a novel loss called \textit{decoupled uniformity}. We propose to integrate prior information, learnt from generative models viewed as feature extractor, or given as auxiliary attributes, into contrastive learning, to make it less dependent on data augmentation. We draw a connection between contrastive learning and the conditional mean embedding theory to derive tight bounds on the downstream classification loss. In an unsupervised setting, we empirically demonstrate that CL benefits from generative models, such as VAE and GAN, to less rely on data augmentations. We validate our framework on vision and medical datasets including CIFAR10, CIFAR100, STL10, ImageNet100, CheXpert and a brain MRI dataset. In the weakly supervised setting, we demonstrate that our formulation provides state-of-the-art results.

****

Stationary Deep Reinforcement Learning with Quantum K-spin Hamiltonian Equation

Xiao-Yang Liu,Zechu Li,Shixun Wu,Xiaodong Wang

Instability is a major issue of deep reinforcement learning (DRL) algorithms --- high variance of cumulative rewards over multiple runs. The instability is mainly caused by the existence of \textit{many local minimas} and worsened by the \textit{multiple fixed points} issue of Bellman's optimality equation. As a fix, we propose a quantum K-spin Hamiltonian regularization term (called \textit{H-term}) to help a policy network converge to a high-quality local minima. First, we take a quantum perspective by modeling a policy as a \textit{K-spin Ising model} and employ a Hamiltonian equation to measure the \textit{energy} of a policy. Then, we derive a novel Hamiltonian policy gradient theorem and design a generic actor-critic algorithm that utilizes the H-term to regularize the policy network. Finally, the proposed method significantly reduces the variance of cumulative rewards by $65.2\% \sim 85.6\%$ on six MuJoCo tasks; achieves an approximation ratio ≤ 1.05 over 90% test cases and reduces its variance by $60.16\% \sim 94.52\%$ on two combinatorial optimization tasks and two non-convex optimization tasks, compared with those of existing algorithms over 20 runs, respectively.

Performance Disparities Between Accents in Automatic Speech Recognition

Alex DiChristofano,Henry Shuster,Shefali Chandra,Neal Patwari

Automatic speech recognition (ASR) services are ubiquitous, transforming speech into text for systems like Amazon’s Alexa, Google’s Assistant, and Microsoft’s Cortana. Past research has identified discriminatory ASR performance as a function of racial group and nationality. In this paper, we expand the discussion about nationality and English language ASR by performing an audit of some of the most popular English ASR services using a large and global data set of speech from The Speech Accent Archive. We show that performance disparities exist as a function of whether or not a speaker’s first language is English and, even when controlling for multiple linguistic covariates, that these disparities have a statistically significant relationship to the political alignment of the speaker’s birth country with respect to the United States’ geopolitical power. We discuss this bias in the context of the historical use of language to maintain global and political power.

****

Do Perceptually Aligned Gradients Imply Robustness?

Roy Ganz,Bahjat Kawar,Michael Elad

Deep learning-based networks have achieved unprecedented success in numerous tasks, among which image classification. Despite these remarkable achievements, recent studies have demonstrated that such classification networks are easily fooled by small malicious perturbations, also known as adversarial examples. This security weakness led to extensive research aimed at obtaining robust models. Beyond the clear robustness benefits of such models, it was also observed that their gradients with respect to the input align with human perception. Several works have identified Perceptually Aligned Gradients (PAG) as a byproduct of robust training, but none have considered it as a standalone phenomenon nor studied its own implications. In this work, we focus on this trait and test whether \emph{Perceptually Aligned Gradients imply Robustness}. To this end, we develop a novel objective to directly promote PAG in training classifiers and examine whether models with such gradients are more robust to adversarial attacks. We present both heuristic and principled ways for obtaining target PAGs, which our method aims to learn. Specifically, we harness recent findings in score-based generative modeling as a source for PAG. Extensive experiments on CIFAR-10 and STL validate that models trained with our method have improved robust performance, exposing the surprising bidirectional connection between PAG and robustness.

****

Sparsity May Cry: Let Us Fail (Current) Sparse Neural Networks Together!

Shiwei Liu,Tianlong Chen,Zhenyu Zhang,Xuxi Chen,Tianjin Huang,AJAY KUMAR JAISWAL,Zhangyang Wang

Sparse Neural Networks (SNNs) have received voluminous attention predominantly due to growing computational and memory footprints of consistently exploding para meter count in large-scale models. Similar to their dense counterparts, recent SNNs generalize just as well and are equipped with numerous favorable benefits (e.g., low complexity, high scalability, and robustness), sometimes even better than the original dense networks. As research effort is focused on developing increasingly sophisticated sparse algorithms, it is startling that a comprehensive benchmark to evaluate the effectiveness of these algorithms has been highly overlooked. In absence of a carefully crafted evaluation benchmark, most if not all, sparse algorithms are evaluated against fairly simple and naive tasks (eg. CIFAR-10/100, ImageNet, GLUE, etc.), which can potentially camouflage many advantages as well unexpected predicaments of SNNs. In pursuit of a more general evaluation and unveiling the true potential of sparse algorithms, we introduce “Sparsity May Cry” Benchmark (SMC-Bench), a collection of carefully-curated 4 diverse tasks with 10 datasets, that accounts for capturing a wide range of domain-specific and sophisticated knowledge. Our systemic evaluation of the most representative sparse algorithms reveals an important obscured observation: the state-of-the-art magnitude- and/or gradient-based sparse algorithms seemingly fail to perform on SMC-Bench when applied out-of-the-box, sometimes at significantly trivial sparsity as low as 5%. The observations seek the immediate attention of the sparsity research community to reconsider the highly proclaimed benefits of SNNs. We further conduct a thorough investigation into the reasons for the failure of common SNNs. Our analysis points out that such failure is intimately related to the “lazy regime” of large model training, which hints us with stronger pruning recipes that alleviate the failure on SMC-Bench (though still more or less suffering). By incorporating these well-thought and diverse tasks, SMC-Bench is designed to favor and encourage the development of more scalable and generalizable sparse algorithms. We open-source SMC-Bench to assist researchers in building next-generation sparse algorithms that scale and generalize: https://github.com/VITA-Group/SMC-Bench.

Multitask Reinforcement Learning by Optimizing Neural Pathways

Samin Yeasar Arnob,Riyasat Ohib,Amy Zhang,Sergey Plis,Doina Precup

Reinforcement learning (RL) algorithms have achieved great success in learning specific tasks, as evidenced by examples such as AlphaGo or fusion control. However, it is still difficult for an RL agent to learn how to solve multiple tasks. In this paper, we propose a novel multitask learning framework, in which multiple specialized pathways through a single network are trained simultaneously, with each pathway focusing on a single task. We show that this approach achieves competitive performance with existing multitask RL methods, while using only 5% of the number of neurons per task. We demonstrate empirically the success of our approach on several continuous control tasks, in both online and offline training.

****

How deep convolutional neural networks lose spatial information with training

Umberto Maria Tomasini,Leonardo Petrini,Francesco Cagnetta,Matthieu Wyart

A central question of machine learning is how deep nets manage to learn tasks in high dimensions. An appealing hypothesis is that they achieve this feat by building a representation of the data where information irrelevant to the task is lost. For image data sets, this view is supported by the observation that after (and not before) training, the neural representation becomes less and less sensitive to diffeomorphisms acting on images as the signal propagates through the net.

This loss of sensitivity correlates with performance, and surprisingly also correlates with a gain of sensitivity to white noise acquired during training. These facts are unexplained, and as we demonstrate still hold when white noise is added to the images of the training set. Here, we (i) show empirically for various architectures that stability to image diffeomorphisms is achieved by spatial pooling in the first half of the net, and by channel pooling in the second half, (ii) introduce a scale-detection task for a simple model of data where pooling is learnt during training, which captures all empirical observations above and (iii) compute in this model how stability to diffeomorphisms and noise scale with depth. The scalings are found to depend on the presence of strides in the net ar chitecture. We find that the increased sensitivity to noise is due to the perturbing noise piling up during pooling, after a ReLU non-linearity is applied to the noise in the internal layers.

****

Which Layer is Learning Faster? A Systematic Exploration of Layer-wise Convergence Rate for Deep Neural Networks

Yixiong Chen,Alan Yuille,Zongwei Zhou

The deeply hierarchical structures enable deep neural networks (DNNs) to fit extremely complex target functions. However, the complex interaction between layers also makes the learning process of a particular layer poorly understood. This work demonstrates that the shallower layers of DNNs tend to converge faster than the deeper layers. We call this phenomenon Layer Convergence Bias. We also uncover the fundamental reason behind this phenomenon: Flatter local minima of shallower layers make their gradients more stable and predictive, allowing for faster training. Another surprising result is that the shallower layers tend to learn the low-frequency components of the target function, while the deeper layers usually learn the high-frequency components. It is consistent with the recent discovery that DNNs learn lower frequency objects faster.

****

Joint Embedding Self-Supervised Learning in the Kernel Regime

Bobak Kiani,Randall Balestriero,Yubei Chen,Seth Lloyd,Yann LeCun

The fundamental goal of self-supervised learning (SSL) is to produce useful representations of data without access to any labels for classifying the data. Modern methods in SSL, which form representations based on known or constructed relationships between samples, have been particularly effective at this task. Here, we aim to extend this framework to incorporate algorithms based on kernel methods where embeddings are constructed by linear maps acting on the feature space of a kernel. In this kernel regime, we derive methods to find the optimal form of the output representations for contrastive and non-contrastive loss functions. This procedure produces a new representation space with an inner product denoted as the induced kernel which generally correlates points which are related by an augmentation in kernel space and de-correlates points otherwise. We analyze our kernel model on small datasets to identify common features of self-supervised learning algorithms and gain theoretical insights into their performance on downstream tasks.

****

Linear convergence for natural policy gradient with log-linear policy parametrization

Carlo Alfano,Patrick Rebeschini

We analyze the convergence rate of the \emph{unregularized} natural policy gradient algorithm with log-linear policy parametrizations in infinite-horizon discounted Markov decision processes. In the deterministic case, when the Q-value is known and can be approximated by a linear combination of a known feature function up to a bias error, we show that a geometrically-increasing step size yields a linear convergence rate towards an optimal policy. We then consider the sample-based case, when the best representation of the Q-value function among linear combinations of a known feature function is known up to an estimation error. In this setting, we show that the algorithm enjoys the same linear guarantees as in the deterministic case up to an error term that depends on the estimation error, the bias error, and the condition number of the feature covariance matrix. Our results build upon the general framework of policy mirror descent and extend previous findings for the softmax tabular parametrization to the log-linear policy class.

****

A Non-Asymptotic Analysis of Oversmoothing in Graph Neural Networks

Xinyi Wu,Zhengdao Chen,William Wei Wang,Ali Jadbabaie

Oversmoothing is a central challenge of building more powerful Graph Neural Networks (GNNs). While previous works have only demonstrated that oversmoothing is inevitable when the number of graph convolutions tends to infinity, in this paper, we precisely characterize the mechanism behind the phenomenon via a non-asympt otic analysis. Specifically, we distinguish between two different effects when applying graph convolutions—an undesirable mixing effect that homogenizes node representations in different classes, and a desirable denoising effect that homogenizes node representations in the same class. By quantifying these two effects on random graphs sampled from the Contextual Stochastic Block Model (CSBM), we show that oversmoothing happens once the mixing effect starts to dominate the denoising effect, and the number of layers required for this transition is $O(\log N/\log (\log N))$ for sufficiently dense graphs with N nodes. We also extend our analysis to study the effects of Personalized PageRank (PPR), or equivalently, the effects of initial residual connections on oversmoothing. Our results suggest that while PPR mitigates oversmoothing at deeper layers, PPR-based architectures still achieve their best performance at a shallow depth and are outperformed by the graph convolution approach on certain graphs. Finally, we support our theoretical results with numerical experiments, which further suggest that the oversmoothing phenomenon observed in practice can be magnified by the difficulty of optimizing deep GNN models.

Class-Incremental Learning with Repetition

Hamed Hemati,Andrea Cossu,Antonio Carta,Julio Hurtado,Lorenzo Pellegrini,Davide Bacciu,Vincenzo Lomonaco,Damian Borth

Real-world data streams naturally include the repetition of previous concepts. From a Continual Learning (CL) perspective, repetition is a property of the environment and, unlike replay, cannot be controlled by the user. Nowadays, Class-Incremental scenarios represent the leading test-bed for assessing and comparing CL strategies. This family of scenarios is very easy to use, but it never allows revisiting previously seen classes, thus completely disregarding the role of repetition. We focus on the family of Class-Incremental with Repetition (CIR) scenarios, where repetition is embedded in the definition of the stream. We propose two stochastic scenario generators that produce a wide range of CIR scenarios starting from a single dataset and a few control parameters. We conduct the first comprehensive evaluation of repetition in CL by studying the behavior of existing CL strategies under different CIR scenarios. We then present a novel replay strategy that exploits repetition and counteracts the natural imbalance present in the stream. On both CIFAR100 and TinyImageNet, our strategy outperforms other replay approaches, which are not designed for environments with repetition.

Scaleformer: Iterative Multi-scale Refining Transformers for Time Series Forecasting

Mohammad Amin Shabani,Amir H. Abdi,Lili Meng,Tristan Sylvain

The performance of time series forecasting has recently been greatly improved by the introduction of transformers. In this paper, we propose a general multi-scale framework that can be applied to state-of-the-art transformer-based time series forecasting models
(FEDformer, Autoformer, etc.). Using iteratively refining a forecasted time series at multiple scales with shared weights, architecture adaptations and a specially-designed normalization scheme, we are able to achieve significant performance improvements with minimal additional computational overhead. Via detailed ablation studies, we demonstrate the effectiveness of our proposed architectural and methodological innovations. Furthermore, our experiments on various public datasets demonstrate that the proposed method outperforms the corresponding baselines. Depending on the choice of transformer architecture, our mutli-scale framework results in mean squared error reductions ranging from 5.5% to 38.5%. Our code is publicly available in https://github.com/BorealisAI/scaleformer.

Theoretical Characterization of How Neural Network Pruning Affects its Generalization

Hongru Yang,Yingbin Liang,Xiaojie Guo,Lingfei Wu,Zhangyang Wang

It has been observed in practice that applying pruning-at-initialization methods to neural networks and training the sparsified networks can not only retain the testing performance of the original dense models, but also sometimes even sligh tly boost the generalization performance. Theoretical understanding for such experimental observations are yet to be developed. This work makes the first attempt to study how different pruning fractions affect the model's gradient descent dynamics and generalization. Specifically, this work considers a classification task for overparameterized two-layer neural networks, where the network is randomly pruned according to different rates at the initialization. It is shown that as long as the pruning fraction is below a certain threshold, gradient descent can drive the training loss toward zero and the network exhibits good generalization performance. More surprisingly, the generalization bound gets better as the pruning fraction gets larger. To complement this positive result, this work further shows a negative result: there exists a large pruning fraction such that while gradient descent is still able to drive the training loss toward zero (by memorizing noise), the generalization performance is no better than random guessing. This further suggests that pruning can change the feature learning process, which leads to the performance drop of the pruned neural network. Up to our knowledge, this is the first generalization result for pruned neural networks, suggesting that pruning can improve the neural network's generalization.

Backdoors Stuck At The Frontdoor: Multi-Agent Backdoor Attacks That Backfire
Siddhartha Datta,Nigel Shadbolt

Malicious agents in collaborative learning and outsourced data collection threaten the training of clean models. Backdoor attacks, where an attacker poisons a model during training to successfully achieve targeted misclassification, are a major concern to train-time robustness. In this paper, we investigate a multi-agent backdoor attack scenario, where multiple attackers attempt to backdoor a victim model simultaneously. A consistent backfiring phenomenon is observed across a wide range of games, where agents suffer from a low collective attack success rate. We examine different modes of backdoor attack configurations, non-cooperation / cooperation, joint distribution shifts, and game setups to return an equilibrium attack success rate at the lower bound. The results motivate the re-evaluation of backdoor defense research for practical environments.

Draft, Sketch, and Prove: Guiding Formal Theorem Provers with Informal Proofs
Albert Qiaochu Jiang,Sean Welleck,Jin Peng Zhou,Timothee Lacroix,Jiacheng Liu,Wenda Li,Mateja Jamnik,Guillaume Lample,Yuhuai Wu

The formalization of existing mathematical proofs is a notoriously difficult process. Despite decades of research on automation and proof assistants, writing formal proofs remains arduous and only accessible to a few experts. While previous studies to automate formalization focused on powerful search algorithms, no attempts were made to take advantage of available informal proofs. In this work, we introduce Draft, Sketch, and Prove (DSP), a method that maps informal proofs to formal proof sketches, and uses the sketches to guide an automated prover by directing its search to easier sub-problems. We investigate two relevant setups where informal proofs are either written by humans or generated by a language model. Our experiments and ablation studies show that large language models are able to produce well-structured formal sketches that follow the same reasoning steps as the informal proofs. Guiding an automated prover with these sketches enhances its performance from 20.9% to 39.3% on a collection of mathematical competition problems.

****

Interpolating Compressed Parameter Subspaces
Siddhartha Datta,Nigel Shadbolt

Though distribution shifts have caused growing concern for machine learning scalability, solutions tend to specialize towards a specific type of distribution shift. Methods for label shift may not succeed against domain or task shift, and vice versa. We learn that constructing a Compressed Parameter Subspaces (CPS), a geometric structure representing distance-regularized parameters mapped to a set of train-time distributions, can maximize average accuracy over a broad range of distribution shifts concurrently. We show sampling parameters within a CPS can mitigate backdoor, adversarial, permutation, stylization and rotation perturbat ions. We also show training a hypernetwork representing a CPS can adapt to seen tasks as well as unseen interpolated tasks.

Liquid Structural State-Space Models

Ramin Hasani,Mathias Lechner,Tsun-Hsuan Wang,Makram Chahine,Alexander Amini,Daniela Rus

A proper parametrization of state transition matrices of linear state-space models (SSMs) followed by standard nonlinearities enables them to efficiently learn representations from sequential data, establishing the state-of-the-art on an extensive series of long-range sequence modeling benchmarks. In this paper, we show that we can improve further when the structured SSM, such as S4, is given by a linear liquid time-constant (LTC) state-space model. LTC neural networks are causal continuous-time neural networks with an input-dependent state transition module, which makes them learn to adapt to incoming inputs at inference. We show that by using a diagonal plus low-rank decomposition of the state transition matrix introduced in S4, and a few simplifications, the LTC-based structured state-space model, dubbed Liquid-S4, improves generalization across sequence modeling tasks with long-term dependencies such as image, text, audio, and medical time-series, with an average performance of 87.32\% on the Long-Range Arena benchmark. On the full raw Speech Command recognition dataset, Liquid-S4 achieves 96.78\% accuracy with a 30\% reduction in parameter counts compared to S4. The additional gain in performance is the direct result of the Liquid-S4's kernel structure that takes into account the similarities of the input sequence samples during training and inference.

Equivariant Hypergraph Diffusion Neural Operators

Peihao Wang,Shenghao Yang,Yunyu Liu,Zhangyang Wang,Pan Li

Hypergraph neural networks (HNNs) using neural networks to encode hypergraphs provide a promising way to model higher-order relations in data and further solve relevant prediction tasks built upon such higher-order relations. However, higher-order relations in practice contain complex patterns and are often highly irregular. So, it is often challenging to design an HNN that suffices to express those relations while keeping computational efficiency. Inspired by hypergraph diffusion algorithms, this work proposes a new HNN architecture named ED-HNN, which provably approximates any continuous equivariant hypergraph diffusion operators that can model a wide range of higher-order relations. ED-HNN can be implemented efficiently by combining star expansions of hypergraphs with standard message passing neural networks. ED-HNN further shows great superiority in processing heterophilic hypergraphs and constructing deep models. We evaluate ED-HNN for node classification on nine real-world hypergraph datasets. ED-HNN uniformly outperforms the best baselines over these nine datasets and achieves more than 2%$\uparrow$ in prediction accuracy over four datasets therein. Our code is available at: https://github.com/Graph-COM/ED-HNN.

Ollivier-Ricci Curvature for Hypergraphs: A Unified Framework

Corinna Coupette,Sebastian Dalleiger,Bastian Rieck

Bridging geometry and topology, curvature is a powerful and expressive invariant. While the utility of curvature has been theoretically and empirically confirmed in the context of manifolds and graphs, its generalization to the emerging domain of hypergraphs has remained largely unexplored. On graphs, the Ollivier-Ricci curvature measures differences between random walks via Wasserstein distances, thus grounding a geometric concept in ideas from probability theory and optimal transport. We develop Orchid, a flexible framework generalizing Ollivier-Ricci curvature to hypergraphs, and prove that the resulting curvatures have favorable theoretical properties. Through extensive experiments on synthetic and real-world hypergraphs from different domains, we demonstrate that Orchid curvatures are both scalable and useful to perform a variety of hypergraph tasks in practice.

Biases in Evaluation of Molecular Optimization Methods and Bias Reduction Strategies

Hiroshi Kajino,Kohei Miyaguchi,Takayuki Osogami

We are interested in in silico evaluation methodology for molecular optimization methods. Given a sample of molecules and their properties of our interest, we wish not only to train a generator of molecules that can find those optimized with respect to a target property but also to evaluate its performance accurately. A common practice is to train a predictor of the target property on the sample and use it for both training and evaluating the generator. We theoretically investigate this evaluation methodology and show that it potentially suffers from two biases; one is due to misspecification of the predictor and the other to reusing the same sample for training and evaluation. We discuss bias reduction methods for each of the biases, and empirically investigate their effectiveness.

Sharper Analysis of Sparsely Activated Wide Neural Networks with Trainable Biases

Hongru Yang,Ziyu Jiang,Ruizhe Zhang,Zhangyang Wang,Yingbin Liang

This work studies training one-hidden-layer overparameterized ReLU networks via gradient descent in the neural tangent kernel (NTK) regime, where, differently from the previous works, the networks' biases are trainable and are initialized to some constant rather than zero. The tantalizing benefit of such initialization is that the neural network will provably have sparse activation pattern before, during and after training, which can enable fast training procedures and, therefore, reduce the training cost. The first set of results of this work characterize the convergence of the network's gradient descent dynamics. The required width is provided to ensure gradient descent can drive the training error towards zero in linear rate. The contribution over previous work is that not only the bias is allowed to be updated by gradient descent under our setting but also a finer analysis is given such that the required width to ensure the network's closeness to its NTK is improved. Secondly, the networks' generalization bound after training is provided. A width-sparsity dependence is presented which yields sparsity-dependent localized Rademacher complexity and same-as-previous (ignoring logarithmic factors) generalization bound. Up to our knowledge, this is the first sparsity-dependent generalization result via localized Rademacher complexity. As a by-product, if the bias initialization is chosen to be zero, the width requirement improves the previous bound for the shallow networks' generalization. Lastly, since the generalization bound has dependence on the smallest eigenvalue of the limiting NTK and the bounds from previous works yield vacuous generalization, this work further studies the least eigenvalue of the limiting NTK. Surprisingly, while it is not shown that trainable biases are necessary, trainable bias helps to identify a nice data-dependent region where a much finer analysis of the NTK's smallest eigenvalue can be conducted, which leads to a much sharper lower bound than the previously known worst-case bound and, consequently, a non-vacuous generalization bound. Experimental evaluation is provided to evaluate our results.

Hard-Meta-Dataset++: Towards Understanding Few-Shot Performance on Difficult Tasks

Samyadeep Basu,Megan Stanley,John F Bronskill,Soheil Feizi,Daniela Massiceti

Few-shot classification is the ability to adapt to any new classification task from only a few training examples. The performance of current top-performing few-shot classifiers varies widely across different tasks where they often fail on a subset of `difficult' tasks.

This phenomenon has real-world consequences for deployed few-shot systems where safety and reliability are paramount, yet little has been done to understand these failure cases. In this paper, we study these difficult tasks to gain a more nuanced understanding of the limitations of current methods. To this end, we develop a general and computationally efficient algorithm called FastDiffSel to extract difficult tasks from any large-scale vision dataset. Notably, our algorithm can extract tasks at least 20x faster than existing methods enabling its use on large-scale datasets. We use FastDiffSel to extract difficult tasks from Meta-Da tasset, a widely-used few-shot classification benchmark, and other challenging large-scale vision datasets including ORBIT, CURE-OR and ObjectNet. These tasks are curated into Hard-MD++, a new few-shot testing benchmark to promote the development of methods that are robust to even the most difficult tasks. We use Hard-MD++ to stress-test an extensive suite of few-shot classification methods and show that state-of-the-art approaches fail catastrophically on difficult tasks. We believe that our extraction algorithm FastDiffSel and Hard-MD++ will aid researchers in further understanding failure modes of few-shot classification models.

REVISITING PRUNING AT INITIALIZATION THROUGH THE LENS OF RAMANUJAN GRAPH

Duc N.M Hoang,Shiwei Liu,Radu Marculescu,Zhangyang Wang

Pruning neural networks at initialization (PaI) has received an upsurge of interest due to its end-to-end saving potential. PaI is able to find sparse subnetworks at initialization that can achieve comparable performance to the full networks. These methods can surpass the trivial baseline of random pruning but suffer from a significant performance gap compared to post-training pruning. Previous approaches firmly rely on weights, gradients, and sanity checks as primary signals when conducting PaI analysis. To better understand the underlying mechanism of PaI, we propose to interpret it through the lens of the Ramanujan Graph - a class of expander graphs that are sparse while being highly connected. It is often believed there should be a strong correlation between the Ramanujan graph and PaI since both are about finding sparse and well-connected neural networks. However, the finer-grained link relating highly sparse and connected networks to their relative performance (i.e., ranking of difference sparse structures at the same specific global sparsity) is still missing. We observe that not only the Ramanujan property for sparse networks shows no significant relationship to PaI’s relative performance, but maximizing it can also lead to the formation of pseudo-random graphs with no structural meanings. We reveal the underlying cause to be Ramanujan Graph’s strong assumption on the upper bound of the largest nontrivial eigenvalue (μˆ) of layers belonging to highly sparse networks. We hence propose Iterative Mean Difference of Bound (IMDB) as a mean to relax the μˆ upper bound. Likewise, we also show there exists a lower bound for μˆ, which we call the Normalized Random Coefficient (NaRC), that gives us an accurate assessment for when sparse but highly connected structure degenerates into naive randomness. Finally, we systematically analyze the behavior of various PaI methods and demonstrate the utility of our proposed metrics in characterizing PaI performance. We show that subnetworks preserving better the IMDB property correlate higher in performance, while NaRC provides us with a possible mean to locate the region where highly connected, highly sparse, and non-trivial Ramanujan expanders exist. Our code is available at: https://github.com/VITA-Group/ramanujan-on-pai.

Self-supervised Speech Enhancement using Multi-Modal Data

Yu-Lin Wei,Bashima Islam,RAJALAXMI RAJAGOPALAN,romit choudhury

Modern earphones come equipped with microphones and inertial measurement units (IMU). When a user wears the earphone, the IMU can serve as a second modality for detecting speech signals. Specifically, as humans speak to their earphones (e.g., during phone calls), the throat’s vibrations propagate through the skull to ultimately induce a vibration in the IMU. The IMU data is heavily distorted (compared to the microphone’s recordings), but IMUs offer a critical advantage — they are not interfered by ambient sounds. This presents an opportunity in multi-modal speech enhancement, i.e., can the distorted but uninterfered IMU signal enhance the user’s speech when the microphone’s signal suffers from strong ambient interference?

We combine the best of both modalities (microphone and IMU) by designing a cooperative and self-supervised network architecture that does not rely on clean speech data from the user. Instead, using only noisy speech recordings, the IMU learns to give hints on where the target speech is likely located. The microphone uses this hint to enrich the speech signal, which then trains the IMU to improve subsequent hints. This iterative approach yields promising results, comparable to a supervised denoiser trained on clean speech signals. When clean signals are a lso available to our architecture, we observe promising SI-SNR improvement. We believe this result can aid speech-related applications in earphones and hearing aids, and potentially generalize to others, like audio-visual denoising.

Sparse MoE as the New Dropout: Scaling Dense and Self-Slimmable Transformers

Tianlong Chen,Zhenyu Zhang,AJAY KUMAR JAISWAL,Shiwei Liu,Zhangyang Wang

Despite their remarkable achievement, gigantic transformers encounter significant drawbacks, including exorbitant computational and memory footprints during training, as well as severe collapse evidenced by a high degree of parameter redundancy. Sparsely-activated Mixture-of-Experts (SMoEs) have shown promise to mitigate the issue of training efficiency, yet they are prone to (1) $\textit{redundant experts}$ due to representational collapse; and (2) $\textit{poor expert scalability for inference and downstream fine-tuning}$, primarily due to overfitting of the learned routing policy to the number of activated experts during training. As recent research efforts are predominantly focused on improving routing policies to encourage expert specializations, this work focuses on $\textit{exploring the overlooked scalability bottleneck of SMoEs}$ and leveraging it to effectively $\textbf{scale dense transformers}$. To this end, we propose a new plug-and-play training framework, $\textbf{SMoE-Dropout}$, to enable scaling transformers to better accuracy in their full capacity without collapse. Specifically, SMoE-Dropout consists of a $\textit{randomly initialized and fixed}$ router network to activate experts and gradually increases the activated expert number as training progresses over time. Transformers trained by SMoE-Dropout naturally exhibit a $\textbf{``self-slimmable”}$ property subject to resource availability, offering smooth and consistent performance boosts with an increase in activated experts during inference or fine-tuning. Our extensive experiments across diverse transformer architectures on a variety of tasks demonstrate the superior performance and substantial computation savings of SMoE-Dropout, compared to dense training baselines with equivalent parameter counts. In particular, our trained BERT outperforms its densely trained counterpart with consistent improvements of {1.03%, 0.78%, 1.09%} on challenging reasoning tasks {$\texttt{ASDiv-A}$, $\texttt{MAWPS}$, $\texttt{SVAMP}$}, respectively. Codes and models are available in https://github.com/VITA-Group/Random-MoE-as-Dropout.

Compositional Semantic Parsing with Large Language Models

Andrew Drozdov,Nathanael Schärli,Ekin Akyürek,Nathan Scales,Xinying Song,Xinyun Chen,Olivier Bousquet,Denny Zhou

Humans can reason compositionally when presented with new tasks. Previous research shows that appropriate prompting techniques enable large language models (LLMs) to solve artificial compositional generalization tasks such as SCAN. In this work, we identify additional challenges in more realistic semantic parsing tasks with larger vocabulary and refine these prompting techniques to address them. Our best method is based on least-to-most prompting: it decomposes the problem using prompting-based syntactic parsing, then uses this decomposition to select appropriate exemplars and to sequentially generate the semantic parse. This method allows us to set a new state of the art for CFQ while requiring only 1% of the training data used by traditional approaches. Due to the general nature of our approach, we expect similar efforts will lead to new results in other tasks and domains, especially for knowledge-intensive applications.

****

TiAda: A Time-scale Adaptive Algorithm for Nonconvex Minimax Optimization

Xiang Li,Junchi YANG,Niao He

Adaptive gradient methods have shown their ability to adjust the stepsizes on the fly in a parameter-agnostic manner, and empirically achieve faster convergence for solving minimization problems. When it comes to nonconvex minimax optimization, however, current convergence analyses of gradient descent ascent (GDA) combined with adaptive stepsizes require careful tuning of hyper-parameters and the knowledge of problem-dependent parameters. Such a discrepancy arises from the primal-dual nature of minimax problems and the necessity of delicate time-scale separation between the primal and dual updates in attaining convergence. In this w ork, we propose a single-loop adaptive GDA algorithm called TiAda for nonconvex minimax optimization that automatically adapts to the time-scale separation. Our algorithm is fully parameter-agnostic and can achieve near-optimal complexities simultaneously in deterministic and stochastic settings of nonconvex-strongly-concave minimax problems. The effectiveness of the proposed method is further justified numerically for a number of machine learning applications.

Generalization Properties of Retrieval-based Models

Soumya Basu,Ankit Singh Rawat,Manzil Zaheer

Many modern high-performing machine learning models such as GPT-3 primarily rely on scaling up models, e.g., transformer networks. Simultaneously, a parallel line of work aims to improve the model performance by augmenting an input instance with other (labeled) instances during inference. Examples of such augmentations include task-specific prompts and similar examples retrieved from the training data by a nonparametric component. Remarkably, retrieval-based methods have enjoyed success on a wide range of problems, ranging from standard natural language processing and vision tasks to protein folding, as demonstrated by many recent efforts, including WebGPT and AlphaFold. Despite growing literature showcasing the promise of these models, the theoretical underpinning for such models remains underexplored. In this paper, we present a formal treatment of retrieval-based models to characterize their generalization ability. In particular, we focus on two classes of retrieval-based classification approaches: First, we analyze a local learning framework that employs an explicit local empirical risk minimization based on retrieved examples for each input instance. Interestingly, we show that breaking down the underlying learning task into local sub-tasks enables the model to employ a low complexity parametric component to ensure good overall accuracy. The second class of retrieval-based approaches we explore learns a global model using kernel methods to directly map an input instance and retrieved examples to a prediction, without explicitly solving a local learning task.

Semi-Variance Reduction for Fair Federated Learning

Saber Malekmohammadi,Guojun Zhang,Yaoliang Yu

Ensuring fairness in Federated Learning (FL) systems, i.e. ensuring a satisfactory performance for all of the diverse clients in the systems, is an important and challenging problem. There are multiple fair FL algorithms in the literature, which have been relatively successful in providing fairness. However, these algorithms mostly emphasize on the loss functions of worst-off clients to improve their performance, which often results in the suppression of well-performing ones. As a consequence, the system's overall average performance is usually sacrificed for achieving fairness. Motivated by this and inspired by two well-known risk modeling methods in Finance, Mean-Variance and Mean-Semi-Variance, we propose and study two new fair FL algorithms, Variance Reduction (VRed) and Semi-Variance Reduction (Semi-VRed). VRed encourages equality between clients loss functions by penalizing their variance. In contrast, Semi-VRed penalizes the discrepancy of only the worst-off clients loss functions from the average loss. Through extensive experiments on multiple vision and language datasets, we show that, Semi-VRed achieves SoTA performance in scenarios with highly heterogeneous data distributions by improving both fairness and the system overall average performance at the same time.

Multi-Modality Alone is Not Enough: Generating Scene Graphs using Cross-Relation-Modality Tokens

Gopika Sudhakaran,Devendra Singh Dhami,Stefan Roth,Kristian Kersting

Recent years have seen a growing interest in Scene Graph Generation (SGG), a comprehensive visual scene understanding task that aims to predict the relationships between objects detected in a scene. One of its key challenges is the strong bias of the visual world around us toward a few frequently occurring relationships, leaving a long tail of under-represented classes. Although infusing additional modalities is one prominent way to improve SGG performance on under-represented classes, we argue that using additional modalities alone is not enough. We pro pose to inject entity relation information (Cross-Relation) and modality dependencies (Cross-Modality) into each embedding token of a transformer which we term primal fusion. The resulting Cross-RElAtion-Modality (CREAM) token acts as a strong inductive bias for the SGG framework. Our experimental results on the Visual Genome dataset demonstrate that our CREAM model outperforms state-of-the-art SGG models by around 20% while being simpler and requiring substantially less computation. Additionally, to analyse the generalisability of the CREAM model we also evaluate it on the Open Images dataset. Finally, we examine the impact of the depth-map quality on SGG performance and empirically show the superiority of our model over the prior state of the art by better capturing the depth data, boosting the performance by a margin of around 25%.

FaiREE: fair classification with finite-sample and distribution-free guarantee
Puheng Li,James Zou,Linjun Zhang

Algorithmic fairness plays an increasingly critical role in machine learning research. Several group fairness notions and algorithms have been proposed. However, the fairness guarantee of existing fair classification methods mainly depend on specific data distributional assumptions, often requiring large sample sizes, and fairness could be violated when there is a modest number of samples, which is often the case in practice. In this paper, we propose FaiREE, a fair classification algorithm which can satisfy group fairness constraints with finite-sample and distribution-free theoretical guarantees. FaiREE can be adapted to satisfying various group fairness notions (e.g., Equality of Opportunity, Equalized Odds, Demographic Parity, etc.) and achieve the optimal accuracy. These theoretical guarantees are further supported by experiments on both synthetic and real data. FaiREE is shown to have favorable performance over state-of-the-art algorithms.

Deep Evidential Reinforcement Learning for Dynamic Recommendations
Dingrong Wang,Krishna Prasad Neupane,Ervine Zheng,Qi Yu

Reinforcement learning (RL) has been applied to build recommender systems (RS) to capture users' evolving preferences and continuously improve the quality of recommendations. In this paper, we propose a novel deep evidential reinforcement learning (DERL) framework that learns a more effective recommendation policy by integrating both the expected reward and evidence-based uncertainty. In particular, DERL conducts evidence-aware exploration to locate items that a user will most likely take interest in the future. Two central components of DERL include a customized recurrent neural network (RNN) and an evidential-actor-critic (EAC) module. The former module is responsible for generating the current state of the environment by aggregating historical information and a sliding window that contains the current user interactions as well as newly recommended items that may encode future interest. The latter module performs evidence-based exploration by maximizing a uniquely designed evidential Q-value to derive a policy giving preference to items with good predicted ratings while remaining largely unknown to the system (due to lack of evidence). These two components are jointly trained by supervised learning and reinforcement learning. Experiments on multiple real-world dynamic datasets demonstrate the state-of-the-art performance of DERL and its capability to capture long-term user interests.

Exponential Generalization Bounds with Near-Optimal Rates for L_q-Stable Algorithms
Xiaotong Yuan,Ping Li

The \emph{stability} of learning algorithms to changes in the training sample has been actively studied as a powerful proxy for reasoning about generalization. Recently, exponential generalization and excess risk bounds with near-optimal rates have been obtained under the stringent and distribution-free notion of uniform stability~\citep{bousquet2020sharper,klochkov2021stability}. In the meanwhile, under the notion of L_q-stability, which is weaker and distribution dependent, exponential generalization bounds are also available yet so far only with sub-optimal rates. Therefore, a fundamental question we would like to address in this paper is whether it is possible to derive near-optimal exponential generaliz

ation bounds for L_q-stable learning algorithms. As the core contribution of the present work, we give an affirmative answer to this question by developing strict analogues of the near-optimal generalization and risk bounds of uniformly stable algorithms for L_q-stable algorithms. Further, we demonstrate the power of our improved L_q-stability and generalization theory by applying it to derive strong sparse excess risk bounds, under mild conditions, for computationally tractable sparsity estimation algorithms such as Iterative Hard Thresholding (IHT).

Disentangling Learning Representations with Density Estimation
Eric Yeats,Frank Y Liu,Hai Li
Disentangled learning representations have promising utility in many applications, but they currently suffer from serious reliability issues. We present Gaussian Channel Autoencoder (GCAE), a method which achieves reliable disentanglement via scalable non-parametric density estimation of the latent space. GCAE avoids the curse of dimensionality of density estimation by disentangling subsets of its latent space with the Dual Total Correlation (DTC) metric, thereby representing its high-dimensional latent joint distribution as a collection of many low-dimensional conditional distributions. In our experiments, GCAE achieves highly competitive and reliable disentanglement scores compared with state-of-the-art baselines.

Coarse-to-fine Knowledge Graph Domain Adaptation based on Distantly-supervised Iterative Training
Hongmin Cai,Wenxiong Liao,Zhengliang Liu,Yuzhong Chen,Tianming Liu,Xiang Li
Modern supervised learning neural network models require a large amount of manually labeled data, which makes the construction of domain-specific knowledge graphs time-consuming and labor-intensive. In parallel, although there has been much research on named entity recognition and relation extraction based on distantly supervised learning, constructing a domain-specific knowledge graph from large collections of textual data without manual annotations is still an urgent problem to be solved. In response, we propose an integrated framework for adapting and re-learning knowledge graphs from one coarse domain (biomedical) to a finer-define domain (oncology). In this framework, we apply distant-supervision on cross-domain knowledge graph adaptation. Consequently, no manual data annotation is required to train the model. We introduce a novel iterative training strategy to facilitate the discovery of domain-specific named entities and triples. Experimental results indicate that the proposed framework can perform domain adaptation and construction of knowledge graph efficiently.
****

Teacher Guided Training: An Efficient Framework for Knowledge Transfer
Manzil Zaheer,Ankit Singh Rawat,Seungyeon Kim,Chong You,Himanshu Jain,Andreas Veit,Rob Fergus,Sanjiv Kumar
The remarkable performance gains realized by large pretrained models, e.g., GPT-3, hinge on the massive amounts of data they are exposed to during training. Analogously, distilling such large models to compact models for efficient deployment also necessitates a large amount of (labeled or unlabeled) training data. In this paper, we propose the teacher-guided training (TGT) framework for training a high-quality compact model that leverages the knowledge acquired by pretrained generative models, while obviating the need to go through a large volume of data. TGT exploits the fact that the teacher has acquired a good representation of the underlying data domain, which typically corresponds to a much lower dimensional manifold than the input space. Furthermore, we can use the teacher to explore input space more efficiently through sampling or gradient-based methods; thus, making TGT especially attractive for limited data or long-tail settings. We formally capture this benefit of proposed data-domain exploration in our generalization bounds. We find that TGT can improve accuracy on several image classification benchmarks as well as a range of text classification and retrieval tasks.

Neural Agents Struggle to Take Turns in Bidirectional Emergent Communication

Valentin Taillandier,Dieuwke Hupkes,Benoît Sagot,Emmanuel Dupoux,Paul Michel

The spontaneous exchange of turns is a central aspect of human communication. Although turn-taking conventions come to us naturally, artificial dialogue agents struggle to coordinate, and must rely on hard-coded rules to engage in interactive conversations with human interlocutors. In this paper, we investigate the conditions under which artificial agents may naturally develop turn-taking conventions in a simple language game. We describe a cooperative task where success is contingent on the exchange of information along a shared communication channel where talking over each other hinders communication. Despite these environmental constraints, neural-network based agents trained to solve this task with reinforcement learning do not systematically adopt turn-taking conventions. However, we find that agents that do agree on turn-taking protocols end up performing better.

Moreover, agents that are forced to perform turn-taking can learn to solve the task more quickly.

This suggests that turn-taking may help to generate conversations that are easier for speakers to interpret.

Class Interference of Deep Networks

Dongcui Diao,Hengshuai Yao,Bei Jiang

Recognizing and telling similar objects apart is even hard for human beings. In this paper, we show that there is a phenomenon of class interference with all deep neural networks. Class interference represents the learning difficulty in data and it constitutes the largest percentage of generalization errors by deep networks. To understand class interference, we propose cross-class tests, class ego directions and interference models. We show how to use these definitions to study minima flatness and class interference of a trained model. We also show how to detect class interference during training through label dancing pattern and class dancing notes.

Observational Robustness and Invariances in Reinforcement Learning via Lexicographic Objectives

Daniel Jarne Ornia,Licio Romao,Lewis Hammond,Manuel Mazo Jr,Alessandro Abate

Policy robustness in Reinforcement Learning (RL) may not be desirable at any price; the alterations caused by robustness requirements from otherwise optimal policies should be explainable and quantifiable. Policy gradient algorithms that have strong convergence guarantees are usually modified to obtain robust policies in ways that do not preserve algorithm guarantees, which defeats the purpose of formal robustness requirements. In this work we study a notion of robustness in partially observable MDPs where state observations are perturbed by a noise-induced stochastic kernel. We characterize the set of policies that are maximally robust by analysing how the policies are altered by this kernel. We then establish a connection between such robust policies and certain properties of the noise kernel, as well as with structural properties of the underlying MDPs, constructing sufficient conditions for policy robustness. We use these notions to propose a robustness-inducing scheme, applicable to any policy gradient algorithm, to formally trade off the reward achieved by a policy with its robustness level through lexicographic optimization, which preserves convergence properties of the original algorithm. We test the the proposed approach through numerical experiments on safety-critical RL environments, and show how the proposed method helps achieve high robustness when state errors are introduced in the policy roll-out.

SeedGNN: Graph Neural Network for Supervised Seeded Graph Matching

Liren Yu,Jiaming Xu,Xiaojun Lin

There have been significant interests in designing Graph Neural Networks (GNNs) for seeded graph matching, which aims to match two (unlabeled) graphs using only topological information and a small set of seeds. However, most previous GNNs for seeded graph matching employ a semi-supervised approach, which requires a large number of seeds and can not learn knowledge transferable to unseen graphs. In contrast, this paper proposes a new supervised approach that can learn from a t

raining set how to match unseen graphs with only a few seeds. At the core of our SeedGNN architecture are two novel modules: 1) a convolution module that can easily learn the capability of counting and using witnesses of different hops; 2) a percolation module that can use easily-matched pairs as new seeds to percolate and match other nodes. We evaluate SeedGNN on both synthetic and real graphs, and demonstrate significant performance improvement over both non-learning and learning algorithms in the existing literature. Further, our experiments confirm that the knowledge learned by SeedGNN from training graphs can be generalized to test graphs with different sizes and categories.

Provable Sharpness-Aware Minimization with Adaptive Learning Rate
Hao Sun,Li Shen,Qihuang Zhong,Liang Ding,Shixiang Chen,Jingwei Sun,Guangzhong Sun,Dacheng Tao
Sharpness aware minimization (SAM) optimizer has been extensively explored as it can converge fast and train deep neural networks efficiently via introducing extra perturbation steps to flatten the landscape of deep learning models. A combination of SAM with adaptive learning rate (AdaSAM) has also been explored to train large-scale deep neural networks without theoretical guarantee due to the dual difficulties in analyzing the perturbation step and the coupled adaptive learning rate. In this paper, we try to analyze the convergence rate of AdaSAM in the stochastic non-convex setting. We theoretically show that AdaSAM admit a $\mathcal{O}(1/\sqrt{bT})$ convergence rate and show linear speedup property with respect to mini-batch size b. To best of our knowledge, we are the first to provide the non-trivial convergence rate of SAM with an adaptive learning rate. To decouple the two stochastic gradient steps with the adaptive learning rate, we first introduce the delayed second-order momentum during the convergence to decompose them to make them independent while taking an expectation. Then we bound them by showing the adaptive learning rate has a limited range, which makes our analysis feasible. At last, we conduct experiments on several NLP tasks and they show that AdaSAM could achieve superior performance compared with SGD, AMSGrad, and SAM optimizer.

Prompting GPT-3 To Be Reliable
Chenglei Si,Zhe Gan,Zhengyuan Yang,Shuohang Wang,Jianfeng Wang,Jordan Lee Boyd-Graber,Lijuan Wang
Large language models (LLMs) show impressive abilities via few-shot prompting. Commercialized APIs such as OpenAI GPT-3 further increase their use in real-world language applications. However, the crucial problem of how to improve the reliability of GPT-3 is still under-explored. While reliability is a broad and vaguely defined term, we decompose reliability into four main facets that correspond to the existing framework of ML safety and are well-recognized to be important: generalizability, social biases, calibration, and factuality. Our core contribution is to establish simple and effective prompts that improve GPT-3’s reliability as it: 1) generalizes out-of-distribution, 2) balances demographic distribution and uses natural language instructions to reduce social biases, 3) calibrates output probabilities, and 4) updates the LLM’s factual knowledge and reasoning chains. With appropriate prompts, GPT-3 is more reliable than smaller-scale supervised models on all these facets. We release all processed datasets, evaluation scripts, and model predictions. Our systematic empirical study not only sheds new insights on the reliability of prompting LLMs, but more importantly, our prompting strategies can help practitioners more reliably use LLMs like GPT-3.

Adversarial Training of Self-supervised Monocular Depth Estimation against Physical-World Attacks
Zhiyuan Cheng,James Chenhao Liang,Guanhong Tao,Dongfang Liu,Xiangyu Zhang
Monocular Depth Estimation (MDE) is a critical component in applications such as autonomous driving. There are various attacks against MDE networks. These attacks, especially the physical ones, pose a great threat to the security of such systems. Traditional adversarial training method requires ground-truth labels and hence cannot be directly applied to self-supervised MDE that does not have dept

h ground truth. Some self-supervised model hardening technique (e.g., contrastive learning) ignores the domain knowledge of MDE and can hardly achieve optimal performance. In this work, we propose a novel adversarial training method for self-supervised MDE models based on view synthesis without using the depth ground truth. We improve adversarial robustness against physical-world attacks using L_0-norm-bounded perturbation in training. We compare our method with supervised learning-based and contrastive learning-based methods that are tailored for MDE. Results on two representative MDE networks show that we achieve better robustness against various adversarial attacks with nearly no benign performance degradation.

Sparsity-Constrained Optimal Transport

Tianlin Liu,Joan Puigcerver,Mathieu Blondel

Regularized optimal transport (OT) is now increasingly used as a loss or as a matching layer in neural networks. Entropy-regularized OT can be computed using the Sinkhorn algorithm but it leads to fully-dense transportation plans, meaning that all sources are (fractionally) matched with all targets. To address this issue, several works have investigated quadratic regularization instead. This regularization preserves sparsity and leads to unconstrained and smooth (semi) dual objectives, that can be solved with off-the-shelf gradient methods. Unfortunately, quadratic regularization does not give direct control over the cardinality (number of nonzeros) of the transportation plan. We propose in this paper a new approach for OT with explicit cardinality constraints on the transportation plan. Our work is motivated by an application to sparse mixture of experts, where OT can be used to match input tokens such as image patches with expert models such as neural networks. Cardinality constraints ensure that at most k tokens are matched with an expert, which is crucial for computational performance reasons. Despite the nonconvexity of cardinality constraints, we show that the corresponding (semi) dual problems are tractable and can be solved with first-order gradient methods. Our method can be thought as a middle ground between unregularized OT (recovered in the limit case $k=1$) and quadratically-regularized OT (recovered when k is large enough). The smoothness of the objectives increases as k increases, giving rise to a trade-off between convergence speed and sparsity of the optimal plan.

A Risk-Averse Equilibrium for Multi-Agent Systems

Oliver Slumbers,David Henry Mguni,Stephen Marcus McAleer,Jun Wang,Yaodong Yang

In multi-agent systems, intelligent agents are tasked with making decisions that lead to optimal outcomes when actions of the other agents are as expected, whilst also being prepared for their unexpected behaviour. In this work, we introduce a novel risk-averse solution concept that allows the learner to accommodate low probability actions by finding the strategy with minimum variance, given any level of expected utility. We first prove the existence of such a risk-averse equilibrium, and propose one fictitious-play type learning algorithm for smaller games that enjoys provable convergence guarantees in games classes including zero-sum and potential. Furthermore, we propose an approximation method for larger games based on iterative population-based training that generates a population of risk- averse agents. Empirically, our equilibrium is shown to be able to reduce the utility variance, specifically in the sense that other agents’ low probability behaviour is better accounted for by our equilibrium in comparison to playing other solutions. Importantly, we show that our population of agents that approximate a risk-averse equilibrium is particularly effective against unseen opposing populations, especially in the case of guaranteeing a minimum level of performance, which is critical to safety-aware multi-agent systems.

SuperWeight Ensembles: Automated Compositional Parameter Sharing Across Diverse Architechtures

Piotr Teterwak,Soren Nelson,Nikoli Dryden,Dina Bashkirova,Kate Saenko,Bryan A. Plummer

Neural net ensembles boost task performance, but have excessive storage requirem ents. Recent work in efficient ensembling has made the memory cost more tractable by sharing learned parameters between ensemble members. Existing efficient ensembles have high predictive accuracy, but they are overly restrictive in two ways: 1) They constrain ensemble members to have the same architecture, limiting their usefulness in applications such as anytime inference, and 2) They reduce the parameter count for a small predictive performance penalty, but do not provide an easy way to trade-off parameter count for predictive performance without increasing inference time. In this paper, we propose SuperWeight Ensembles, an approach for architecture-agnostic parameter sharing. SuperWeight Ensembles share parameters between layers which have sufficiently similar computation, even if they have different shapes. This allows anytime prediction of heterogeneous ensembles by selecting a subset of members during inference, which is a flexibility not supported by prior work. In addition, SuperWeight Ensembles provide control over the total number of parameters used, allowing us to increase or decrease the number of parameters without changing model architecture. On the anytime prediction task, our method shows a consistent boost over prior work while allowing for more flexibility in architectures and efficient parameter sharing. SuperWeight Ensembles preserve the performance of prior work in the low-parameter regime, and even outperform fully-parameterized ensembles with 17% fewer parameters on CIFAR-100 and 50% fewer parameters on ImageNet.

Human alignment of neural network representations

Lukas Muttenthaler,Jonas Dippel,Lorenz Linhardt,Robert A. Vandermeulen,Simon Kornblith

Today’s computer vision models achieve human or near-human level performance across a wide variety of vision tasks. However, their architectures, data, and learning algorithms differ in numerous ways from those that give rise to human vision. In this paper, we investigate the factors that affect the alignment between the representations learned by neural networks and human mental representations inferred from behavioral responses. We find that model scale and architecture have essentially no effect on the alignment with human behavioral responses, whereas the training dataset and objective function both have a much larger impact. These findings are consistent across three datasets of human similarity judgments collected using two different tasks. Linear transformations of neural network representations learned from behavioral responses from one dataset substantially improve alignment with human similarity judgments on the other two datasets. In addition, we find that some human concepts such as food and animals are well-represented by neural networks whereas others such as royal or sports-related objects are not. Overall, although models trained on larger, more diverse datasets achieve better alignment with humans than models trained on ImageNet alone, our results indicate that scaling alone is unlikely to be sufficient to train neural networks with conceptual representations that match those used by humans.

Imitation Learning for Mean Field Games with Correlated Equilibria

Zhiyu Zhao,Renyuan Xu,Haifeng Zhang,Jun Wang,Mingyuan Zhang,Yaodong Yang

Imitation learning (IL) aims at achieving optimal actions by learning from demonstrated behaviors without knowing the reward function and transition kernels. Conducting IL with a large population of agents is challenging as agents' interactions grow exponentially with respect to the population size. Mean field theory provides an efficient tool to study multi-agent problems by aggregating information on the population level. While the approximation is tractable, it is non-trivial to restore mean field Nash equilibria (MFNE) from demonstrations. Importantly, there are many real-world problems that cannot be explained by the classic MFNE concept; this includes the traffic network equilibrium induced from the public routing recommendations and the pricing equilibrium of goods generated on the E-commerce platform.   In both examples, correlated devices are introduced to the equilibrium due to the intervention from the platform. To accommodate this, we propose a novel solution concept named adaptive mean field correlated equilibrium (AMFCE) that generalizes MFNE. On the theory side, we first prove the existence of AMFCE, and establish a novel framework based on IL and AMFCE with entropy regularization (MaxEnt-AMFCE) to recover the AMFCE policy from real-world demonstrations. Signatures from the rough path theory are then applied to characterize the mean-field evolution. A significant benefit of MaxEnt-AMFCE is that it can recover both the equilibrium policy and the correlation device from data. We test our MaxEnt-AMFCE against the state-of-the-art IL algorithms for MFGs on several tasks (including a real-world traffic flow prediction problem), results justify the effectiveness of our proposed method and show its potential to predicting and explaining large population behavior under correlated signals.

Turning the Curse of Heterogeneity in Federated Learning into a Blessing for Out-of-Distribution Detection

Shuyang Yu,Junyuan Hong,Haotao Wang,Zhangyang Wang,Jiayu Zhou

Deep neural networks have witnessed huge successes in many challenging prediction tasks and yet they often suffer from out-of-distribution (OoD) samples, misclassifying them with high confidence. Recent advances show promising OoD detection performance for centralized training, and however, OoD detection in federated learning (FL) is largely overlooked, even though many security sensitive applications such as autonomous driving and voice recognition authorization are commonly trained using FL for data privacy concerns. The main challenge that prevents previous state-of-the-art OoD detection methods from being incorporated to FL is that they require large amount of real OoD samples. However, in real-world scenarios, such large-scale OoD training data can be costly or even infeasible to obtain, especially for resource-limited local devices. On the other hand, a notorious challenge in FL is data heterogeneity where each client collects non-identically and independently distributed (non-iid) data. We propose to take advantage of such heterogeneity and turn the curse into a blessing that facilitates OoD detection in FL. The key is that for each client, non-iid data from other clients (unseen external classes) can serve as an alternative to real OoD samples. Specifically, we propose a novel Federated Out-of-Distribution Synthesizer (FOSTER), which learns a class-conditional generator to synthesize virtual external-class OoD samples, and maintains data confidentiality and communication efficiency required by FL. Experimental results show that our method outperforms the state-of-the-art by 2.49%, 2.88%, 1.42% AUROC, and 0.01%, 0.89%, 1.74% ID accuracy, on CIFAR-10, CIFAR-100, and STL10, respectively.

Clustering and Ordering Variable-Sized Sets: The Catalog Problem

Mateusz Maria Jurewicz,Graham W. Taylor,Leon Derczynski

Prediction of a varying number of ordered clusters from sets of any cardinality is a challenging task for neural networks, combining elements of set representation, clustering and learning to order. This task arises in many diverse areas, ranging from medical triage, through multi-channel signal analysis for petroleum exploration to product catalog structure prediction. This paper focuses on the latter, which exemplifies a number of challenges inherent to adaptive ordered clustering, referred to further as the eponymous Catalog Problem. These include learning variable cluster constraints, exhibiting relational reasoning and managing combinatorial complexity. Despite progress in both neural clustering and set-to-sequence methods, no joint, fully differentiable model exists to-date. We develop such a modular architecture, referred to further as Neural Ordered Clusters (NOC), enhance it with a specific mechanism for learning cluster-level cardinality constraints, and provide a robust comparison of its performance in relation to alternative models. We test our method on three datasets, including synthetic catalog structures and PROCAT, a dataset of real-world catalogs consisting of over 1.5M products, achieving state-of-the-art results on a new, more challenging formulation of the underlying problem, which has not been addressed before. Additionally, we examine the network's ability to learn higher-order interactions and investigate its capacity to learn both compositional and structural rulesets.

RangeAugment: Efficient Online Augmentation with Range Learning

Sachin Mehta,Saeid Naderiparizi,Fartash Faghri,Maxwell Horton,Lailin Chen,Ali Farhadi,Oncel Tuzel,Mohammad Rastegari

State-of-the-art automatic augmentation methods (e.g., AutoAugment and RandAugment) for visual recognition tasks diversify training data using a large set of augmentation operations. The range of magnitudes of many augmentation operations (e.g., brightness and contrast) is continuous. Therefore, to make search computationally tractable, these methods use fixed and manually-defined magnitude ranges for each operation, which may lead to sub-optimal policies. To answer the open question on the importance of magnitude ranges for each augmentation operation, we introduce RangeAugment that allows us to efficiently learn the range of magnitudes for individual as well as composite augmentation operations. RangeAugment uses an auxiliary loss based on image similarity as a measure to control the range of magnitudes of augmentation operations. As a result, RangeAugment has a single scalar parameter for search, image similarity, which we simply optimize via linear search. RangeAugment integrates seamlessly with any model and learns model- and task-specific augmentation policies. With extensive experiments on the ImageNet dataset across different networks, we show that RangeAugment achieves competitive performance to state-of-the-art automatic augmentation methods with 4-5 times fewer augmentation operations. Experimental results on semantic segmentation and contrastive learning further shows RangeAugment's effectiveness.

How Predictors Affect Search Strategies in Neural Architecture Search?

TianJin Deng,Jia Wu

Predictor-based Neural Architecture Search (NAS) is an important topic since it can efficiently reduce the computational cost of evaluating candidate architectures. Most existing predictor-based NAS algorithms aim to design different predictors to improve prediction performance. Unfortunately, even a promising performance predictor may suffer from the accuracy decline due to long-term and continuous usage, thus leading to the degraded performance of the search strategy. That naturally gives rise to the following problems: how predictors affect search strategies and how to appropriately use the predictor? In this paper, we take reinforcement learning (RL) based search strategy to study theoretically and empirically the impact of predictors on search strategies. We first formulate a predictor-RL-based NAS algorithm as model-based RL and analyze it with a guarantee of monotonic improvement at each trail. Then, based on this analysis, we propose a simple procedure of predictor usage, named mixed batch, which contains ground-truth data and prediction data. The proposed procedure can efficiently reduce the impact of predictor errors on search strategies with maintaining performance growth. Our algorithm, Predictor-based Neural Architecture Search with Mixed batch (PNASM), outperforms traditional NAS algorithms and prior state-of-the-art predictor-based NAS algorithms on three NAS-Bench-201 tasks.

Unbiased Stochastic Proximal Solver for Graph Neural Networks with Equilibrium States

Mingjie Li,Yifei Wang,Yisen Wang,Zhouchen Lin

Graph Neural Networks (GNNs) are widely used deep learning models that can extract meaningful representations from graph datasets and achieve great success in many machine learning tasks. Among them, graph neural networks with iterative iterations like unfolded GNNs and implicit GNNs can effectively capture long-range dependencies in graphs and demonstrate superior performance on large graphs since they can mathematically ensure its convergence to some nontrivial solution after lots of aggregations. However, the aggregation time for such models costs a lot as they need to aggregate the full graph in each update. Such weakness limits the scalability of the implicit graph models. To tackle such limitations, we propose two unbiased stochastic proximal solvers inspired by the stochastic proximal gradient descent method and its variance reduction variant called USP and USP-VR solvers. From the point of stochastic optimization, we theoretically prove that our solvers are unbiased, which can converge to the same solution as the original solvers for unfolded GNNs and implicit GNNs. Furthermore, the computation complexities for unfolded GNNs and implicit GNNs with our proposed solvers are significantly less than their vanilla versions. Experiments on various large grap

h datasets show that our proposed solvers are more efficient and can achieve state-of-the-art performance.

Energy Transformer

Benjamin Hoover,Yuchen Liang,Bao Pham,Rameswar Panda,Hendrik Strobelt,Duen Horng Chau,Mohammed J Zaki,Dmitry Krotov

Transformers have become the de facto models of choice in machine learning, typically leading to impressive performance on many applications. At the same time, the architectural development in the transformer world is mostly driven by empirical findings, and the theoretical understanding of their architectural building blocks is rather limited. In contrast, Dense Associative Memory models or Modern Hopfield Networks have a well-established theoretical foundation, but have not yet demonstrated truly impressive practical results. We propose a transformer architecture that replaces the sequence of feedforward transformer blocks with a single large Associative Memory model. Our novel architecture, called Energy Transformer (or ET for short), has many of the familiar architectural primitives that are often used in the current generation of transformers. However, it is not identical to the existing architectures. The sequence of transformer layers in ET is purposely designed to minimize a specifically engineered energy function, which is responsible for representing the relationships between the tokens. As a consequence of this computational principle, the attention in ET is different from the conventional attention mechanism. In this work, we introduce the theoretical foundations of ET, explore it's empirical capabilities using the image completion task, and obtain strong quantitative results on the graph anomaly detection task.

Privacy-Preserving Vision Transformer on Permutation-Encrypted Images

Fusheng Hao,Fengxiang He,Yikai Wang,Fuxiang Wu,Jun Cheng,Dacheng Tao

Massive human-related data is collected to train neural networks for computer vision tasks. Potential incidents, such as data leakages, expose significant privacy risks to applications. In this paper, we propose an efficient privacy-preserving learning paradigm, where images are first encrypted via one of the two encryption strategies: (1) random shuffling to a set of equally-sized patches and (2) mixing-up sub-patches of the images. Then, a permutation-equivariant vision transformer is designed to learn on the encrypted images for vision tasks, including image classification and object detection. Extensive experiments on ImageNet and COCO show that the proposed paradigm achieves comparable accuracy with the competitive methods. Moreover, decrypting the encrypted images is solving an NP-hard jigsaw puzzle or an ill-posed inverse problem, which is empirically shown intractable to be recovered by the powerful vision transformer-based attackers. We thus show that the proposed paradigm can destroy human-recognizable contents while preserving machine-learnable information. Code will be released publicly.
****

DiGress: Discrete Denoising diffusion for graph generation

Clement Vignac,Igor Krawczuk,Antoine Siraudin,Bohan Wang,Volkan Cevher,Pascal Frossard

This work introduces DiGress, a discrete denoising diffusion model for generating graphs with categorical node and edge attributes.

Our model utilizes a discrete diffusion process that progressively edits graphs with noise, through the process of adding or removing edges and changing the categories.

A graph transformer network is trained to revert this process, simplifying the problem of distribution learning over graphs into a sequence of node and edge classification tasks.

We further improve sample quality by introducing a Markovian noise model that preserves the marginal distribution of node and edge types during diffusion, and by incorporating auxiliary graph-theoretic features.

A procedure for conditioning the generation on graph-level features is also proposed.

DiGress achieves state-of-the-art performance on molecular and non-molecular dat

asets, with up to 3x validity improvement on a planar graph dataset.
It is also the first model to scale to the large GuacaMol dataset containing 1.3M drug-like molecules without the use of molecule-specific representations.

****

DIFFormer: Scalable (Graph) Transformers Induced by Energy Constrained Diffusion

Qitian Wu,Chenxiao Yang,Wentao Zhao,Yixuan He,David Wipf,Junchi Yan

Real-world data generation often involves complex inter-dependencies among instances, violating the IID-data hypothesis of standard learning paradigms and posing a challenge for uncovering the geometric structures for learning desired instance representations. To this end, we introduce an energy constrained diffusion model which encodes a batch of instances from a dataset into evolutionary states that progressively incorporate other instances' information by their interactions. The diffusion process is constrained by descent criteria w.r.t.~a principled energy function that characterizes the global consistency of instance representations over latent structures. We provide rigorous theory that implies closed-form optimal estimates for the pairwise diffusion strength among arbitrary instance pairs, which gives rise to a new class of neural encoders, dubbed as DIFFormer, with two instantiations: a simple version with linear complexity for prohibitive instance numbers, and an advanced version for learning complex structures. Experiments highlight the wide applicability of our model as a general-purpose encoder backbone with superior performance in various tasks, such as semi-supervised node classification, image/text classification, and spatial-temporal dynamics prediction.

Neural Lagrangian Schr\"{o}dinger Bridge: Diffusion Modeling for Population Dynamics

Takeshi Koshizuka,Issei Sato

Population dynamics is the study of temporal and spatial variation in the size of populations of organisms and is a major part of population ecology. One of the main difficulties in analyzing population dynamics is that we can only obtain observation data with coarse time intervals from fixed-point observations due to experimental costs or measurement constraints. Recently, modeling population dynamics by using continuous normalizing flows (CNFs) and dynamic optimal transport has been proposed to infer the sample trajectories from a fixed-point observed population. While the sample behavior in CNFs is deterministic, the actual sample in biological systems moves in an essentially random yet directional manner. Moreover, when a sample moves from point A to point B in dynamical systems, its trajectory typically follows the principle of least action in which the corresponding action has the smallest possible value. To satisfy these requirements of the sample trajectories, we formulate the Lagrangian Schrödinger bridge (LSB) problem and propose to solve it approximately by modeling the advection-diffusion process with regularized neural SDE. We also develop a model architecture that enables faster computation of the loss function. Experimental results show that the proposed method can efficiently approximate the population-level dynamics even for high-dimensional data and that using the prior knowledge introduced by the Lagrangian enables us to estimate the sample-level dynamics with stochastic behavior.

Jump-Start Reinforcement Learning

Ikechukwu Uchendu,Ted Xiao,Yao Lu,Banghua Zhu,Mengyuan Yan,Joséphine Simon,Matthew Bennice,Chuyuan Fu,Cong Ma,Jiantao Jiao,Sergey Levine,Karol Hausman

Reinforcement learning (RL) provides a theoretical framework for continuously improving an agent’s behavior via trial and error. However, efficiently learning policies from scratch can be very difficult, particularly for tasks that present exploration challenges. In such settings, it might be desirable to initialize RL with an existing policy, offline data, or demonstrations. However, naively performing such initialization in RL often works poorly, especially for value-based methods. In this paper, we present a meta algorithm that can use offline data, demonstrations, or a pre-existing policy to initialize an RL policy, and is compatible with any RL approach. In particular, we propose Jump-Start Reinforcement L earning (JSRL), an algorithm that employs two policies to solve tasks: a guide-policy, and an exploration-policy. By using the guide-policy to form a curriculum of starting states for the exploration-policy, we are able to efficiently improve performance on a set of simulated robotic tasks. We show via experiments that it is able to significantly outperform existing imitation and reinforcement learning algorithms, particularly in the small-data regime. In addition, we provide an upper bound on the sample complexity of JSRL and show that with the help of a guide-policy, one can improve the sample complexity for non-optimism exploration methods from exponential in horizon to polynomial.

AD-NEGF: An End-to-End Differentiable Quantum Transport Simulator for Sensitivity Analysis and Inverse Problems

Zhanghao Zhouyin,Xiang Chen,Peng Zhang,Jun Wang,Lei Wang,Hong Guo

Quantum transport theory describes transport phenomena from first principles, which is essential for domains such as semiconductor fabrication. As a representative, the Non-Equilibrium Green Function (NEGF) method achieves superiority in numerical accuracy. However, its tremendous computational cost makes it unbearable for high-throughput simulation tasks such as sensitivity analysis, inverse design, etc. In this work, we propose AD-NEGF, to the best of our knowledge the first Automatic Differentiation (AD) based quantum transport simulator. AD-NEGF calculates gradient information efficiently by utilizing automatic differentiation and implicit layer techniques, while guaranteeing the correctness of the forward simulation. Such gradient information enables accurate and efficient calculation of differential physical quantities and solving inverse problems that are intractable by traditional optimization methods.

Incomplete to complete multiphysics forecasting - a hybrid approach for learning unknown phenomena

Nilam Nandkishor Tathawadekar,Nguyen Anh Khoa Doan,Camilo Fernando Silva,Nils Thuerey

Modeling complex dynamical systems where only partial knowledge of their physical mechanisms is available is a crucial problem across all scientific and engineering disciplines. Purely data-driven approaches, which only make use of an artificial neural network and data, often fail to accurately simulate the evolution of the system dynamics over a sufficiently long time and in a physically consistent manner. Therefore, we propose a hybrid approach that uses a neural network model in combination with an incomplete PDE solver that provides known but incomplete physical information. In this study, we demonstrate that the results obtained from the incomplete PDEs can be efficiently corrected at every time step by the proposed hybrid neural network – PDE solver model, so that the effect of the unknown physics present in the system is correctly accounted for. For validation purposes, the obtained simulations of the hybrid model are successfully compared against results coming from the complete set of PDEs describing the full physics of the considered system. We demonstrate the validity of the proposed approach on a reactive flow, an archetypal multi-physics system that combines fluid mechanics and chemistry, the latter being the physics considered unknown. Experiments are made on planar and Bunsen-type flames at various operating conditions. The hybrid neural network - PDE approach correctly models the flame evolution of the cases under study for significantly long time windows, yields improved generalization, and allows for larger simulation time steps.

Bi-Level Dynamic Parameter Sharing among Individuals and Teams for Promoting Collaborations in Multi-Agent Reinforcement Learning

Yan Liu,Ying Tiffany He,Fei Richard Yu,Zhong Ming

Parameter sharing has greatly contributed to the success of multi-agent reinforcement learning in recent years. However, most existing parameter sharing mechanisms are static, and parameters are indiscriminately shared among individuals, ignoring the dynamic environments and different roles of multiple agents. In addition, although a single-level selective parameter sharing mechanism can promote the diversity of strategies, it is hard to establish complementary and cooperativ e relationships between agents. To address these issues, we propose a bi-level dynamic parameter sharing mechanism among individuals and teams for promoting effective collaborations (BDPS). Specifically, at the individual level, we define virtual dynamic roles based on the long-term cumulative advantages of agents and share parameters among agents in the same role. At the team level, we combine agents of different virtual roles and share parameters of agents in the same group. Through the joint efforts of these two levels, we achieve a dynamic balance between the individuality and commonality of agents, enabling agents to learn more complex and complementary collaborative relationships. We evaluate BDPS on a challenging set of StarCraft II micromanagement tasks. The experimental results show that our method outperforms the current state-of-the-art baselines, and we demonstrate the reliability of our proposed structure through ablation experiments.

How to prepare your task head for finetuning

Yi Ren,Shangmin Guo,Wonho Bae,Danica J. Sutherland

In the era of deep learning, transferring information from a pretrained network to a downstream task by finetuning has many benefits. The choice of task head plays an important role in fine-tuning, as the pretrained and downstream tasks are usually different. Although there exist many different designs for finetuning, a full understanding of when and why these algorithms work has been elusive. We analyze how the choice of task head controls feature adaptation and hence influences the downstream performance. By decomposing the feature's learning dynamics, we find the key aspect is the training accuracy and loss at the beginning of finetuning, which determines the "energy" available for the feature's adaptation. We identify a significant trend in the effect of changes in this initial energy on the resulting features after finetuning. Specifically, as the energy increases, the Euclidean and cosine distances between the resulting and original features increase, while their dot product (and the resulting features’ norm) first increases and then decreases. Inspired by this, we give several practical principles that lead to better downstream performance. We analytically prove this trend in an overparamterized linear setting and verify its applicability to different experimental settings.

Loss Landscapes are All You Need: Neural Network Generalization Can Be Explained Without the Implicit Bias of Gradient Descent

Ping-yeh Chiang,Renkun Ni,David Yu Miller,Arpit Bansal,Jonas Geiping,Micah Goldblum,Tom Goldstein

It is commonly believed that the implicit regularization of optimizers is needed for neural networks to generalize in the overparameterized regime. In this paper, we observe experimentally that this implicit regularization behavior is {\em generic}, i.e. it does not depend strongly on the choice of optimizer. We demonstrate this by training neural networks using several gradient-free optimizers, which do not benefit from properties that are often attributed to gradient-based optimizers.   This includes a guess-and-check optimizer that generates uniformly random parameter vectors until finding one that happens to achieve perfect train accuracy, and a zeroth-order Pattern Search optimizer that uses no gradient computations. In the low sample and few-shot regimes, where zeroth order optimizers are most computationally tractable, we find that these non-gradient optimizers achieve test accuracy comparable to SGD. The code to reproduce results can be found at https://github.com/Ping-C/optimizer .

DiffuSeq: Sequence to Sequence Text Generation with Diffusion Models

Shansan Gong,Mukai Li,Jiangtao Feng,Zhiyong Wu,Lingpeng Kong

Recently, diffusion models have emerged as a new paradigm for generative models. Despite the success in domains using continuous signals such as vision and audio, adapting diffusion models to natural language is under-explored due to the discrete nature of texts, especially for conditional generation. We tackle this challenge by proposing DiffuSeq: a diffusion model designed for sequence-to-sequence (Seq2Seq) text generation tasks. Upon extensive evaluation over a wide range of Seq2Seq tasks, we find DiffuSeq achieving comparable or even better performance than six established baselines, including a state-of-the-art model that is based on pre-trained language models. Apart from quality, an intriguing property of DiffuSeq is its high diversity during generation, which is desired in many Seq2Seq tasks. We further include a theoretical analysis revealing the connection between DiffuSeq and autoregressive/non-autoregressive models. Bringing together theoretical analysis and empirical evidence, we demonstrate the great potential of diffusion models in complex conditional language generation tasks. Code is available at https://github.com/Shark-NLP/DiffuSeq

Rethinking Deep Spiking Neural Networks: A Multi-Layer Perceptron Approach

Luziwei Leng,Boyan Li,Ran Cheng,Shuaijie Shen,Kaixuan Zhang,Jianguo Zhang,Jianxing Liao

By adopting deep convolution architectures, spiking neural networks (SNNs) have recently achieved competitive performances with their artificial counterparts in image classification, meanwhile with much lower computation cost due to event-driven and sparse activation. However, the multiplication-free inference (MFI) principle makes SNNs incompatible with attention or transformer mechanisms which have shown significant performance gains on high resolution vision tasks. Inspired from recent works on multi-layer perceptrons (MLPs), we explore an efficient spiking MLP design using batch normalization instead of layer normalization in both the token and the channel block to be compatible with MFI. We further strengthen the network’s local feature learning ability with a spiking patch encoding layer, which significantly improves the network performance. Based on these building blocks, we explore an optimal skip connection configuration and develop an efficient multi-stage spiking MLP network combining global receptive field and local feature extraction, achieving full spike-based computation. Without pre-training or other advanced SNN training techniques, the spiking MLP network achieves 66.39% top-1 accuracy on the ImageNet-1K dataset, surpassing the state-of-the-art directly trained spiking ResNet-34 by 2.67% under similar model capacity meanwhile with shorter simulation steps and much less computation cost. Another larger variant of the network achieves 68.84% top-1 accuracy, rivaling the spiking VGG-16 network with 4 times smaller model capacity. Our work demonstrates the effectiveness of an alternative deep SNN architecture combining both global and local learning abilities. More interestingly, finally we show a close resemblance of the trained receptive field of our network to cells in the cortex. Code will be publicly available.

Collaborative Symmetricity Exploitation for Offline Learning of Hardware Design Solver

Haeyeon Kim,Minsu Kim,Joungho Kim,Jinkyoo Park

This paper proposes \textit{collaborative symmetricity exploitation} (CSE) framework to train a solver for the decoupling capacitor placement problem (DPP) benchmark, one of the significant hardware design problems. Due to the sequentially coupled multi-level property of the hardware design process, the design condition of DPP changes depending on the design of higher-level problems. Also, the online evaluation of real-world electrical performance through simulation is extremely costly. Thus, a data-efficient offline learning method to train a solver (i.e., contextualized policy) with high generalization capability over changing task conditions is necessary. In this paper, we apply the CSE framework to train a DPP solver using a limited number of offline expert data. Leveraging the symmetricity for offline learning of hardware design solver has two major advantages: it increases data-efficiency by reducing the solution space and improves generalization capability by capturing the invariant nature present regardless of changing conditions. The proposed CSE is composed of two learning schemes: expert exploitation and self-exploitation. Expert exploitation induces symmetricity during the imitation learning process with offline expert data and self-exploitation induces symmetricity during the consistency learning process with self-generated data. Extensive experiments verified that CSE with zero-shot inference outperforms the neural baselines and iterative conventional design methods on the DPP benc hmark. Furthermore, CSE showed promising extrapolation capability as it greatly outperforms the expert method used to generate the offline data for training. Scalability and flexibility of the proposed method were also verified for practical use of CSE in industry.

Policy Expansion for Bridging Offline-to-Online Reinforcement Learning

Haichao Zhang,Wei Xu,Haonan Yu

Pre-training with offline data and online fine-tuning using reinforcement learning is a promising strategy for learning control policies by leveraging the best of both worlds in terms of sample efficiency and performance. One natural approach is to initialize the policy for online learning with the one trained offline. In this work, we introduce a policy expansion scheme for this task. After learning the offline policy, we use it as one candidate policy in a policy set, and further learn another policy that will be responsible for further learning as an expansion to the policy set. The two policies will be composed in an adaptive manner for interacting with the environment. With this approach, the policy previously learned offline is fully retained during online learning, thus mitigating the potential issues such as destroying the useful behaviors of the offline policy in the initial stage of online learning while allowing the offline policy participate in the exploration naturally in an adaptive manner. Moreover, new useful behaviors can potentially be captured by the newly added policy through learning.

Experiments are conducted on a number of tasks and the results demonstrate the effectiveness of the proposed approach.

On The Implicit Bias of Weight Decay in Shallow Univariate ReLU Networks

Boris Hanin

We give a complete characterization of the implicit bias of infinitesimal weight decay in the modest setting of univariate one layer ReLU networks. Our main result is a surprisingly simple geometric description of all one layer ReLU networks that exactly fit a dataset $\mathcal D= \set{(x_i,y_i)}$ with the minimum value of the ℓ_2-norm of the neuron weights. Specifically, we prove that such functions must be either concave or convex between any two consecutive data sites x_i and x_{i+1}. Our description implies that interpolating ReLU networks with weak ℓ_2-regularization achieve the best possible generalization for learning $1d$ Lipschitz functions, up to universal constants.

Mitigating Memorization of Noisy Labels via Regularization between Representations

Hao Cheng,Zhaowei Zhu,Xing Sun,Yang Liu

Designing robust loss functions is popular in learning with noisy labels while existing designs did not explicitly consider the overfitting property of deep neural networks (DNNs). As a result, applying these losses may still suffer from overfitting/memorizing noisy labels as training proceeds. In this paper, we first theoretically analyze the memorization effect and show that a lower-capacity model may perform better on noisy datasets. However, it is non-trivial to design a neural network with the best capacity given an arbitrary task. To circumvent this dilemma, instead of changing the model architecture, we decouple DNNs into an encoder followed by a linear classifier and propose to restrict the function space of a DNN by a representation regularizer. Particularly, we require the distance between two self-supervised features to be positively related to the distance between the corresponding two supervised model outputs.

Our proposed framework is easily extendable and can incorporate many other robust loss functions to further improve performance. Extensive experiments and theoretical analyses support our claims. Code is available at https://github.com/UCSC-REAL/SelfSup_NoisyLabel.

Graph Neural Networks are Inherently Good Generalizers: Insights by Bridging GNNs and MLPs

Chenxiao Yang,Qitian Wu,Jiahua Wang,Junchi Yan

Graph neural networks (GNNs), as the de-facto model class for representation learning on graphs, are built upon the multi-layer perceptrons (MLP) architecture with additional message passing layers to allow features to flow across nodes. While conventional wisdom commonly attributes the success of GNNs to their advanced expressivity, we conjecture that this is not the main cause of GNNs' superiority in node-level prediction tasks. This paper pinpoints the major source of GNNs' performance gain to their intrinsic generalization capability, by introducing an intermediate model class dubbed as P(ropagational)MLP, which is identical to standard MLP in training, but then adopts GNN's architecture in testing. Intriguingly, we observe that PMLPs consistently perform on par with (or even exceed) their GNN counterparts, while being much more efficient in training.

This finding provides a new perspective for understanding the learning behavior of GNNs, and can be used as an analytic tool for dissecting various GNN-related research problems including expressivity, generalization, over-smoothing and heterophily. As an initial step to analyze PMLP, we show its essential difference to MLP at infinite-width limit lies in the NTK feature map in the post-training stage. Moreover, through extrapolation analysis (i.e., generalization under distribution shifts), we find that though most GNNs and their PMLP counterparts cannot extrapolate non-linear functions for extreme out-of-distribution data, they have greater potential to generalize to testing data near the training data support as natural advantages of the GNN architecture used for inference.

Learning Cut Selection for Mixed-Integer Linear Programming via Hierarchical Sequence Model

Zhihai Wang,Xijun Li,Jie Wang,Yufei Kuang,Mingxuan Yuan,Jia Zeng,Yongdong Zhang,Feng Wu

Cutting planes (cuts) are important for solving mixed-integer linear programs (MILPs), which formulate a wide range of important real-world applications. Cut selection---which aims to select a proper subset of the candidate cuts to improve the efficiency of solving MILPs---heavily depends on (P1) which cuts should be preferred, and (P2) how many cuts should be selected. Although many modern MILP solvers tackle (P1)-(P2) by manually designed heuristics, machine learning offers a promising approach to learn more effective heuristics from MILPs collected from specific applications. However, many existing learning-based methods focus on learning which cuts should be preferred, neglecting the importance of learning the number of cuts that should be selected. Moreover, we observe from extensive empirical results that (P3) what order of selected cuts should be preferred has a significant impact on the efficiency of solving MILPs as well. To address this challenge, we propose a novel hierarchical sequence model (HEM) to learn cut selection policies via reinforcement learning. Specifically, HEM consists of a two-level model: (1) a higher-level model to learn the number of cuts that should be selected, (2) and a lower-level model---that formulates the cut selection task as a sequence to sequence learning problem---to learn policies selecting an ordered subset with the size determined by the higher-level model. To the best of our knowledge, HEM is the first method that can tackle (P1)-(P3) in cut selection simultaneously from a data-driven perspective. Experiments show that HEM significantly improves the efficiency of solving MILPs compared to human-designed and learning-based baselines on both synthetic and large-scale real-world MILPs, including MIPLIB 2017. Moreover, experiments demonstrate that HEM well generalizes to MILPs that are significantly larger than those seen during training.

BSTT: A Bayesian Spatial-Temporal Transformer for Sleep Staging

Yuchen Liu,Ziyu Jia

Sleep staging is helpful in assessing sleep quality and diagnosing sleep disorders. However, how to adequately capture the temporal and spatial relations of the brain during sleep remains a challenge. In particular, existing methods cannot adaptively infer spatial-temporal relations of the brain under different sleep stages. In this paper, we propose a novel Bayesian spatial-temporal relation inference neural network, named Bayesian spatial-temporal transformer (BSTT), for sl eep staging. Our model is able to adaptively infer brain spatial-temporal relations during sleep for spatial-temporal feature modeling through a well-designed Bayesian relation inference component. Meanwhile, our model also includes a spatial transformer for extracting brain spatial features and a temporal transformer for capturing temporal features. Experiments show that our BSTT outperforms state-of-the-art baselines on ISRUC and MASS datasets. In addition, the visual analysis shows that the spatial-temporal relations obtained by BSTT inference have certain interpretability for sleep staging.

Self-Guided Noise-Free Data Generation for Efficient Zero-Shot Learning

Jiahui Gao,Renjie Pi,LIN Yong,Hang Xu,Jiacheng Ye,Zhiyong Wu,WEIZHONG ZHANG,Xiaodan Liang,Zhenguo Li,Lingpeng Kong

There is a rising interest in further exploring the zero-shot learning potential of large pre-trained language models (PLMs). A new paradigm called data-generation-based zero-shot learning has achieved impressive success. In this paradigm, the synthesized data from the PLM acts as the carrier of knowledge, which is used to train a task-specific model with orders of magnitude fewer parameters than the PLM, achieving both higher performance and efficiency than prompt-based zero-shot learning methods on PLMs. The main hurdle of this approach is that the synthesized data from PLM usually contains a significant portion of low-quality samples. Fitting on such data will greatly hamper the performance of the task-specific model, making it unreliable for deployment. Previous methods remedy this issue mainly by filtering synthetic data using heuristic metrics(e.g., output confidence), or refining the data with the help of a human expert, which comes with excessive manual tuning or expensive costs. In this paper, we propose a novel noise-robust re-weighting framework SunGen to automatically construct high-quality data for zero-shot classification problems. Our framework features the ability to learn the sample weights indicating data quality without requiring any human annotation. We theoretically and empirically verify the ability of our method to help construct good-quality synthetic datasets. Notably, SunGen-LSTM yields a 9.8% relative improvement than the baseline on average accuracy across eight different established text classification tasks.

Beyond re-balancing: distributionally robust augmentation against class-conditional distribution shift in long-tailed recognition

Keliang Li,Hong Chang,Shiguang Shan,Xilin CHEN

As a fundamental and practical problem, long-tailed recognition has drawn burning attention. In this paper, we investigate an essential but rarely noticed issue in long-tailed recognition, Class-Conditional Distribution (CCD) shift due to scarce instances, which exhibits a significant discrepancy between the empirical CCDs for training and test data, especially for tail classes. We observe empirical evidence that the shift is a key factor that limits the performance of existing long-tailed learning methods, and provide novel understanding of these methods in the
course of our analysis. Motivated by this, we propose an adaptive data augmentation method, Distributionally Robust Augmentation (DRA), to learn models more robust to CCD shift. The convergence and generalization of DRA are theoretically guaranteed. Experimental results verify that DRA outperforms related data augmentation methods without extra training cost and significantly improves the performance of some existing long-tailed recognition methods.

Improving Deep Policy Gradients with Value Function Search

Enrico Marchesini,Christopher Amato

Deep Policy Gradient (PG) algorithms employ value networks to drive the learning of parameterized policies and reduce the variance of the gradient estimates. However, value function approximation gets stuck in local optima and struggles to fit the actual return, limiting the variance reduction efficacy and leading policies to sub-optimal performance. This paper focuses on improving value approximation and analyzing the effects on Deep PG primitives such as value prediction, v ariance reduction, and correlation of gradient estimates with the true gradient. To this end, we introduce a Value Function Search that employs a population of perturbed value networks to search for a better approximation. Our framework does not require additional environment interactions, gradient computations, or ensembles, providing a computationally inexpensive approach to enhance the supervised learning task on which value networks train. Crucially, we show that improving Deep PG primitives results in improved sample efficiency and policies with higher returns using common continuous control benchmark domains.

MEDICAL IMAGE UNDERSTANDING WITH PRETRAINED VISION LANGUAGE MODELS: A COMPREHENSIVE STUDY

Ziyuan Qin,Hua Hui Yi,Qicheng Lao,Kang Li

The large-scale pre-trained vision language models (VLM) have shown remarkable domain transfer capability on natural images. However, it remains unknown whether this capability can also apply to the medical image domain. This paper thoroughly studies the knowledge transferability of pre-trained VLMs to the medical domain, where we show that well-designed medical prompts are the key to elicit knowledge from pre-trained VLMs. We demonstrate that by prompting with expressive attributes that are shared between domains, the VLM can carry the knowledge across domains and improve its generalization. This mechanism empowers VLMs to recognize novel objects with fewer or without image samples. Furthermore, to avoid the laborious manual designing process, we develop three approaches for automatic generation of medical prompts, which can inject expert-level medical knowledge and image-specific information into the prompts for fine-grained grounding. We conduct extensive experiments on thirteen different medical datasets across various modalities, showing that our well-designed prompts greatly improve the zero-shot performance compared to the default prompts, and our fine-tuned models surpass the supervised models by a significant margin.

Temporal Coherent Test Time Optimization for Robust Video Classification

Chenyu Yi,SIYUAN YANG,Yufei Wang,Haoliang Li,Yap-peng Tan,Alex Kot

Deep neural networks are likely to fail when the test data is corrupted in real-world deployment (e.g., blur, weather, etc.). Test-time optimization is an effective way that adapts models to generalize to corrupted data during testing, which has been shown in the image domain. However, the techniques for improving video classification corruption robustness remain few. In this work, we propose a Temporal Coherent Test-time Optimization framework (TeCo) to utilize spatio-temporal information in test-time optimization for robust video classification. To exploit information in video with self-supervised learning, TeCo minimizes the entropy of the prediction based on the global content from video clips. Meanwhile, it also feeds local content to regularize the temporal coherence at the feature level. TeCo retains the generalization ability of various video classification models and achieves significant improvements in corruption robustness across Mini Kinetics-C and Mini SSV2-C. Furthermore, TeCo sets a new baseline in video classification corruption robustness via test-time optimization.

Offline Communication Learning with Multi-source Datasets

Yihuan Mao,Rui Hu,Lulu Zheng,Jianhao Wang,Chongjie Zhang

Scalability and partial observability are two major challenges faced by multi-agent reinforcement learning. Recently researchers propose offline MARL algorithms to improve scalability by reducing online exploration cost, while the problem of partial observability is often ignored in the offline MARL setting. Communication is a promising approach to alleviate the miscoordination caused by partially observability, thus in this paper we focus on offline communication learning where agents learn from an fixed dataset. We find out that learning communications in an end-to-end manner from a given offline dateset without communication information is intractable, since the correct communication protocol space is too sparse compared with the exponentially growing joint state-action space when the number of agents increases. Besides, unlike offline policy learning which can be guided by reward signals, offline communication learning is struggling since com munication messages implicitly impact the reward. Moreover, in real-world applications, offline MARL datasets are often collected from multi-source, leaving offline MARL communication learning more challenging. Therefore, we present a new benchmark which contains a diverse set of challenging offline MARL communication tasks with single/multi-source datasets, and propose a novel Multi-Head structure for Communication Imitation learning (MHCI) algorithm that automatically adapts to the distribution of the dataset. Empirical result shows the effectiveness of our method on various tasks of the new offline communication learning benchmark.

****

A Learning Based Hypothesis Test for Harmful Covariate Shift

Tom Ginsberg,Zhongyuan Liang,Rahul G Krishnan

The ability to quickly and accurately identify covariate shift at test time is a critical and often overlooked component of safe machine learning systems deployed in high-risk domains. While methods exist for detecting when predictions should not be made on out-of-distribution test examples, identifying distributional level differences between training and test time can help determine when a model should be removed from the deployment setting and retrained. In this work, we define harmful covariate shift (HCS) as a change in distribution that may weaken the generalization of a predictive model. To detect HCS, we use the discordance between an ensemble of classifiers trained to agree on training data and disagree on test data. We derive a loss function for training this ensemble and show that the disagreement rate and entropy represent powerful discriminative statistics for HCS. Empirically, we demonstrate the ability of our method to detect harmful covariate shift with statistical certainty on a variety of high-dimensional datasets. Across numerous domains and modalities, we show state-of-the-art performance compared to existing methods, particularly when the number of observed test samples is small.

Less is More: Rethinking Few-Shot Learning and Recurrent Neural Nets

Deborah Pereg,Martin Villiger,Brett Bouma,Polina Golland

The statistical supervised learning framework assumes an input-output set with a joint probability distribution that is reliably represented by the training dataset. The learner is then required to output a prediction rule learned from the training dataset's input-output pairs. In this work, we provide meaningful insights into the asymptotic equipartition property (AEP) \citep{Shannon:1948} in the context of machine learning, and illuminate some of its potential ramifications for few-shot learning. We provide theoretical guarantees for reliable learning under the information-theoretic AEP, and for the generalization error with respect to the sample size. We then focus on a highly efficient recurrent neural net (RNN) framework and propose a reduced-entropy algorithm for few-shot learning. We also propose a mathematical intuition for the RNN as an approximation of a sparse coding solver. We verify the applicability, robustness, and computational efficiency of the proposed approach with image deblurring and optical coherence tomography (OCT) speckle suppression. Our experimental results demonstrate significant potential for improving learning models' sample efficiency, generalization, and time complexity, that can therefore be leveraged for practical real-time applications.

Deep Transformers without Shortcuts: Modifying Self-attention for Faithful Signal Propagation

Bobby He,James Martens,Guodong Zhang,Aleksandar Botev,Andrew Brock,Samuel L Smith,Yee Whye Teh

Skip connections and normalisation layers form two standard architectural components that are ubiquitous for the training of Deep Neural Networks (DNNs), but whose precise roles are poorly understood. Recent approaches such as Deep Kernel Shaping have made progress towards reducing our reliance on them, using insights from wide NN kernel theory to improve signal propagation in vanilla DNNs (which we define as networks without skips or normalisation). However, these approaches are incompatible with the self-attention layers present in transformers, whose

kernels are intrinsically more complicated to analyse and control. And so the question remains: \emph{is it possible to train deep vanilla transformers?} We answer this question in the affirmative by designing several approaches that use combinations of parameter initialisations, bias matrices and location-dependent rescaling to achieve faithful signal propagation in vanilla transformers. Our methods address various intricacies specific to signal propagation in transformers, including the interaction with positional encoding and causal masking. In experiments on WikiText-103 and C4, our approaches enable deep transformers without normalisation to train at speeds matching their standard counterparts, and deep vanilla transformers to reach the same performance as standard ones after about 5 times more iterations.
****
Towards Understanding Robust Memorization in Adversarial Training
Binghui Li,Yuanzhi Li
Adversarial training is a standard method to train neural networks to be robust to adversarial perturbation. However, in contrast with benign overfitting in the standard deep learning setting, which means that over-parameterized neural networks surprisingly generalize well for unseen data, while adversarial training method is able to achieve low robust training error, there still exists a significant robust generalization gap, which promotes us exploring what mechanism leads to robust overfitting during learning process. In this paper, we propose an implicit bias called $\textit{robust memorization}$ in adversarial training under the realistic data assumption. By function approximation theory, we prove that ReLU nets with efficient size have the ability to achieve robust memorization, while robust generalization requires exponentially large models. Then, we demonstrate robust memorization in adversarial training from both empirical and theoretical perspectives. In particular, we empirically investigate the dynamics of loss landscape over input, and we also provide theoretical analysis of robust memorization on data with linear separable assumption. Finally, we prove novel generalization bounds based on robust memorization, which further explains why deep neural networks have both high clean test accuracy and robust overfitting at the same time.
****
Self-Supervised Geometric Correspondence for Category-Level 6D Object Pose Estimation in the Wild
Kaifeng Zhang,Yang Fu,Shubhankar Borse,Hong Cai,Fatih Porikli,Xiaolong Wang
While 6D object pose estimation has wide applications across computer vision and robotics, it remains far from being solved due to the lack of annotations. The problem becomes even more challenging when moving to category-level 6D pose, which requires generalization to unseen instances. Current approaches are restricted by leveraging annotations from simulation or collected from humans. In this paper, we overcome this barrier by introducing a self-supervised learning approach trained directly on large-scale real-world object videos for category-level 6D pose estimation in the wild. Our framework reconstructs the canonical 3D shape of an object category and learns dense correspondences between input images and the canonical shape via surface embedding. For training, we propose novel geometrical cycle-consistency losses which construct cycles across 2D-3D spaces, across different instances and different time steps. The learned correspondence can be applied for 6D pose estimation and other downstream tasks such as keypoint transfer. Surprisingly, our method, without any human annotations or simulators, can achieve on-par or even better performance than previous supervised or semi-supervised methods on in-the-wild images. Code and videos are available at https://kywind.github.io/self-pose.

Incorporating Explicit Uncertainty Estimates into Deep Offline Reinforcement Learning
David Brandfonbrener,Remi Tachet des Combes,Romain Laroche
Most theoretically motivated work in the offline reinforcement learning setting requires precise uncertainty estimates. This requirement restricts the algorithms derived in that work to the tabular and linear settings where such estimates e

xist. In this work, we develop a novel method for incorporating scalable uncertainty estimates into an offline reinforcement learning algorithm called deep-SPIBB that extends the SPIBB family of algorithms to environments with larger state and action spaces. We use recent innovations in uncertainty estimation from the deep learning community to get more scalable uncertainty estimates to plug into deep-SPIBB. While these uncertainty estimates do not allow for the same theoretical guarantees as in the tabular case, we argue that the SPIBB mechanism for incorporating uncertainty is more robust and flexible than pessimistic approaches that incorporate the uncertainty as a value function penalty. We bear this out empirically, showing that deep-SPIBB outperforms pessimism based approaches with access to the same uncertainty estimates and performs at least on par with a variety of other strong baselines across several environments and datasets.

Non-parametric Outlier Synthesis

Leitian Tao,Xuefeng Du,Jerry Zhu,Yixuan Li

Out-of-distribution (OOD) detection is indispensable for safely deploying machine learning models in the wild. One of the key challenges is that models lack supervision signals from unknown data, and as a result, can produce overconfident predictions on OOD data. Recent work on outlier synthesis modeled the feature space as parametric Gaussian distribution, a strong and restrictive assumption that might not hold in reality. In this paper, we propose a novel framework, non-parametric outlier synthesis (NPOS), which generates artificial OOD training data and facilitates learning a reliable decision boundary between ID and OOD data. Importantly, our proposed synthesis approach does not make any distributional assumption on the ID embeddings, thereby offering strong flexibility and generality. We show that our synthesis approach can be mathematically interpreted as a rejection sampling framework. Extensive experiments show that NPOS can achieve superior OOD detection performance, outperforming the competitive rivals by a significant margin. Code is publicly available at https://github.com/deeplearning-wisc/npos.

Robust Self-Supervised Learning with Lie Groups

Mark Ibrahim,Diane Bouchacourt,Ari S. Morcos

Deep learning has led to remarkable advances in computer vision. Even so, today’s best models are brittle when presented with variations that differ even slightly from those seen during training. Minor shifts in the pose, color, or illumination of an object can lead to catastrophic misclassifications. State-of-the art models struggle to understand how a set of variations can affect different objects. We propose a framework for instilling a notion of how objects vary in more realistic settings. Our approach applies the formalism of Lie groups to capture continuous transformations to improve models’ robustness to distributional shifts. We apply our framework on top of state-of-the-art self-supervised learning (SSL) models, finding that explicitly modeling transformations with Lie groups leads to substantial performance gains of greater than 10% for MAE on both known instances seen in typical poses now presented in new poses, and on unknown instances in any pose. We also apply our approach to ImageNet, finding that the Lie operator improves performance by almost 4%. These results demonstrate the promise of learning transformations to improve model robustness.

Self-Paced Learning Enhanced Physics-informed Neural Networks for Solving Partial Differential Equations

Xiaoting Han

There is a hit discussion on solving partial differential equation by neural network. The famous PINN (physics-informed neural networks) has drawn worldwide attention since it was put forward. Despite its success in solving nonlinear partial differential equation, the difficulty in converging and the inefficiency in training process are definitely huge concerns. Normally, data for PINN is randomly chosen for a given distribution. Additionally, it's fitted to a model in a meaningless way. Curriculum Learning is a learning strategy that trains a model from easy samples to hard ones, which represents the meaningful human learning order

. Self-paced Learning (SPL) is one of the significant branches of Automatic Curriculum Learning, which takes example-wise the training loss as Difficulty Measurer. SPL is an efficient strategy in enhancing the convergence rate of numerous models. In this paper, we propose a novel SPL-PINN learning framework, with SPL to accelerate the convergence progress of PINN. We demonstrate the effectiveness of SPL-PINN in a typical parabolic equation and Burgers equation.

Moving Beyond Handcrafted Architectures in Self-Supervised Learning

Sharath Girish,Debadeepta Dey,Neel Joshi,Vibhav Vineet,Shital Shah,Caio Cesar Teodoro Mendes,Abhinav Shrivastava,Yale Song

The current literature on self-supervised learning (SSL) focuses on developing learning objectives to train neural networks more effectively on unlabeled data. The typical development process involves taking well-established architectures, e.g., ResNet demonstrated on ImageNet, and using them to evaluate newly developed objectives on downstream scenarios. While convenient, this does not take into account the role of architectures which has been shown to be crucial in the supervised learning literature. In this work, we establish extensive evidence showing that architecture plays a significant role in SSL. We conduct a large-scale study with over 100 variants of ResNet and MobileNet architectures and evaluate them across 11 downstream scenarios in the SSL setting. We show that there is no one network that performs consistently well across the scenarios. Based on this, we propose to learn not only network weights but also architecture topologies in the SSL regime. We show that ``self-supervised architectures'' significantly outperform popular handcrafted architectures (ResNet-50 and MobileNetV2) on major image classification benchmarks (ImageNet-1K, iNat2021, and more). Our results suggest that it is time to consider moving beyond handcrafted architectures in SSL and start thinking about incorporating architecture search into self-supervised learning objectives.

Approximation and non-parametric estimation of functions over high-dimensional spheres via deep ReLU networks

Namjoon Suh,Tian-Yi Zhou,Xiaoming Huo

We develop a new approximation and estimation analysis of deep feed-forward neural networks (FNNs) with the Rectified Linear Unit (ReLU) activation. The functions of interests for the approximation and estimation are assumed to be from Sobolev spaces defined over the d-dimensional unit sphere with smoothness index $r>0$. In the regime where r is in the constant order (i.e., $r=\mathcal{O}(1)$), it is shown that at most d^d active parameters are required for getting d^{-C} approximation rate for some constant $C>0$. In contrast, in the regime where the index r grows in the order of d (i.e., $r=\mathcal{O}(d)$) asymptotically, we prove the approximation error decays in the rate $d^{-d^{\beta}}$ with $0<\beta<1$ up to some constant factor independent of d. The required number of active parameters in the networks for the approximation increases polynomially in d as $d\rightarrow{\infty}$. In addition to this, it is shown that bound on the excess risk has a d^d factor, when $r=\mathcal{O}(1)$, whereas it has $d^{\mathcal{O}(1)}$ factor, when $r=\mathcal{O}(d)$. We emphasize our findings by making comparisons to the results on approximation and estimation errors of deep ReLU FNN when functions are from Sobolev spaces defined over d-dimensional cube. Here, we show that with the current state-of-the-art result, d^{d} factor remain both in the approximation and estimation error, regardless of the order of r.

****

Embedding Fourier for Ultra-High-Definition Low-Light Image Enhancement

Chongyi Li,Chun-Le Guo,man zhou,Zhexin Liang,Shangchen Zhou,Ruicheng Feng,Chen Change Loy

Ultra-High-Definition (UHD) photo has gradually become the standard configuration in advanced imaging devices. The new standard unveils many issues in existing approaches for low-light image enhancement (LLIE), especially in dealing with the intricate issue of joint luminance enhancement and noise removal while remaining efficient. Unlike existing methods that address the problem in the spatial do main, we propose a new solution, UHDFour, that embeds Fourier transform into a cascaded network. Our approach is motivated by a few unique characteristics in the Fourier domain: 1) most luminance information concentrates on amplitudes while noise is closely related to phases, and 2) a high-resolution image and its low-resolution version share similar amplitude patterns. Through embedding Fourier into our network, the amplitude and phase of a low-light image are separately processed to avoid amplifying noise when enhancing luminance. Besides, UHDFour is scalable to UHD images by implementing amplitude and phase enhancement under the low-resolution regime and then adjusting the high-resolution scale with few computations. We also contribute the first real UHD LLIE dataset, UHD-LL, that contains 2,150 low-noise/normal-clear 4K image pairs with diverse darkness and noise levels captured in different scenarios. With this dataset, we systematically analyze the performance of existing LLIE methods for processing UHD images and demonstrate the advantage of our solution. We believe our new framework, coupled with the dataset, would push the frontier of LLIE towards UHD. The code and dataset are available at https://li-chongyi.github.io/UHDFour/.

Population-Based Reinforcement Learning for Combinatorial Optimization Problems

Nathan Grinsztajn,Daniel Furelos-Blanco,Thomas D Barrett

Applying reinforcement learning to combinatorial optimization problems is attractive as it obviates the need for expert knowledge or pre-solved instances. However, it is unrealistic to expect an agent to solve these (often NP-)hard problems in a single shot at inference due to their inherent complexity, thus leading approaches are often augmented with additional search strategies, from stochastic sampling and beam-search to explicit fine-tuning.

In this paper, we argue for the benefits of learning a population of complementary agents, which can be simultaneously rolled out at inference. To this end, we introduce Poppy, a simple theoretically grounded training procedure for populations. Instead of relying on a predefined or hand-crafted notion of diversity, Poppy induces an unsupervised specialization targeted solely at maximizing the performance of the whole population. We show that Poppy leads to a set of complementary heuristics, and obtain state-of-the-art results on three popular NP-hard problems: the traveling salesman (TSP), the capacitated vehicle routing (CVRP), and 0-1 knapsack (KP). On TSP specifically, Poppy divides by 5 the optimality gap while reducing the inference time by more than 10 compared to previous state-of-the-art reinforcement learning approaches.

Adversarial Attack Detection Through Network Transport Dynamics

Skander Karkar,patrick gallinari,Alain Rakotomamonjy

Adversarial attacks are perturbations to the input that don't change its class for a human observer, but fool a neural network into changing its prediction. In this paper, we propose a detector of such attacks that is based on the view of residual networks as discrete dynamical systems. The detector tells clean inputs from abnormal ones by comparing the discrete vector fields they follow throughout the network's layers before the final classification layer. We compare this detector favorably to other detectors on seen and unseen attacks. We also show that regularizing this vector field during training makes the network more regular on the data distribution's support, thus making the network's activations on clean samples more distinguishable from those of abnormal samples. This regularization of the network's dynamics improves the performance of any detection method that uses the internal embeddings as inputs, while also improving the network's test accuracy.

On the Relationship Between Adversarial Robustness and Decision Region in Deep Neural Networks

Seongjin Park,Haedong Jeong,Giyoung Jeon,Jaesik Choi

In general, Deep Neural Networks (DNNs) are evaluated by the generalization performance measured on unseen data excluded from the training phase. Along with the development of DNNs, the generalization performance converges to the state-of-the-art and it becomes difficult to evaluate DNNs solely based on this metric. Th e robustness against adversarial attack has been used as an additional metric to evaluate DNNs by measuring their vulnerability. However, few studies have been performed to analyze the adversarial robustness in terms of the geometry in DNNs. In this work, we perform an empirical study to analyze the internal properties of DNNs that affect model robustness under adversarial attacks. In particular, we propose the novel concept of the Populated Region Set (PRS), where training samples are populated more frequently, to represent the internal properties of DNNs in a practical setting. From systematic experiments with the proposed concept, we provide empirical evidence to validate that a low PRS ratio has a strong relationship with the adversarial robustness of DNNs. We also devise PRS regularizer leveraging the characteristics of PRS to improve the adversarial robustness without adversarial training.

Confounder Identification-free Causal Visual Feature Learning

Xin Li,Zhizheng Zhang,Guoqiang Wei,Cuiling Lan,Wenjun Zeng,Xin Jin,Zhibo Chen

Confounders in deep learning are in general detrimental to model's generalization where they infiltrate feature representations. Therefore, learning causal features that are free of interference from confounders is important. Most previous causal learning based approaches employ back-door criterion to mitigate the adverse effect of certain specific confounder, which require the explicit identification of confounder. However, in real scenarios, confounders are typically diverse and difficult to be identified. In this paper, we propose a novel Confounder Identification-free Causal Visual Feature Learning (CICF) method, which obviates the need for identifying confounders. CICF models the interventions among different samples based on front-door criterion, and then approximates the global-scope intervening effect upon the instance-level interventions from the perspective of optimization. In this way, we aim to find a reliable optimization direction, which avoids the intervening effects of confounders, to learn causal features. Furthermore, we uncover the relation between CICF and the popular meta-learning strategy MAML, and provide an interpretation of why MAML works from the theoretical perspective of causal learning for the first time. Thanks to the effective learning of causal features, our CICF enables models to have superior generalization capability. Extensive experiments on domain generalization benchmark datasets demonstrate the effectiveness of our CICF, which achieves the state-of-the-art performance.

Enhanced Temporal Knowledge Embeddings with Contextualized Language Representations

Zhen Han,Ruotong Liao,Beiyan Liu,Yao Zhang,Zifeng Ding,Jindong Gu,Heinz Koeppl,Hinrich Schuetze,Volker Tresp

World knowledge exists in both structured (tables, knowledge graphs) and unstructured forms (texts). Recently, there have been extensive research efforts in the integration of structured factual knowledge and unstructured textual knowledge. However, most studies focus on incorporating static factual knowledge into pre-trained language models, while there is less work on enhancing temporal knowledge graph embedding using textual knowledge. Existing integration approaches can not apply to temporal knowledge graphs (tKGs) since they often assume knowledge embedding is time-invariant. In fact, the entity embedding in tKG embedding models usually evolves over time, which poses the challenge of aligning temporally relevant textual information with entities. To this end, we propose Enhanced Temporal Knowledge Embeddings with Contextualized Language Representations (ECOLA), which uses tKG quadruple as an implicit measure to temporally align textual data and the time-evolving entity representations and uses a novel knowledge-text prediction task to inject textual information into temporal knowledge embedding. ECOLA jointly optimizes the knowledge-text prediction objective and the temporal knowledge embedding objective, and thus, can simultaneously take full advantage of textual and structured knowledge. Since existing datasets do not provide tKGs with aligned textual data, we introduce three new datasets for training and evaluating ECOLA. Experimental results on the temporal knowledge graph completion task show that ECOLA outperforms state-of-the-art tKG embedding models by a large

margin.

Learning Adversarial Linear Mixture Markov Decision Processes with Bandit Feedback and Unknown Transition

Canzhe Zhao,Ruofeng Yang,Baoxiang Wang,Shuai Li

We study reinforcement learning (RL) with linear function approximation, unknown transition, and adversarial losses in the bandit feedback setting. Specifically, the unknown transition probability function is a linear mixture model \citep{AyoubJSWY20,ZhouGS21,HeZG22} with a given feature mapping, and the learner only observes the losses of the experienced state-action pairs instead of the whole loss function. We propose an efficient algorithm LSUOB-REPS which achieves $\widetilde{O}(dS^2\sqrt{K}+\sqrt{HSAK})$ regret guarantee with high probability, where d is the ambient dimension of the feature mapping, S is the size of the state space, A is the size of the action space, H is the episode length and K is the number of episodes. Furthermore, we also prove a lower bound of order $\Omega(dH\sqrt{K}+\sqrt{HSAK})$ for this setting. To the best of our knowledge, we make the first step to establish a provably efficient algorithm with a sublinear regret guarantee in this challenging setting and solve the open problem of \citet{HeZG22}.

Weakly Supervised Knowledge Transfer with Probabilistic Logical Reasoning for Object Detection

Martijn Oldenhof,Adam Arany,Yves Moreau,Edward De Brouwer

Training object detection models usually requires instance-level annotations, such as the positions and labels of all objects present in each image. Such supervision is unfortunately not always available and, more often, only image-level information is provided, also known as weak supervision.

Recent works have addressed this limitation by leveraging knowledge from a richly annotated domain. However, the scope of weak supervision supported by these approaches has been very restrictive, preventing them to use all available information. In this work, we propose ProbKT, a framework based on probabilistic logical reasoning to train object detection models with arbitrary types of weak supervision. We empirically show on different datasets that using all available information is beneficial as our ProbKT leads to significant improvement on target domain and better generalisation compared to existing baselines. We also showcase the ability of our approach to handle complex logic statements as supervision signal.

****

A Call to Reflect on Evaluation Practices for Failure Detection in Image Classification

Paul F Jaeger,Carsten Tim Lüth,Lukas Klein,Till J. Bungert

Reliable application of machine learning-based decision systems in the wild is one of the major challenges currently investigated by the field. A large portion of established approaches aims to detect erroneous predictions by means of assigning confidence scores. This confidence may be obtained by either quantifying the model's predictive uncertainty, learning explicit scoring functions, or assessing whether the input is in line with the training distribution. Curiously, while these approaches all state to address the same eventual goal of detecting failures of a classifier upon real-world application, they currently constitute largely separated research fields with individual evaluation protocols, which either exclude a substantial part of relevant methods or ignore large parts of relevant failure sources. In this work, we systematically reveal current pitfalls caused by these inconsistencies and derive requirements for a holistic and realistic evaluation of failure detection. To demonstrate the relevance of this unified perspective, we present a large-scale empirical study for the first time enabling benchmarking confidence scoring functions w.r.t all relevant methods and failure sources. The revelation of a simple softmax response baseline as the overall best performing method underlines the drastic shortcomings of current evaluation in the plethora of publicized research on confidence scoring. Code and trained models are at https://github.com/https://github.com/IML-DKFZ/fd-shifts

Signs in the Lottery: Structural Similarities Between Winning Tickets

Isabel Holler,Mats Leon Richter,Ulf Krumnack

Winning tickets are sparse subnetworks of a deep network that can be trained in isolation to the same performance as the full network. Winning tickets have been found in many different contexts, however their structural characteristics are not well understood. We propose that the signs of the connections in winning tickets play a crucial role. We back this claim by introducing a sign-based structural comparison
metric that allows to distinguish winning tickets from other sparse networks. We further analyze typical (signed) patterns in convolutional kernels of winning tickets and find structures that resemble patterns found in trained networks.

Computational Doob h-transforms for Online Filtering of Discretely Observed Diffusions

Nicolas Chopin,Andras Fulop,Jeremy Heng,Alexandre H. Thiery

This paper is concerned with online filtering of discretely observed nonlinear diffusion processes. Our approach is based on the fully adapted auxiliary particle filter, which involves Doob's h-transforms that are typically intractable. We propose a computational framework to approximate these h-transforms by solving the underlying backward Kolmogorov equations using nonlinear Feynman-Kac formulas and neural networks. The methodology allows one to train a locally optimal particle filter prior to the data-assimilation procedure. Numerical experiments illustrate that the proposed approach can be orders of magnitude more efficient than the bootstrap particle filter in the regime of highly informative observations, when the observations are extreme under the model, and if the state dimension is large.

Reconciling feature sharing and multiple predictions with   MIMO Vision Transformers

Rémy Sun,Clément Masson,Nicolas THOME,Matthieu Cord

Multi-input multi-output training improves network performance by optimizing multiple subnetworks simultaneously. In this paper, we propose MixViT, the first MIMO framework for vision transformers that takes advantage of ViTs' innate mechanisms to share features between subnetworks. This is in stark contrast to traditional MIMO CNNs that are limited by their inability to mutualize features. Unlike them, MixViT only separates subnetworks in the last layers thanks to a novel source attribution that ties tokens to specific subnetworks. As such, we retain the benefits of multi-output supervision while training strong features useful to both subnetworks. We verify MixViT leads to significant gains across multiple architectures (ConViT, CaiT) and datasets (CIFAR, TinyImageNet, ImageNet-100, and ImageNet-1k) by fitting multiple subnetworks at the end of a base model.

A Neural Mean Embedding Approach for Back-door and Front-door Adjustment

Liyuan Xu,Arthur Gretton

We consider the estimation of average and counterfactual treatment effects, under two settings: back-door adjustment and front-door adjustment. The goal in both cases is to recover the treatment effect without having an access to a hidden confounder. This objective is attained by first estimating the conditional mean of the desired outcome variable given relevant covariates (the ``first stage" regression), and then taking the (conditional) expectation of this function as a ``second stage" procedure.

We propose to compute these conditional expectations directly using a regression function to the learned input features of the first stage, thus avoiding the need for sampling or density estimation. All functions and features (and in particular, the output features in the second stage) are neural networks learned adaptively from data, with the sole requirement that the final layer of the first stage should be linear. The proposed method is shown to converge to the true causal parameter, and outperforms the recent state-of-the-art methods on challenging causal benchmarks, including settings involving high-dimensional image data.

Chopping Formers is what you need in Vision

Francesca Babiloni,Thomas Tanay,Matteo Maggioni,Jiankang Deng,Ales Leonardis,Stefanos Zafeiriou

This work presents a new dynamic and fully-connected layer (DFC) that generalizes existing layers and is free from hard inductive biases. Then, it describes how to factorize the DFC weights efficiently.

Using the Einstein convention as framework, we define the DFC as a fully connected layer with the weight tensor created as a function of the input. DFC is the non-linear extension of the most general case of linear layer for neural network, and therefore all major neural network layers, from convolution to self-attention, are particular cases of DFCs. A stack of DFCs interleaved by non-linearities defines a new super-class of neural networks: \emph{Formers}.

DFC has four major characteristics: it is Dynamic and Spatially Adaptive, it has a Global Receptive Field, and it mixes all the available channels' information.

In their complete form, DFCs are powerful layers free from hard inductive biases, but their use is limited in practice by their prohibitive computational cost. To overcome this limitation and deploy DFC in real computer-vision applications, we propose to use the CP decomposition, showing that it is possible to factorize the DFC layer into smaller, manageable blocks without losing any representational power. Finally, we propose ChoP'D Former, an architecture making use of a new decomposition of the DFC layer into five sequential operations, each incorporating one characteristic of the original DFC tensor. Chop'D Former leverages dynamic gating and integral image, achieves global spatial reasoning with constant time complexity, and has a receptive field that can adapt depending on the task. Extensive experiments demonstrate that our ChoP'D Former is competitive with state-of-the-art results on three well-known computer vision benchmarks, namely Large-Scale Classification, Object Detection, and Instance Segmentation, suppressing the need for expensive architecture search and hyperparameter optimization.

Towards Estimating Transferability using Hard Subsets

Tarun Ram Menta,Surgan Jandial,Akash Patil,Vimal K B,Saketh Bachu,Balaji Krishnamurthy,Vineeth N. Balasubramanian,Chirag Agarwal,Mausoom Sarkar

As transfer learning techniques are increasingly used to transfer knowledge from the source model to the target task, it becomes important to quantify which source models are suitable for a given target task without performing computationally expensive fine-tuning. In this work, we propose HASTE (HArd Subset TransfErability), a new strategy to estimate the transferability of a source model to a particular target task using only a harder subset of target data. By leveraging the model’s internal and output representations, we introduce two techniques – one class-agnostic and another class-specific – to identify harder subsets and show that HASTE can be used with any existing transferability metric to improve their reliability. We further analyze the relation between HASTE and the optimal average log-likelihood as well as negative conditional entropy and empirically validate our theoretical bounds. Our experimental results across multiple source model architectures, target datasets, and transfer learning tasks show that HASTE-modified metrics are consistently better or on par with the state-of-the-art transferability metrics.

Data Pricing Mechanism Based on Property Rights Compensation Distribution

shiqian Liu,Peizheng Wang,Chao Wu

While machine learning (ML) benefits from data, it also faces the challenges of ambiguous data ownership, including privacy violations and increased costs of using data. Yet existing approaches to data valuation may focus on preventing privacy breaches, but do not truly protect data ownership. This is because a data trading marketplace that protects data ownership should achieve this goal: once data is traded, its ownership does not transfer to a new owner but merely enlarges its coverage. Considering that the transfer of property rights in the process of data trading makes compensation necessary, this paper proposes the first data valuation mechanism based on modern property rights theory. Specifically, we propose the integration of property rights to improve the final revenue of the entire workflow called the “data chain” while compensating process executors who lost ownership after integration. Then, we consider the expectations of both the integrator and the integrated party during the compensation allocation. For the former, we apply compound interest to assess a total compensation equivalent to the time value for the Data chain. For the latter, we respect and meet their expectations as much as possible. To achieve this, we provide the framework based on Least-core to assign the compensation and prove that our framework can also work compared to existing algorithms. Finally, to cope with more complex situations, we adjust the traditional Least-core and demonstrate theoretically and experimentally that the compensation mechanism is feasible and effective in solving the data pricing problem.

Knowledge-Driven Active Learning

Gabriele Ciravegna,Frederic Precioso,Marco Gori

The deployment of Deep Learning (DL) models is still precluded in those contexts where the amount of supervised data is limited. To answer this issue, active learning strategies aim at minimizing the amount of labelled data required to train a DL model. Most active strategies are based on uncertain sample selection, and even often restricted to samples lying close to the decision boundary. These techniques are theoretically sound, but an understanding of the selected samples based on their content is not straightforward, further driving non-experts to consider DL as a black-box. For the first time, here we propose a different approach, taking into consideration common domain-knowledge and enabling non-expert users to train a model with fewer samples. In our Knowledge-driven Active Learning (KAL) framework, rule-based knowledge is converted into logic constraints and their violation is checked as a natural guide for sample selection. We show that even simple relationships among data and output classes offer a way to spot predictions for which the model need supervision. The proposed approach (i) outperforms many active learning strategies in terms of average F1 score, particularly in those contexts where domain knowledge is rich. Furthermore, we empirically demonstrate that (ii) KAL discovers data distribution lying far from the initial training data unlike uncertainty-based strategies, (iii) it ensures domain experts that the provided knowledge is respected by the model on test data, and (iv) it can be employed even when domain-knowledge is not available by coupling it with a XAI technique. Finally, we also show that KAL is also suitable for object recognition tasks and, its computational demand is low, unlike many recent active learning strategies.

TranSpeech: Speech-to-Speech Translation With Bilateral Perturbation

Rongjie Huang,Jinglin Liu,Huadai Liu,Yi Ren,Lichao Zhang,Jinzheng He,Zhou Zhao

Direct speech-to-speech translation (S2ST) with discrete units leverages recent progress in speech representation learning. Specifically, a sequence of discrete representations derived in a self-supervised manner are predicted from the model and passed to a vocoder for speech reconstruction, while still facing the following challenges: 1) Acoustic multimodality: the discrete units derived from speech with same content could be indeterministic due to the acoustic property (e.g., rhythm, pitch, and energy), which causes deterioration of translation accuracy; 2) high latency: current S2ST systems utilize autoregressive models which predict each unit conditioned on the sequence previously generated, failing to take full advantage of parallelism. In this work, we propose TranSpeech, a speech-to-speech translation model with bilateral perturbation. To alleviate the acoustic multimodal problem, we propose bilateral perturbation (BiP), which consists of the style normalization and information enhancement stages, to learn only the linguistic information from speech samples and generate more deterministic representations. With reduced multimodality, we step forward and become the first to establish a non-autoregressive S2ST technique, which repeatedly masks and predicts unit choices and produces high-accuracy results in just a few cycles. Experimental results on three language pairs demonstrate that BiP yields an improvement o f 2.9 BLEU on average compared with a baseline textless S2ST model. Moreover, our parallel decoding shows a significant reduction of inference latency, enabling speedup up to 21.4x than autoregressive technique. Audio samples are available at https://TranSpeech.github.io

D4FT: A Deep Learning Approach to Kohn-Sham Density Functional Theory

Tianbo Li,Min Lin,Zheyuan Hu,Kunhao Zheng,Giovanni Vignale,Kenji Kawaguchi,A.H. Castro Neto,Kostya S. Novoselov,Shuicheng YAN

Kohn-Sham Density Functional Theory (KS-DFT) has been traditionally solved by the Self-Consistent Field (SCF) method. Behind the SCF loop is the physics intuition of solving a system of non-interactive single-electron wave functions under an effective potential. In this work, we propose a deep learning approach to KS-DFT. First, in contrast to the conventional SCF loop, we propose to directly minimize the total energy by reparameterizing the orthogonal constraint as a feed-forward computation. We prove that such an approach has the same expressivity as the SCF method, yet reduces the computational complexity from O(N^4) to O(N^3). Second, the numerical integration which involves a summation over the quadrature grids can be amortized to the optimization steps. At each step, stochastic gradient descent (SGD) is performed with a sampled minibatch of the grids. Extensive experiments are carried out to demonstrate the advantage of our approach in terms of efficiency and stability. In addition, we show that our approach enables us to explore more complex neural-based wave functions.

Warping the Space: Weight Space Rotation for Class-Incremental Few-Shot Learning

Do-Yeon Kim,Dong-Jun Han,Jun Seo,Jaekyun Moon

Class-incremental few-shot learning, where new sets of classes are provided sequentially with only a few training samples, presents a great challenge due to catastrophic forgetting of old knowledge and overfitting caused by lack of data. During finetuning on new classes, the performance on previous classes deteriorates quickly even when only a small fraction of parameters are updated, since the previous knowledge is broadly associated with most of the model parameters in the original parameter space. In this paper, we introduce WaRP, the \textit{weight space rotation process}, which transforms the original parameter space into a new space so that we can push most of the previous knowledge compactly into only a few important parameters. By properly identifying and freezing these key parameters in the new weight space, we can finetune the remaining parameters without affecting the knowledge of previous classes. As a result, WaRP provides an additional room for the model to effectively learn new classes in future incremental sessions. Experimental results confirm the effectiveness of our solution and show the improved performance over the state-of-the-art methods.

****

Learning to Reason and Act in Cascading Processes

Yuval Atzmon,Eli Meirom,Shie Mannor,Gal Chechik

Training agents to control a dynamic environment is a fundamental task in AI. In many environments the dynamics can be summarized by a small set of events that capture the semantic behavior of the system. Typically, these events form chains or cascades. We often wish to change the system behavior using a single intervention that propagates through the cascade. For instance, one may trigger a biochemical cascade to switch the state of a cell, or reroute a truck in logistic chains to meet an unexpected, urgent delivery.

We introduce a new supervised learning setup called "Cascade". An agent observes a system with a known dynamics evolving from some initial state. It is given a structured semantic instruction and needs to make an intervention that triggers a cascade of events, such that the system reaches an alternative (counterfactual) behavior. We provide a test-bed for this problem, consisting of physical objects.

We combine semantic tree search with an event-driven forward model and devise an algorithm that learns to efficiently search in exponentially large semantic trees of continuous spaces. We demonstrate that our approach learns to effectively follow instructions to intervene in previously unseen complex scenes. When provi ded an observed cascade of events, it can also reason about alternative outcomes.

Over-parameterized Model Optimization with Polyak-{\L}ojasiewicz Condition
Yixuan Chen,Yubin Shi,Mingzhi Dong,Xiaochen Yang,Dongsheng Li,Yujiang Wang,Robert Dick,Qin Lv,Yingying Zhao,Fan Yang,Ning Gu,Li Shang
This work pursues the optimization of over-parameterized deep models for superior training efficiency and test performance. We first theoretically emphasize the importance of two properties of over-parameterized models, i.e., the convergence gap and the generalization gap. Subsequent analyses unveil that these two gaps can be upper-bounded by the ratio of the Lipschitz constant and the Polyak-{\L}ojasiewicz (PL) constant, a crucial term abbreviated as the \emph{condition number}. Such discoveries have led to a structured pruning method with a novel pruning criterion. That is, we devise a gating network that dynamically detects and masks out those poorly-behaved nodes of a deep model during the training session. To this end, this gating network is learned via minimizing the \emph{condition number} of the target model, and this process can be implemented as an extra regularization loss term. Experimental studies demonstrate that the proposed method outperforms the baselines in terms of both training efficiency and test performance, exhibiting the potential of generalizing to a variety of deep network architectures and tasks.

Differentially private Bias-Term Only Fine-tuning of Foundation Models
Zhiqi Bu,Yu-Xiang Wang,Sheng Zha,George Karypis
We study the problem of differentially private (DP) fine-tuning of large pre-trained models — a recent privacy-preserving approach suitable for solving downstream tasks with sensitive data. Existing work has demonstrated that high accuracy is possible under strong privacy constraint, yet requires significant computational overhead or modifications to the network architecture.

We propose differentially private bias-term fine-tuning (DP-BiTFiT), which matches the state-of-the-art accuracy for DP algorithms and the efficiency of the standard BiTFiT. DP-BiTFiT is model agnostic (not modifying the network architecture), parameter efficient (only training about 0.1% of the parameters), and computation efficient (almost removing the overhead caused by DP, in both the time and space complexity). On a wide range of tasks, DP-BiTFiT is $2\sim 30\times$ faster and uses $2\sim 8\times$ less memory than DP full fine-tuning, even faster than the standard full fine-tuning. This amazing efficiency enables us to conduct DP fine-tuning on language and vision tasks with long-sequence texts and high-resolution images, which were computationally difficult using existing methods.

****

Jointly Learning Visual and Auditory Speech Representations from Raw Data
Alexandros Haliassos,Pingchuan Ma,Rodrigo Mira,Stavros Petridis,Maja Pantic
We present RAVEn, a self-supervised multi-modal approach to jointly learn visual and auditory speech representations. Our pre-training objective involves encoding masked inputs, and then predicting contextualised targets generated by slowly-evolving momentum encoders. Driven by the inherent differences between video and audio, our design is asymmetric w.r.t. the two modalities' pretext tasks: Whereas the auditory stream predicts both the visual and auditory targets, the visual one predicts only the auditory targets. We observe strong results in low- and high-resource labelled data settings when fine-tuning the visual and auditory encoders resulting from a single pre-training stage, in which the encoders are jointly trained. Notably, RAVEn surpasses all self-supervised methods on visual speech recognition (VSR) on LRS3, and combining RAVEn with self-training using only 30 hours of labelled data even outperforms a recent semi-supervised method trained on 90,000 hours of non-public data. At the same time, we achieve state-of-the-art results in the LRS3 low-resource setting for auditory speech recognition (as well as for VSR). Our findings point to the viability of learning powerful speech representations entirely from raw video and audio, i.e., without relying on handcrafted features. Code and models are available at https://github.com/ahali

assos/raven.

Diminishing Return of Value Expansion Methods in Model-Based Reinforcement Learning

Daniel Palenicek,Michael Lutter,Joao Carvalho,Jan Peters

Model-based reinforcement learning is one approach to increase sample efficiency. However, the accuracy of the dynamics model and the resulting compounding error over modelled trajectories are commonly regarded as key limitations. A natural question to ask is: How much more sample efficiency can be gained by improving the learned dynamics models? Our paper empirically answers this question for the class of model-based value expansion methods in continuous control problems. Value expansion methods should benefit from increased model accuracy by enabling longer rollout horizons and better value function approximations. Our empirical study, which leverages oracle dynamics models to avoid compounding model errors, shows that (1) longer horizons increase sample efficiency, but the gain in improvement decreases with each additional expansion step, and (2) the increased model accuracy only marginally increases the sample efficiency compared to learned models with identical horizons. Therefore, longer horizons and increased model accuracy yield diminishing returns in terms of sample efficiency. These improvements in sample efficiency are particularly disappointing when compared to model-free value expansion methods. Even though they introduce no computational overhead, we find their performance to be on-par with model-based value expansion methods. Therefore, we conclude that the limitation of model-based value expansion methods is not the model accuracy of the learned models. While higher model accuracy is beneficial, our experiments show that even a perfect model will not provide an un-rivaled sample efficiency but that the bottleneck lies elsewhere.
****

Differentially Private Optimization on Large Model at Small Cost

Zhiqi Bu,Yu-Xiang Wang,Sheng Zha,George Karypis

Differentially private (DP) optimization is the standard paradigm to learn large neural networks that are accurate and privacy-preserving. The computational cost for DP deep learning, however, is notoriously heavy due to the per-sample gradient clipping. Existing DP implementations are $2-1000\times$ more costly in time and space complexity than the standard (non-private) training. In this work, we develop a novel Book-Keeping (BK) technique that implements existing DP optimizers (thus achieving the same accuracy), with a substantial improvement on the computational cost. Specifically, BK enables DP training on large models and high dimensional data to be roughly as efficient as the standard training, whereas previous DP algorithms can be inefficient or incapable of training due to memory error. The computational advantage of BK is supported by the complexity analysis as well as extensive experiments on vision and language tasks. Our implementation achieves state-of-the-art (SOTA) accuracy with very small extra cost: on GPT2 and at the same memory cost, BK has 1.0$\times$ the time complexity of the standard training (0.75$\times$ training speed in practice), and 0.6$\times$ the time complexity of the most efficient DP implementation (1.24$\times$ training speed in practice). We will open-source the codebase for the BK algorithm.

CLIP-ViP: Adapting Pre-trained Image-Text Model to Video-Language Alignment

Hongwei Xue,Yuchong Sun,Bei Liu,Jianlong Fu,Ruihua Song,Houqiang Li,Jiebo Luo

Pre-trained image-text models, like CLIP, have demonstrated the strong power of vision-language representation learned from a large scale of web-collected image-text data. In light of the well-learned visual features, there are works that transfer image representation to the video domain and achieve good results. However, adapting image-text pre-trained models to video-text pre-training (i.e., post-pretraining) has not demonstrated a significant advantage yet. In this paper, we tackle this challenge by raising and addressing two questions: 1) what are the factors hindering post-pretraining CLIP from improving performance on video-text tasks, and 2) how to mitigate the impact of these factors. Through a series of comparative experiments and analyses, we find that the data scale and domain gap between language sources have large impacts. By these observations, we propos

e an Omnisource Cross-modal Learning method equipped with a Video Proxy mechanism on the basis of CLIP, namely CLIP-ViP. Extensive results show that our approach improves the performance of CLIP on video-text retrieval by a large margin. Our model achieves state-of-the-art results on a variety of datasets, including MSR-VTT, DiDeMo, LSMDC, and ActivityNet. We release our code and pre-trained CLIP-ViP models at \url{https://github.com/microsoft/XPretrain/tree/main/CLIP-ViP}.

Pre-training via Denoising for Molecular Property Prediction
Sheheryar Zaidi,Michael Schaarschmidt,James Martens,Hyunjik Kim,Yee Whye Teh,Alvaro Sanchez-Gonzalez,Peter Battaglia,Razvan Pascanu,Jonathan Godwin
Many important problems involving molecular property prediction from 3D structures have limited data, posing a generalization challenge for neural networks. In this paper, we describe a pre-training technique based on denoising that achieves a new state-of-the-art in molecular property prediction by utilizing large datasets of 3D molecular structures at equilibrium to learn meaningful representations for downstream tasks. Relying on the well-known link between denoising autoencoders and score-matching, we show that the denoising objective corresponds to learning a molecular force field -- arising from approximating the Boltzmann distribution with a mixture of Gaussians -- directly from equilibrium structures. Our experiments demonstrate that using this pre-training objective significantly improves performance on multiple benchmarks, achieving a new state-of-the-art on the majority of targets in the widely used QM9 dataset. Our analysis then provides practical insights into the effects of different factors -- dataset sizes, model size and architecture, and the choice of upstream and downstream datasets -- on pre-training.
****
Equivariant Energy-Guided SDE for Inverse Molecular Design
Fan Bao,Min Zhao,Zhongkai Hao,Peiyao Li,Chongxuan Li,Jun Zhu
Inverse molecular design is critical in material science and drug discovery, where the generated molecules should satisfy certain desirable properties. In this paper, we propose equivariant energy-guided stochastic differential equations (EEGSDE), a flexible framework for controllable 3D molecule generation under the guidance of an energy function in diffusion models. Formally, we show that EEGSDE naturally exploits the geometric symmetry in 3D molecular conformation, as long as the energy function is invariant to orthogonal transformations. Empirically, under the guidance of designed energy functions, EEGSDE significantly improves the baseline on QM9, in inverse molecular design targeted to quantum properties and molecular structures. Furthermore, EEGSDE is able to generate molecules with multiple target properties by combining the corresponding energy functions linearly.
****
Contrastive Value Learning: Implicit Models for Simple Offline RL
Bogdan Mazoure,Benjamin Eysenbach,Ofir Nachum,Jonathan Tompson
Model-based reinforcement learning (RL) methods are appealing in the offline setting because they allow an agent to reason about the consequences of actions without interacting with the environment. Prior methods learn a 1-step dynamics model, which predicts the next state given the current state and action. These models do not immediately tell the agent which actions to take, but must be integrated into a larger RL framework. Can we model the environment dynamics in a different way, such that the learned model does directly indicate the value of each action? In this paper, we propose Contrastive Value Learning (CVL), which learns an implicit, multi-step model of the environment dynamics. This model can be learned without access to reward functions, but nonetheless can be used to directly estimate the value of each action, without requiring any TD learning. Because this model represents the multi-step transitions implicitly, it avoids having to predict high-dimensional observations and thus scales to high-dimensional tasks. Our experiments demonstrate that CVL outperforms prior offline RL methods on complex continuous control benchmarks.

Vectorial Graph Convolutional Networks

ZhongYu Li,Geng Zhao,Hao Ning

Graph Convolutional Networks (GCN) have drawn considerable attention recently due to their outstanding performance in processing graph-structured data. However, GCNs still limited to the undirected graph because they theoretically require a symmetric matrix as the basis for the Laplacian transform. This causes the isotropic problem of the operator and reduced sensitivity in response to different information. In order to solve the problem, we generalize the spectral convolution operator to directed graphs by field extension, which improves the edge representations from scalars to vectors. Therefore, it brings in the concept of direction. That is to say, and even homogeneous information can become distinguishable by its differences in directions.In this paper, we propose the Vectorial Graph Convolutional Network(VecGCN) and the experimental evidence showing the advantages of a variety of directed graph node classification and link prediction tasks.

Traversing Between Modes in Function Space for Fast Ensembling

Eunggu Yun,Hyungi Lee,Giung Nam,Juho Lee

Deep ensemble is a simple yet powerful way to improve the performance of deep neural networks. Under this motivation, recent works on mode connectivity have shown that parameters of ensembles are connected by low-loss subspaces, and one can efficiently collect ensemble parameters in those subspaces. While this provides a way to efficiently train ensembles, for inference, one should still execute multiple forward passes using all the ensemble parameters, which often becomes a serious bottleneck for real-world deployment. In this work, we propose a novel framework to reduce such costs. Given a low-loss subspace connecting two modes of a neural network, we build an additional neural network predicting outputs of the original neural network evaluated at a certain point in the low-loss subspace. The additional neural network, what we call a “ bridge”, is a lightweight network taking minimal features from the original network, and predicting outputs for the low-loss subspace without forward passes through the original network. We empirically demonstrate that we can indeed train such bridge networks and significantly reduce inference costs with the help of the bridge networks.

Poisson Process for Bayesian Optimization

Xiaoxing Wang,Jiaxing Li,Chao Xue,Wei Liu,Chaoyue Wang,Weifeng Liu,Xiaokang Yang,Junchi Yan,Dacheng Tao

Bayesian Optimization (BO) is a sample-efficient, model-based method for optimizing black-box functions which can be expensive to evaluate. Traditionally, BO seeks a probabilistic surrogate model, such as Tree-structured Parzen Estimator (TPE), Sequential Model Algorithm Configuration (SMAC), and Gaussian process (GP), based on the exact observed values. However, compared to the value response, relative ranking is hard to be disrupted due to noise resulting in better robustness. Moreover, it has better practicality when the exact value responses are intractable, but information about candidate preferences can be acquired. Thus, this work introduces an efficient BO framework, named PoPBO, consisting of a novel ranking-based response surface based on Poisson process and two acquisition functions to accommodate the proposed surrogate model. We show empirically that PoPBO improves efficacy and efficiency on both simulated and real-world benchmarks, including HPO and NAS.

DPMAC: Differentially Private Communication for Cooperative Multi-Agent Reinforcement Learning

Canzhe Zhao,Yanjie Ze,Jing Dong,Baoxiang Wang,Shuai Li

Communication lays the foundation for cooperation in human society and in multi-agent reinforcement learning (MARL). Humans also desire to maintain their privacy when communicating with others, yet such privacy concern has not been considered in existing works in MARL. We propose the \textit{differentially private multi-agent communication} (DPMAC) algorithm, which protects the sensitive information of individual agents by equipping each agent with a local message sender with rigorous (ϵ, δ)-differential privacy (DP) guarantee. In contrast to directly perturbing the messages with predefined DP noise as commonly done in privacy-preserving scenarios, we adopt a stochastic message sender for each agent respectively and incorporate the DP requirement into the sender, which automatically adjusts the learned message distribution to alleviate the instability caused by DP noise. Further, we prove the existence of a Nash equilibrium in cooperative MARL with privacy-preserving communication, which suggests that this problem is game-theoretically learnable. Extensive experiments demonstrate a clear advantage of DPMAC over baseline methods in privacy-preserving scenarios.

Q-learning with regularization converges with non-linear non-stationary features

Diogo S. Carvalho,Francisco S. Melo,Pedro A. Santos

The deep Q-learning architecture is a neural network composed of non-linear hidden layers that learn features of states and actions and a final linear layer that learns the Q-values of the features. The parameters of both components can possibly diverge. Regularization of the updates is known to solve the divergence problem of fully linear architectures, where features are stationary and known a priori. We propose a deep Q-learning scheme that uses regularization of the final linear layer of architecture, updating it along a faster time-scale, and stochastic full-gradient descent updates for the non-linear features at a slower time-scale. We prove the proposed scheme converges with probability 1. Finally, we provide a bound on the error introduced by regularization of the final linear layer of the architecture.

On the Feasibility of Cross-Task Transfer with Model-Based Reinforcement Learning

Yifan Xu,Nicklas Hansen,Zirui Wang,Yung-Chieh Chan,Hao Su,Zhuowen Tu

Reinforcement Learning (RL) algorithms can solve challenging control problems directly from image observations, but they often require millions of environment interactions to do so. Recently, model-based RL algorithms have greatly improved sample-efficiency by concurrently learning an internal model of the world, and supplementing real environment interactions with imagined rollouts for policy improvement. However, learning an effective model of the world from scratch is challenging, and in stark contrast to humans that rely heavily on world understanding and visual cues for learning new skills. In this work, we investigate whether internal models learned by modern model-based RL algorithms can be leveraged to solve new, distinctly different tasks faster. We propose Model-Based Cross-Task Transfer (XTRA), a framework for sample-efficient online RL with scalable pretraining and finetuning of learned world models. By offline multi-task pretraining and online cross-task finetuning, we achieve substantial improvements over a baseline trained from scratch; we improve mean performance of model-based algorithm EfficientZero by 23%, and by as much as 71% in some instances. Fast and Precise: Adjusting Planning Horizon with Adaptive Subgoal Search

Micha■ Zawalski,Micha■ Tyrolski,Konrad Czechowski,Tomasz Odrzygó■d■,Damian Stachura,Piotr Pi■kos,Yuhuai Wu,■ukasz Kuci■ski,Piotr Mi■o■

Complex reasoning problems contain states that vary in the computational cost required to determine the right action plan. To take advantage of this property, we propose Adaptive Subgoal Search (AdaSubS), a search method that adaptively adjusts the planning horizon. To this end, AdaSubS generates diverse sets of subgoals at different distances. A verification mechanism is employed to filter out unreachable subgoals swiftly, making it possible to focus on feasible further subgoals. In this way, AdaSubS benefits from the efficiency of planning with longer-term subgoals and the fine control with shorter-term ones, and thus scales well to difficult planning problems. We show that AdaSubS significantly surpasses hierarchical planning algorithms on three complex reasoning tasks: Sokoban, the Rubik’s Cube, and the inequality-proving benchmark INT.

A Simple Yet Powerful Deep Active Learning With Snapshots Ensembles

Seohyeon Jung,Sanghyun Kim,Juho Lee

Given an unlabeled pool of data and the experts who can label them, active learning aims to build an agent that can effectively acquire data to be queried to the experts, maximizing the gain in performance when trained with them. While there are several principles for active learning, a prevailing approach is to estimate uncertainties of predictions for unlabeled samples and use them to define acquisition functions. Active learning with the uncertainty principle works well for deep learning, especially for large-scale image classification tasks with deep neural networks. Still, it is often overlooked how the uncertainty of predictions is estimated, despite the common findings on the difficulty of accurately estimating uncertainties of deep neural networks. In this paper, we highlight the effectiveness of snapshot ensembles for deep active learning. Compared to the previous approaches based on Monte-Carlo dropout or deep ensembles, we show that a simple acquisition strategy based on uncertainties estimated from parameter snapshots gathered from a single optimization path significantly improves the quality of the acquired samples. Based on this observation, we further propose an efficient active learning algorithm that maintains a single learning trajectory throughout the entire active learning episodes, unlike the existing algorithms training models from scratch for every active learning episode. Through the extensive empirical comparison, we demonstrate the effectiveness of snapshot ensembles for deep active learning.

Normalizing Flows for Interventional Density Estimation

Valentyn Melnychuk,Dennis Frauen,Stefan Feuerriegel

Existing machine learning methods for causal inference usually estimate quantities expressed via the mean of potential outcomes (e.g., average treatment effect). However, such quantities do not capture the full information about the distribution of potential outcomes. In this work, we estimate the density of potential outcomes after interventions from observational data. For this, we propose a novel, fully-parametric deep learning method called Interventional Normalizing Flows. Specifically, we combine two normalizing flows, namely (i) a teacher flow for estimating nuisance parameters and (ii) a student flow for a parametric estimation of the density of potential outcomes. We further develop a tractable optimization objective via a one-step bias correction for an efficient and doubly robust estimation of the student flow parameters. As a result our Interventional Normalizing Flows offer a properly normalized density estimator. Across various experiments, we demonstrate that our Interventional Normalizing Flows are expressive and highly effective, and scale well with both sample size and high-dimensional confounding. To the best of our knowledge, our Interventional Normalizing Flows are the first fully-parametric, deep learning method for density estimation of potential outcomes.

Backdoor or Feature? A New Perspective on Data Poisoning

Alaa Khaddaj,Guillaume Leclerc,Aleksandar Makelov,Kristian Georgiev,Andrew Ilyas,Hadi Salman,Aleksander Madry

In a backdoor attack, an adversary adds maliciously constructed ("backdoor") examples into a training set to make the resulting model vulnerable to manipulation. Defending against such attacks---that is, finding and removing the backdoor examples---typically involves viewing these examples as outliers and using techniques from robust statistics to detect and remove them.

In this work, we present a new perspective on backdoor attacks. We argue that without structural information on the training data distribution, backdoor attacks are indistinguishable from naturally-occuring features in the data (and thus impossible to ``detect'' in a general sense). To circumvent this impossibility, we assume that a backdoor attack corresponds to the strongest feature in the training data. Under this assumption---which we make formal---we develop a new framework for detecting backdoor attacks. Our framework naturally gives rise to a corresponding algorithm whose efficacy we show both theoretically and experimentally.

A Curriculum Perspective to Robust Loss Functions

Zebin Ou,Yue Zhang

Learning with noisy labels is a fundamental problem in machine learning. Much work has been done in designing loss functions that are theoretically robust against label noise. However, it remains unclear why robust loss functions can underfit and why loss functions deviating from theoretical robustness conditions can appear robust. To elucidate these questions, we show that most robust loss functions differ only in the sample-weighting curriculums they implicitly define. The curriculum perspective enables straightforward analysis of the training dynamics with each loss function, which has not been considered in existing theoretical approaches. We show that underfitting can be attributed to marginal sample weights during training, and noise robustness can be attributed to larger weights for clean samples than noisy samples. With a simple fix to the curriculums, robust loss functions that severely underfit can become competitive with the state-of-the-art.

Decoupled Training for Long-Tailed Classification With Stochastic Representations

Giung Nam,Sunguk Jang,Juho Lee

Decoupling representation learning and classifier learning has been shown to be effective in classification with long-tailed data. There are two main ingredients in constructing a decoupled learning scheme; 1) how to train the feature extractor for representation learning so that it provides generalizable representations and 2) how to re-train the classifier that constructs proper decision boundaries by handling class imbalances in long-tailed data. In this work, we first apply Stochastic Weight Averaging (SWA), an optimization technique for improving the generalization of deep neural networks, to obtain better generalizing feature extractors for long-tailed classification. We then propose a novel classifier re-training algorithm based on stochastic representation obtained from the SWA-Gaussian, a Gaussian perturbed SWA, and a self-distillation strategy that can harness the diverse stochastic representations based on uncertainty estimates to build more robust classifiers. Extensive experiments on CIFAR10/100-LT, ImageNet-LT, and iNaturalist-2018 benchmarks show that our proposed method improves upon previous methods both in terms of prediction accuracy and uncertainty estimation.

IT-NAS: Integrating Lite-Transformer into NAS for Architecture Seletion

Zihao Sun,Yu Hu,Longxing Yang,Shun Lu,Jilin Mei,Yinhe Han

Neural Architecture Search (NAS) aims to search for the best network in the pre-defined search space. However, much work focuses on the search strategy but little on the architecture selection process. Despite the fact that the weight-sharing based NAS has promoted the search efficiency, we notice that the architecture selection is quite unstable or circuitous. For instance, the differentiable NAS may derive the suboptimal architecture due to the performance collapse caused by bi-level optimization, or the One-shot NAS requires sampling and evaluating a large number of candidate structures. Recently, the self-attention mechanism achieves better performance in terms of the long-range modeling capabilities. Considering that different operations are widely distributed in the search space, we suggest leveraging the self-attention mechanism to extract the relationship among them and to determine which operation is superior to others. Therefore, we integrate Lite-Transformer into NAS for architecture selection. Specifically, we regard the feature map of each candidate operation as distinct patches and feed them into the Lite-Transformer module along with an additional Indicator Token (called IT). The cross attention among various operations can be extracted by the self-attention mechanism, and the importance of each candidate operation is then shown by the softmax result between the query of indicator token (IT) and other values of operational tokens. We experimentally demonstrate that our framework can select the truly representative architecture in different search spaces and achieves 2.39% test error on CIFAR-10 in DARTS search space, and 24.1% test error on ImageNet in the ProxylessNAS search space, as well as the stable and better performance in NAS-Bench-201 search space and S1-S4 search spaces, outperforming state-of-the-art NAS methods.

Reduce, Reuse, Recycle: Compositional Generation with Energy-Based Diffusion Models and MCMC

Yilun Du,Conor Durkan,Robin Strudel,Joshua B. Tenenbaum,Sander Dieleman,Rob Fergus,Jascha Sohl-Dickstein,Arnaud Doucet,Will Sussman Grathwohl

Since their introduction, diffusion models have quickly become the prevailing approach to generative modeling in many domains. They can be interpreted as learning the gradients of a time-varying sequence of log-probability density functions. This interpretation has motivated classifier-based and classifier-free guidance as methods for post-hoc control of diffusion models. In this work, we build upon these ideas using the score-based interpretation of diffusion models, and explore alternative ways to condition, modify, and reuse diffusion models for tasks involving compositional generation and guidance. In particular, we investigate why certain types of composition fail using current techniques and present a number of solutions. We conclude that the sampler (not the model) is responsible for this failure and propose new samplers, inspired by MCMC, which enable successful compositional generation. Further, we propose an energy-based parameterization of diffusion models which enables the use of new compositional operators and more sophisticated, Metropolis-corrected samplers. Intriguingly we find these samplers lead to notable improvements in compositional generation across a wide variety of problems such as classifier-guided ImageNet modeling and compositional text-to-image generation.

Martingale Posterior Neural Processes

Hyungi Lee,Eunggu Yun,Giung Nam,Edwin Fong,Juho Lee

A Neural Process (NP) estimates a stochastic process implicitly defined with neural networks given a stream of data, rather than pre-specifying priors already known, such as Gaussian processes. An ideal NP would learn everything from data without any inductive biases, but in practice, we often restrict the class of stochastic processes for the ease of estimation. One such restriction is the use of a finite-dimensional latent variable accounting for the uncertainty in the functions drawn from NPs. Some recent works show that this can be improved with more “data-driven” source of uncertainty such as bootstrapping. In this work, we take a different approach based on the martingale posterior, a recently developed alternative to Bayesian inference. For the martingale posterior, instead of specifying prior-likelihood pairs, a predictive distribution for future data is specified. Under specific conditions on the predictive distribution, it can be shown that the uncertainty in the generated future data actually corresponds to the uncertainty of the implicitly defined Bayesian posteriors. Based on this result, instead of assuming any form of the latent variables, we equip a NP with a predictive distribution implicitly defined with neural networks and use the corresponding martingale posteriors as the source of uncertainty. The resulting model, which we name as Martingale Posterior Neural Process (MPNP), is demonstrated to outperform baselines on various tasks.

GuoFeng: A Discourse-aware Evaluation Benchmark for Language Understanding, Translation and Generation

Longyue Wang,Zefeng Du,DongHuai Liu,Deng Cai,Dian Yu,Haiyun Jiang,Yan Wang,Shuming Shi,Zhaopeng Tu

Modeling discourse -- the linguistic phenomena that go beyond individual sentences, is a fundamental and challenging problem in natural language processing (NLP). However, existing evaluation benchmarks mainly focus on the evaluation of inter-sentence properties and overlook important discourse phenomena that cross sentences. To bridge the gap, we propose a GuoFeng benchmark that can evaluate intra-sentence discourse properties across a diverse set of NLP tasks, covering understanding, translation, and generation. GuoFeng consists of 9 document-level testsets in the literature domain, which contain rich discourse phenomena (e.g. cohesion and coherence) in Chinese and/or English. For linguistic analysis, we also propose a diagnostic test suite that can examine whether the target models learn discourse knowledge. We evaluate 17 general- and in-domain models based on Transformer and advanced pre-training architectures, showing that fine-grained pretraining based on document-level training data consistently improves the modeling of discourse information. We will release the datasets, pretrained models, and leaderboard, which we hope can significantly facilitate research in this field.

Multi-View Independent Component Analysis with Shared and Individual Sources

Teodora Pandeva,Patrick Forré

Independent component analysis (ICA) is a blind source separation method for linear disentanglement of independent latent sources from observed data. We investigate the special setting of noisy linear ICA where the observations are split among different views, each receiving a mixture of shared and individual sources. We prove that the corresponding linear structure is identifiable, and the shared sources can be recovered, provided that sufficiently many diverse views and data points are available. To computationally estimate the sources, we optimize a constrained form of the joint log-likelihood of the observed data among all views. We show empirically that our objective recovers the sources in high dimensional settings, also in the case when the measurements are corrupted by noise. Finally, we apply the proposed model in a challenging real-life application, where the estimated shared sources from two large transcriptome datasets (observed data) provided by two different labs (two different views) lead to a more plausible representation of the underlying graph structure than existing baselines.

Centralized Training with Hybrid Execution in Multi-Agent Reinforcement Learning

Pedro Pinto Santos,Diogo S. Carvalho,Miguel Serras Vasco,Francisco S. Melo,Alberto Sardinha,Pedro A. Santos,Ana Paiva

We introduce hybrid execution in multi-agent reinforcement learning (MARL), a new paradigm in which agents aim to successfully perform cooperative tasks with any communication level at execution time by taking advantage of information-sharing among the agents. Under hybrid execution, the communication level can range from a setting in which no communication is allowed between agents (fully decentralized), to a setting featuring full communication (fully centralized). To formalize our setting, we define a new class of multi-agent partially observable Markov decision processes (POMDPs) that we name hybrid-POMDPs, which explicitly models a communication process between the agents. We contribute MARO, an approach that combines an autoregressive predictive model to estimate missing agents' observations, and a dropout-based RL training scheme that simulates different communication levels during the centralized training phase. We evaluate MARO on standard scenarios and extensions of previous benchmarks tailored to emphasize the negative impact of partial observability in MARL. Experimental results show that our method consistently outperforms baselines, allowing agents to act with faulty communication while successfully exploiting shared information.

Towards Open Temporal Graph Neural Networks

Kaituo Feng,Changsheng Li,Xiaolu Zhang,JUN ZHOU

Graph neural networks (GNNs) for temporal graphs have recently attracted increasing attentions, where a common assumption is that the class set for nodes is closed. However, in real-world scenarios, it often faces the open set problem with the dynamically increased class set as the time passes by. This will bring two big challenges to the existing dynamic GNN methods: (i) How to dynamically propagate appropriate information in an open temporal graph, where new class nodes are often linked to old class nodes. This case will lead to a sharp contradiction. This is because typical GNNs are prone to make the embeddings of connected nodes become similar, while we expect the embeddings of these two interactive nodes to be distinguishable since they belong to different classes. (ii) How to avoid catastrophic knowledge forgetting over old classes when learning new classes occurred in temporal graphs. In this paper, we propose a general and principled learning approach for open temporal graphs, called OTGNet, with the goal of addressing the above two challenges. We assume the knowledge of a node can be disentangl ed into class-relevant and class-agnostic one, and thus explore a new message passing mechanism by extending the information bottleneck principle to only propagate class-agnostic knowledge between nodes of different classes, avoiding aggregating conflictive information. Moreover, we devise a strategy to select both important and diverse triad sub-graph structures for effective class-incremental learning. Extensive experiments on three real-world datasets of different domains demonstrate the superiority of our method, compared to the baselines.

Learning Discriminative Representations for Chromosome Classification with Small Datasets

Minghui Li,Haoxi Zhang,Renhao Zhou,Linfeng Yu

Chromosome classification is crucial for karyotype analysis in cytogenetics. Karyotype analysis is a fundamental approach for clinical cytogeneticists to identify numerical and structural chromosomal abnormalities. However, classifying chromosomes accurately and robustly in clinical application is still challenging due to: 1) rich deformations of chromosome shape, 2) similarity of chromosomes, and 3) imbalanced and insufficient labelled dataset. This paper proposes a novel pipeline for the automatic classification of chromosomes. Unlike existing methods, our approach is primarily based on learning meaningful data representations rather than only finding classification features in given samples. The proposed pipeline comprises three stages: The first stage extracts meaningful visual features of chromosomes by utilizing ResNet with triplet loss. The second stage optimizes features from stage one to obtain a linear discriminative representation via maximal coding rate reduction. It ensures the clusters representing different chromosome types are far away from each other while embeddings of the same type are close to each other in the cluster. The third stage is to identify chromosomes. Based on the meaningful feature representation learned in the previous stage, traditional machine learning algorithms such as SVM are adequate for the classification task. Evaluation results on a publicly available dataset show that our method achieves 97.22% accuracy and is better than state-of-the-art methods.

ViewCo: Discovering Text-Supervised Segmentation Masks via Multi-View Semantic Consistency

Pengzhen Ren,Changlin Li,Hang Xu,Yi Zhu,Guangrun Wang,Jianzhuang Liu,Xiaojun Chang,Xiaodan Liang

Recently, great success has been made in learning visual representations from text supervision, facilitating the emergence of text-supervised semantic segmentation. However, existing works focus on pixel grouping and cross-modal semantic alignment, while ignoring the correspondence among multiple augmented views of the same image. To overcome such limitation, we propose multi-View Consistent learning (ViewCo) for text-supervised semantic segmentation. Specifically, we first propose text-to-views consistency modeling to learn correspondence for multiple views of the same input image. Additionally, we propose cross-view segmentation consistency modeling to address the ambiguity issue of text supervision by contrasting the segment features of Siamese visual encoders. The text-to-views consistency benefits dense assignment of the visual features by encouraging different crops to align with the same text, while the cross-view segmentation consistency modeling provides additional self-supervision, overcoming the limitation of ambiguous text supervision for segmentation masks. Trained with large-scale image-text data, our model can directly segment objects of arbitrary categories in a zero-shot manner. Extensive experiments show that ViewCo outperforms state-of-the-art methods on average by up to 2.9%, 1.6%, and 2.4% mIoU on PASCAL VOC2012, PASCAL Context, and COCO, respectively.

Simplicity bias in 1-hidden layer neural networks

Depen Morwani,Praneeth Netrapalli,jatin batra,Karthikeyan Shanmugam,Prateek Jain

Recent works \citep{shah2020pitfalls,chen2021intriguing} have demonstrated that neural networks exhibit extreme \emph{simplicity bias} (SB). That is, they learn \emph{only the simplest} features to solve a task at hand, even in the presence of other, more robust but more complex features. Due to lack of a general and rigorous definition of \emph{features}, these works showcase SB on \emph{semi-synthetic} datasets such as Color-MNIST, MNIST-CIFAR where defining features is relatively easier.

In this work, we rigorously define as well as thoroughly establish SB for \emph{one hidden layer} neural networks. More concretely, (i) we define SB as the network essentially being a function of a low dimensional projection of the inputs (ii) theoretically, we show that when the data is linearly separable, the network primarily depends on only the linearly separable (1-dimensional) subspace even in the presence of an arbitrarily large number of other, more complex features which could have led to a significantly more robust classifier, (iii) empirically, we show that models trained on \emph{real} datasets such as Imagenette and Waterbirds-Landbirds indeed depend on a low dimensional projection of the inputs, thereby demonstrating SB on these datasets, iv) finally, we present a natural ensemble approach that encourages diversity in models by training successive models on features not used by earlier models, and demonstrate that it yields models that are significantly more robust to Gaussian noise.

FedEED: Efficient Federated Distillation with Ensemble of Aggregated Models
Ho Man Kwan,Shenghui Song
In this paper, we study the key components of the knowledge distillation-based model aggregation in federated learning (FL). We first propose a generalized distillation framework where the process of federated distillation is divided into three key stages. By investigating the contributions of each stage, we introduce a new FL framework, named Federated Efficient Ensemble Distillation (FedEED), where the ensemble teacher is created based on aggregated models. Experiment results showed that FedEED outperforms the state-of-the-art methods, including FedAvg and FedDF, on the benchmark datasets. Besides performance, FedEED also demonstrated improved scalability and privacy when compared with existing distillation-based aggregation algorithms. In particular, FedEED does not require direct access to users' model, which can protect the users' privacy. Furthermore, due to the ensemble created by aggregated models, FedEED is highly scalable, and the asymmetric distillation scheme allows parallelism between server-side distillation and clients-side local training, which could speed up the training of large scale learning system.

Critical Batch Size Minimizes Stochastic First-Order Oracle Complexity of Deep Learning Optimizer using Hyperparameters Close to One
Hideaki Iiduka
Practical results have shown that deep learning optimizers using small constant learning rates, hyperparameters close to one, and large batch sizes can find the model parameters of deep neural networks that minimize the loss functions. We first show theoretical evidence that the momentum method (Momentum) and adaptive moment estimation (Adam) perform well in the sense that the upper bound of the theoretical performance measure is small with a small constant learning rate, hyperparameters close to one, and a large batch size. Next, we show that there exists a batch size called the critical batch size minimizing the stochastic first-order oracle (SFO) complexity, which is the stochastic gradient computation cost, and that SFO complexity increases once the batch size exceeds the critical batch size. Finally, we provide numerical results that support our theoretical results. That is, the numerical results indicate that Adam using a small constant learning rate, hyperparameters close to one, and the critical batch size minimizing SFO complexity has faster convergence than Momentum and stochastic gradient descent (SGD).

Jointist: Simultaneous Improvement of Multi-instrument Transcription and Music Source Separation via Joint Training
Kin Wai Cheuk,Keunwoo Choi,Qiuqiang Kong,Bochen Li,Minz Won,Ju-Chiang Wang,Yun-Ning Hung,Dorien Herremans
In this paper, we introduce Jointist, an instrument-aware multi-instrument frame

work that is capable of transcribing, recognizing, and separating multiple musical instruments from an audio clip.
Jointist consists of an instrument recognition module that conditions the other two modules: a transcription module that outputs instrument-specific piano rolls, and a source separation module that utilizes instrument information and transcription results. The joint training of the transcription and source separation modules serves to improve the performance of both tasks. The instrument module is optional and can be directly controlled by human users. This makes Jointist a flexible user-controllable framework.

Our challenging problem formulation makes the model highly useful in the real world given that modern popular music typically consists of multiple instruments. Its novelty, however, necessitates a new perspective on how to evaluate such a model. In our experiments, we assess the proposed model from various aspects, providing a new evaluation perspective for multi-instrument transcription. Subjective listening test shows that Jointist achieves state-of-the-art performance on popular music, outperforming existing multi-instrument transcription models such as MT3. %We also argue that transcription models can be used as a preprocessing module for other music analysis tasks. We conducted experiments on several downstream tasks, and found that the proposed method improved transcription by more than 1 percentage points (ppt.); source separation by 5 SDR, downbeat detection by 1.8 ppt., chord recognition by 1.4 ppt., and key estimation by 1.4 ppt., when utilizing transcription results obtained from Jointist.
****
Where prior learning can and can't work in unsupervised inverse problems
Benoît Malézieux,Florent Michel,Matthieu Kowalski,Thomas Moreau
Linear inverse problems consist in recovering a signal from its noisy observation in a lower dimensional space. Many popular resolution methods rely on data-driven algorithms that learn a prior from pairs of signals and observations to overcome the loss of information. However, these approaches are difficult, if not impossible, to adapt to unsupervised contexts -- where no ground truth data are available -- due to the need for learning from clean signals. This paper studies situations that do or do not allow learning a prior in unsupervised inverse problems. First, we focus on dictionary learning and point out that recovering the dictionary is unfeasible without constraints when the signal is observed through only one measurement operator. It can, however, be learned with multiple operators, given that they are diverse enough to span the whole signal space. Then, we study methods where weak priors are made available either through optimization constraints or deep learning architectures. We empirically emphasize that they perform better than hand-crafted priors only if they are adapted to the inverse problem.
****
When are smooth-ReLUs ReLU-like?
Ermal Rrapaj,Luca Celotti,Qiyao Wei,Martin Magill
ReLU is one of the most popular activations in deep learning, especially thanks to its stabilizing effect on training. However, because it is non-differentiable at the origin, it complicates the use of analysis methods that examine derivatives, such as the Neural Tangent Kernel (NTK). Many smooth relaxations try to retain the practical benefits of ReLU while increasing network regularity. Although their success has ranged widely, some notable architectures (e.g., the BERT family) do utilize them. We present a theoretical characterization of smooth-ReLUs within fully-connected feed-forward neural networks. In addition to the well-known SWISH and GeLU, we introduce GumbelLU, AlgebraicLU, and GudermanLU, as new relaxations. All these activations can be characterized by a positive temperature parameter which we can lower to continuously improve the approximation. By studying the interplay of initialization schemes with temperature, we confirm that when these relaxations converge uniformly to ReLU, the statistical properties of the corresponding neural networks at initialization also converge to those of ReLU networks. Moreover, we derive temperature-dependent critical initialization schemes with which networks based on these activations exhibit stable ReLU-like

behavior at any temperature. Finally, we empirically study both classes of networks on MNIST and CIFAR-10 in the full-batch training regime. We show that, while all networks exhibit very similar train loss trajectories at criticality, smooth-ReLU networks feature differentiable NTKs throughout training, whereas ReLU networks exhibit stochastic NTK fluctuations. Our results clarify how smooth-ReLU relaxations reproduce the practical benefits of ReLU in everywhere-smooth neural networks.

SpectraNet: multivariate forecasting and imputation under distribution shifts and missing data

Cristian Ignacio Challu,Peihong Jiang,Ying Nian Wu,Laurent Callot

In this work, we tackle two widespread challenges in real applications for time-series forecasting that have been largely understudied: distribution shifts and missing data. We propose SpectraNet, a novel multivariate time-series forecasting model that dynamically infers a latent space spectral decomposition to capture current temporal dynamics and correlations on the recent observed history. A Convolution Neural Network maps the learned representation by sequentially mixing its components and refining the output. Our proposed approach can simultaneously produce forecasts and interpolate past observations and can, therefore, greatly simplify production systems by unifying imputation and forecasting tasks into a single model. SpectraNet achieves SoTA performance simultaneously on both tasks on five benchmark datasets, compared to forecasting and imputation models, with up to 92% fewer parameters and comparable training times. On settings with up to 80% missing data, SpectraNet has average performance improvements of almost 50% over the second-best alternative.

An Evolutionary Approach to Dynamic Introduction of Tasks in Large-scale Multitask Learning Systems

Andrea Gesmundo,Jeff Dean

Multitask learning assumes that models capable of learning from multiple tasks can achieve better quality and efficiency via knowledge transfer, a key feature of human learning. Though, state of the art ML models rely on high customization for each task and leverage size and data scale rather than scaling the number of tasks. Also, continual learning, that adds the temporal aspect to multitask, is often focused to the study of common pitfalls such as catastrophic forgetting instead of being studied at a large scale as a critical component to build the next generation artificial intelligence.

We propose an evolutionary method capable of generating large scale multitask models that support the dynamic addition of new tasks. The generated multitask models are sparsely activated and integrates a task-based routing that guarantees bounded compute cost and fewer added parameters per task as the model expands. The proposed method relies on a knowledge compartmentalization technique to achieve immunity against catastrophic forgetting and other common pitfalls such as gradient interference and negative transfer. We demonstrate empirically that the proposed method can jointly solve and achieve competitive results on 69 public image classification tasks, for example improving the state of the art on a competitive benchmark such as cifar10 by achieving a 15% relative error reduction compared to the best model trained on public data.

Uncertainty and Traffic Light Aware Pedestrian Crossing Intention Prediction

Minali Upreti,Jayanth Ramesh,Chandan R Kumar,Bodhisattwa Chakraborty,VIKRAM BALISAVIRA,Phillip Czech,Vitali Kaiser,Markus Roth

Predicting Vulnerable Road User (VRU) crossing intention is one of the major challenges in automated driving. Crossing intention prediction systems trained only on pedestrian features underperform in situations that are most obvious to humans, as the latter take additional context features into consideration. Moreover, such systems tend to be over-confident for out-of-distribution samples, therefore making them less reliable to be used by downstream tasks like sensor fusion and trajectory planning for automated vehicles. In this work, we demonstrate that the results of crossing intention prediction systems can be improved by incorpo

rating traffic light status as an additional input. Further, we make the model robust and interpretable by estimating uncertainty. Experiments on the PIE dataset show that the F1-score improved from 0.77 to 0.82 and above for three different baseline systems when considering traffic-light context. By adding uncertainty, we show increased uncertainty values for out-of-distribution samples, therefore leading to interpretable and reliable predictions of crossing intention.

Benchmarking Constraint Inference in Inverse Reinforcement Learning
Guiliang Liu,Yudong Luo,Ashish Gaurav,Kasra Rezaee,Pascal Poupart

When deploying Reinforcement Learning (RL) agents into a physical system, we must ensure that these agents are well aware of the underlying constraints. In many real-world problems, however, the constraints are often hard to specify mathematically and unknown to the RL agents. To tackle these issues, Inverse Constrained Reinforcement Learning (ICRL) empirically estimates constraints from expert demonstrations. As an emerging research topic, ICRL does not have common benchmarks, and previous works tested algorithms under hand-crafted environments with manually-generated expert demonstrations. In this paper, we construct an ICRL benchmark in the context of RL application domains, including robot control, and autonomous driving. For each environment, we design relevant constraints and train expert agents to generate demonstration data. Besides, unlike existing baselines that learn a deterministic constraint, we propose a variational ICRL method to model a posterior distribution of candidate constraints. We conduct extensive experiments on these algorithms under our benchmark and show how they can facilitate studying important research challenges for ICRL. The benchmark, including the instructions for reproducing ICRL algorithms, is available at https://github.com/Guiliang/ICRL-benchmarks-public.

Forward and Backward Lifelong Learning with Time-dependent Tasks
Veronica Alvarez,Santiago Mazuelas,Jose A. Lozano

For a sequence of classification tasks that arrive over time, lifelong learning methods can boost the effective sample size of each task by leveraging information from preceding and succeeding tasks (forward and backward learning). However, backward learning is often prone to a so-called catastrophic forgetting in which a task’s performance gets worse while trying to repeatedly incorporate information from succeeding tasks. In addition, current lifelong learning techniques are designed for i.i.d. tasks and cannot capture the usual higher similarities between consecutive tasks. This paper presents lifelong learning methods based on minimax risk classifiers (LMRCs) that effectively exploit forward and backward learning and account for time-dependent tasks. In addition, we analytically characterize the increase in effective sample size provided by forward and backward learning in terms of the tasks’ expected quadratic change. The experimental evaluation shows that LMRCs can result in a significant performance improvement, especially for reduced sample sizes.

Memory Gym: Partially Observable Challenges to Memory-Based Agents
Marco Pleines,Matthias Pallasch,Frank Zimmer,Mike Preuss

Memory Gym is a novel benchmark for challenging Deep Reinforcement Learning agents to memorize events across long sequences, be robust to noise, and generalize. It consists of the partially observable 2D and discrete control environments Mortar Mayhem, Mystery Path, and Searing Spotlights. These environments are believed to be unsolvable by memory-less agents because they feature strong dependencies on memory and frequent agent-memory interactions. Empirical results based on Proximal Policy Optimization (PPO) and Gated Recurrent Unit (GRU) underline the strong memory dependency of the contributed environments. The hardness of these environments can be smoothly scaled, while different levels of difficulty (some of them unsolved yet) emerge for Mortar Mayhem and Mystery Path. Surprisingly, Searing Spotlights poses a tremendous challenge to GRU-PPO, which remains an open puzzle. Even though the
randomly moving spotlights reveal parts of the environment’s ground truth, environmental ablations hint that these pose a severe perturbation to agents that lev

erage recurrent model architectures as their memory.

Worst-case Few-shot Evaluation: Are Neural Networks Robust Few-shot Learners?

Yudong Wang,Ma Chang,Qingxiu Dong,Lingpeng Kong,Zhifang Sui,Jingjing Xu

Neural networks have achieved remarkable performance on various few-shot tasks. However, recent studies reveal that existing few-shot models often exploit the spurious correlations between training and test sets, achieving a high performance that is hard to generalize. Motivated that a robust few-shot learner should accurately classify data given any valid training set, we consider a worst-case few-shot evaluation that computes worst-case generalization errors by constructing a challenging few-shot set. Specifically, we search for the label-balanced subset of a full-size training set that results in the largest expected risks. Since the search space is enormous, we propose an efficient method NMMD-attack to optimize the target by maximizing NMMD distance (maximum mean discrepancy based on neural tangent kernel). Experiments show that NMMD-attack can successfully attack various architectures. The large gap between average performance and worst-case performance shows that neural networks still suffer from poor robustness. We appeal to more worst-case benchmarks for better robust few-shot evaluation.

Discovering Policies with DOMiNO: Diversity Optimization Maintaining Near Optimality

Tom Zahavy,Yannick Schroecker,Feryal Behbahani,Kate Baumli,Sebastian Flennerhag,Shaobo Hou,Satinder Singh

In this work we propose a Reinforcement Learning (RL) agent that can discover complex behaviours in a rich environment with a simple reward function. We define diversity in terms of state-action occupancy measures, since policies with different occupancy measures visit different states on average. More importantly, defining diversity in this way allows us to derive an intrinsic reward function for maximizing the diversity directly. Our agent, DOMiNO, stands for Diversity Optimization Maintaining Near Optimally. It is based on maximizing a reward function with two components: the extrinsic reward and the diversity intrinsic reward, which are combined with Lagrange multipliers to balance the quality-diversity trade-off. Any RL algorithm can be used to maximize this reward and no other changes are needed. We demonstrate that given a simple reward functions in various control domains, like height (stand) and forward velocity (walk), DOMiNO discovers diverse and meaningful behaviours. We also perform extensive analysis of our approach, compare it with other multi-objective baselines, demonstrate that we can control both the quality and the diversity of the set via interpretable hyperparameters, and show that the set is robust to perturbations of the environment.

SpeedyZero: Mastering Atari with Limited Data and Time

Yixuan Mei,Jiaxuan Gao,Weirui Ye,Shaohuai Liu,Yang Gao,Yi Wu

Many recent breakthroughs of deep reinforcement learning (RL) are mainly built upon large-scale distributed training of model-free methods using millions to billions of samples. On the other hand, state-of-the-art model-based RL methods can achieve human-level sample efficiency but often take a much longer over all training time than model-free methods. However, high sample efficiency and fast training time are both important to many real-world applications. We develop SpeedyZero, a distributed RL system built upon a state-of-the-art model-based RL method, EfficientZero, with a dedicated system design for fast distributed computation. We also develop two novel algorithmic techniques, Priority Refresh and Clipped LARS, to stabilize training with massive parallelization and large batch size. SpeedyZero maintains on-par sample efficiency compared with EfficientZero while achieving a 14.5X speedup in wall-clock time, leading to human-level performances on the Atari benchmark within 35 minutes using only 300k samples. In addition, we also present an in-depth analysis on the fundamental challenges in further scaling our system to bring insights to the community.

HT-Net: Hierarchical Transformer based Operator Learning Model for Multiscale P

DEs
Xinliang Liu,Bo Xu,Lei Zhang
Complex nonlinear interplays of multiple scales give rise to many interesting physical phenomena and pose major difficulties for the computer simulation of multiscale PDE models in areas such as reservoir simulation, high frequency scattering and turbulence modeling. In this paper, we introduce a hierarchical transformer (HT-Net) scheme to efficiently learn the solution operator for multiscale PDEs. We construct a hierarchical architecture with scale adaptive interaction range, such that the features can be computed in a nested manner and with a controllable linear cost. Self-attentions over a hierarchy of levels can be used to encode and decode the multiscale solution space over all scale ranges. In addition, we adopt an empirical H^1 loss function to counteract the spectral bias of the neural network approximation for multiscale functions. In the numerical experiments, we demonstrate the superior performance of the HT-Net scheme compared with state-of-the-art (SOTA) methods for representative multiscale problems.

Multi-Agent Multi-Game Entity Transformer
Rundong Wang,Weixuan Wang,Xianhan Zeng,Liang Wang,Zhenjie Lian,Yiming Gao,Feiyu Liu,Siqin Li,Xianliang Wang,QIANG FU,Yang Wei,Lanxiao Huang,Longtao Zheng,Zinovi Rabinovich,Bo An
Building large-scale generalist pre-trained models for many tasks is becoming an emerging and potential direction in reinforcement learning (RL). Research such as Gato and Multi-Game Decision Transformer have displayed outstanding performance and generalization capabilities on many games and domains. However, there exists a research blank about developing highly capable and generalist models in multi-agent RL (MARL), which can substantially accelerate progress towards general AI. To fill this gap, we propose Multi-Agent multi-Game ENtity TrAnsformer (MAGENTA) from the entity perspective as an orthogonal research to previous time-sequential modeling. Specifically, to deal with different state/observation spaces in different games, we analogize games as languages, thus training different "tokenizers" for various games. The feature inputs are split according to different entities and tokenized in the same continuous space. Then, two types of transformer-based model are proposed as permutation-invariant architectures to deal with various numbers of entities and capture the attention over different entities. MAGENTA is trained on Honor of Kings, Starcraft II micromanagement, and Neural MMO with a single set of transformer weights. Extensive experiments show that MAGENTA can play games across various categories with arbitrary numbers of agents and increase the efficiency of fine-tuning in new games and scenarios by 50\%-100\%. See our project page at \url{https://sites.google.com/view/rl-magenta}.

On the Convergence of Gradient Flow on Multi-layer Linear Models
Hancheng Min,Rene Vidal,Enrique Mallada
In this paper, we analyze the convergence of gradient flow on a multi-layer linear model with a loss function of the form $f(W_1W_2\cdots W_L)$. We show that when f satisfies the gradient dominance property, proper weight initialization leads to exponential convergence of the gradient flow to a global minimum of the loss. Moreover, the convergence rate depends on two trajectory-specific quantities that are controlled by the weight initialization: the \emph{imbalance matrices}, which measure the difference between the weights of adjacent layers, and the least singular value of the \emph{weight product} $W=W_1W_2\cdots W_L$. Our analysis provides improved rate bounds for several multi-layer network models studied in the literature, leading to novel characterizations of the effect of weight imbalance on the rate of convergence. Our results apply to most regression losses and extend to classification ones.

Neural Architecture Design and Robustness: A Dataset
Steffen Jung,Jovita Lukasik,Margret Keuper
Deep learning models have proven to be successful in a wide range of machine learning tasks. Yet, they are often highly sensitive to perturbations on the input

data which can lead to incorrect decisions with high confidence, hampering their deployment for practical use-cases. Thus, finding architectures that are (more) robust against perturbations has received much attention in recent years. Just like the search for well-performing architectures in terms of clean accuracy, this is usually involves a tedious trial-and-error process with one additional challenge: the evaluation of a network's robustness is significantly more expensive than its evaluation for clean accuracy. Thus, the aim of this paper is to facilitate better streamlined research on architectural design choices with respect to their impact on robustness as well as, for example, the evaluation of surrogate measures for robustness. We therefore borrow one of the most commonly considered search spaces for neural architecture search for image classification, NAS-Bench-201, which contains a manageable size of 6466 non-isomorphic network designs. We evaluate all these networks on a range of common adversarial attacks and corruption types and introduce a database on neural architecture design and robustness evaluations. We further present three exemplary use cases of this dataset, in which we (i) benchmark robustness measurements based on Jacobian and Hessian matrices for their robustness predictability, (ii) perform neural architecture search on robust accuracies, and (iii) provide an initial analysis of how architectural design choices affect robustness. We find that carefully crafting the topology of a network can have substantial impact on its robustness, where networks with the same parameter count range in mean adversarial robust accuracy from 20%-41%. Code and data is available at http://robustness.vision/.

Does Deep Learning Learn to Abstract? A Systematic Probing Framework

Shengnan An,Zeqi Lin,Bei Chen,Qiang Fu,Nanning Zheng,Jian-Guang Lou

Abstraction is a desirable capability for deep learning models, which means to induce abstract concepts from concrete instances and flexibly apply them beyond the learning context. At the same time, there is a lack of clear understanding about both the presence and further characteristics of this capability in deep learning models. In this paper, we introduce a systematic probing framework to explore the abstraction capability of deep learning models from a transferability perspective. A set of controlled experiments are conducted based on this framework, providing strong evidence that two probed pre-trained language models (PLMs), T5 and GPT2, have the abstraction capability. We also conduct in-depth analysis, thus shedding further light: (1) the whole training phase exhibits a "memorize-then-abstract" two-stage process; (2) the learned abstract concepts are gathered in a few middle-layer attention heads, rather than being evenly distributed throughout the model; (3) the probed abstraction capabilities exhibit robustness against concept mutations, and are more robust to low-level/source-side mutations than high-level/target-side ones; (4) generic pre-training is critical to the emergence of abstraction capability, and PLMs exhibit better abstraction with larger model sizes and data scales.

Learning to mine approximate network motifs

Carlos Oliver,Dexiong Chen,Vincent Mallet,Pericles Philippopoulos,Karsten Borgwardt

Frequent and structurally related subgraphs, also known as network motifs, are valuable features of many datasets. However, strong combinatorial bottlenecks have made it difficult to extract motifs and use them in learning tasks without strong constraints on the motif properties. In this work we propose a representation learning method based on learnable graph coarsening, MotiFiesta which is the first to be able to extract large and approximate motifs in a fully differentiable manner. We build benchmark datasets and evaluation metrics which test the ability our proposed and future models to capture different aspects of motif discovery where ground truth motifs are not known. Finally, explore the notion of exploiting learned motifs as an inductive bias in real-world datasets by showing competitive performance on motif-based featuresets with established real-world benchmark datasets against concurrent architectures.

Automatic Clipping: Differentially Private Deep Learning Made Easier and Stronge r

Zhiqi Bu,Yu-Xiang Wang,Sheng Zha,George Karypis

Per-example gradient clipping is a key algorithmic step that enables practical differential private (DP) training for deep learning models. The choice of clipping threshold R, however, is shown to be vital for achieving high accuracy under DP. We propose an easy-to-use replacement, called automatic clipping, that eliminates the need to tune R for any DP optimizers, including DP-SGD, DP-Adam, DP-LAMB and many others.

The automatic variants are as private and computationally efficient as existing DP optimizers, but require no DP-specific hyperparameters and thus make DP training as amenable as the standard non-private training. We give a rigorous convergence analysis of automatic DP-SGD in the non-convex setting, which shows that it {can enjoy an asymptotic convergence rate that matches the standard SGD, under a symmetric gradient noise assumption of the per-sample gradients.} We also demonstrate on various language and vision tasks that automatic clipping outperforms or matches the state-of-the-art, and can be easily employed with minimal changes to existing codebases.

Trust Your ∇: Gradient-based Intervention Targeting for Causal Discovery

Mateusz Olko,Micha■ Zaj■c,Aleksandra Nowak,Nino Scherrer,Yashas Annadani,Stefan Bauer,■ukasz Kuci■ski,Piotr Mi■o■

Inferring causal structure from data is a challenging task of fundamental importance in science. Observational data are often insufficient to identify a system’s causal structure uniquely. While conducting interventions (i.e., experiments) can improve the identifiability, such samples are usually challenging and expensive to obtain. Hence, experimental design approaches for causal discovery aim to minimize the number of interventions by estimating the most informative intervention target. In this work, we propose a novel gradient-based intervention targeting method, abbreviated GIT, that 'trusts' the gradient estimator of a gradient-based causal discovery framework to provide signals for intervention acquisition function. We provide extensive experiments in simulated and real-world datasets and demonstrate that GIT performs on par with competitive baselines, surpassing them in the low-data regime.

Improving Out-of-distribution Generalization with Indirection Representations

Kha Pham,Hung Le,Man Ngo,Truyen Tran

We propose a generic module named Indirection Layer (InLay), which leverages indirection and data internal relationships to effectively construct symbolic indirect representations to improve out-of-distribution generalization capabilities of various neural architectures. InLay receives data input in the form of a sequence of objects, treats it as a complete weighted graph whose vertices are the objects and edge weights are scalars representing relationships between vertices. The input is first mapped via indirection to a symbolic graph with data-independent and trainable vertices. This symbolic graph is then propagated, resulting in new vertex features whose indirection will be used for prediction steps afterward. Theoretically, we show that the distances between indirection representations are bounded by the distances between corresponding graphs, implying that unseen samples with very different surface statistics can still be close in the representation space to the seen samples if they share similar internal relationships. We demonstrate that InLay is consistently effective in improving out-of-distribution generalization throughout a comprehensive suite of experiments, including IQ problems, distorted image classification, and few-shot domain adaptation NLP classification. We also conduct ablation studies to verify different design choices of InLay.

Accelerating Guided Diffusion Sampling with Splitting Numerical Methods

Suttisak Wizadwongsa,Supasorn Suwajanakorn

Guided diffusion is a technique for conditioning the output of a diffusion model at sampling time without retraining the network for each specific task. However, one drawback of diffusion models, whether they are guided or unguided, is thei r slow sampling process.

Recent techniques can accelerate unguided sampling by applying high-order numerical methods to the sampling process when viewed as differential equations. On the contrary, we discover that the same techniques do not work for guided sampling, and little has been explored about its acceleration. This paper explores the culprit of this problem and provides a solution based on operator splitting methods, motivated by our key finding that classical high-order numerical methods are unsuitable for the conditional function. Our proposed method can re-utilize the high-order methods for guided sampling and can generate images with the same quality as a 250-step DDIM baseline using 32-58% less sampling time on ImageNet256.

We also demonstrate usage on a wide variety of conditional generation tasks, such as text-to-image generation, colorization, inpainting, and super-resolution.

RealSinger: Ultra-Realistic Singing Voice Generation via Stochastic Differential Equations

Shoule Wu,Ziqiang Shi

Synthesizing high-quality singing voice from music score is a challenging problem in music generation and has many practical applications. Samples generated by existing singing voice synthesis (SVS) systems can roughly reflect the lyrics, pitch and duration in a given score, but they fail to contain necessary details. In this paper, based on stochastic differential equations (SDE) we propose RealSinger to generate 22.05kHz ultra-realistic singing voice conditioned on a music score. Our RealSinger learns to find the stochastic process path from a source of white noise to the target singing voice manifold under the conditional music score, allowing to sing the music score while maintaining the local voice details of the target singer. During training, our model learns to accurately predict the direction of movement in the ambient Euclidean space onto the low-dimensional singing voice manifold. RealSinger's framework is very flexible. It can either generate intermediate feature representations of the singing voice, such as mel-spectrogram, or directly generate the final waveform, as in the end-to-end style which rectify defects and accumulation errors introduced by two-stage connected singing synthesis systems. An extensive subjective and objective test on benchmark datasets shows significant gains in perceptual quality using RealSinger. The mean opinion scores (MOS) obtained with RealSinger are closer to those of the human singer's original high-fidelity singing voice than to those obtained with any state-of-the-art method. Audio samples are available at https://realsinger.github.io/.

Demystifying Approximate RL with ϵ-greedy Exploration: A Differential Inclusion View

Aditya Gopalan,Gugan Thoppe

Q-learning and SARSA(0) with ϵ-greedy exploration are leading reinforcement learning methods, and their tabular forms converge to the optimal Q-function under reasonable conditions. However, with function approximation, they exhibit unexpected behaviors, such as i.) policy oscillation and chattering, and ii.) convergence to different attractors (possibly even the worst policy) on different runs, ii.) multiple attractors, and iii.) worst policy convergence, apart from the textbook instability. Accordingly, a theory to explain these phenomena has been a long-standing open problem, even for basic linear function approximation (Sutton, 1999). Our work uses differential inclusion theory to provide the first framework for resolving this problem. We further illustrate via numerical examples how this framework helps explain these algorithms' asymptotic behaviors.

****

Batch Multivalid Conformal Prediction

Christopher Jung,Georgy Noarov,Ramya Ramalingam,Aaron Roth

We develop fast distribution-free conformal prediction algorithms for obtaining multivalid coverage on exchangeable data in the batch setting. Multivalid coverage guarantees are stronger than marginal coverage guarantees in two ways: (1) They hold even conditional on group membership---that is, the target coverage lev el $1-\alpha$ holds conditionally on membership in each of an arbitrary (potentially intersecting) group in a finite collection $\mathcal{G}$ of regions in the feature space. (2) They hold even conditional on the value of the threshold used to produce the prediction set on a given example. In fact multivalid coverage guarantees hold even when conditioning on group membership and threshold value simultaneously.

We give two algorithms: both take as input an arbitrary non-conformity score and an arbitrary collection of possibly intersecting groups $\mathcal{G}$, and then can equip arbitrary black-box predictors with prediction sets. Our first algorithm is a direct extension of quantile regression, needs to solve only a single convex minimization problem, and produces an estimator which has group-conditional guarantees for each group in $\mathcal{G}$. Our second algorithm is iterative, and gives the full guarantees of multivalid conformal prediction: prediction sets that are valid conditionally both on group membership and non-conformity threshold. We evaluate the performance of both of our algorithms in an extensive set of experiments.

Transferring Pretrained Diffusion Probabilistic Models

Fuming You,Zhou Zhao

Diffusion Probabilistic Models (DPMs) achieve impressive performance in visual generative tasks recently. However, the success of DPMs heavily relies on large amounts of data and optimization steps, which limits the application of DPMs to small datasets and limited computational resources. In this paper, we investigate transfer learning in DPMs to leverage the DPMs pretrained on large-scale datasets for generation with limited data. Firstly, we show that previous methods like training from scratch or determining the transferable parts is not suitable for the DPM due to its U-Net based denoising architecture with the external denoising timestep input. To address it, we present a condition-based tuning approach to take full advantages of existing pretrained models. Concretely, we obtain the semantic embeddings of condition images by the pretrained CLIP model, and then inject these semantic informations to the pretrained DPM via a ''Attention-NonLinear'' (ANL) module. The adaptation to a new task can be achieved by only tuning the ANL module inserted into the pretrained DPM hierarchically. To further enhance the diversity of generated images, we introduce a masked sampling strategy based on the condition mechanism. Extensive experiments validate the effectiveness and efficiency of our proposed tuning approach in generative task transfer and data augmentation for semi-supervised learning.

ELBO-ing Stein Mixtures

Ola Rønning,Christophe Ley,Ahmad Salim Al-Sibahi,Thomas Hamelryck

Stein variational gradient descent (SVGD) \citep{DBLP:conf/nips/LiuW16} is a particle-based technique for Bayesian inference. SVGD has recently gained popularity because it combines the ability of variational inference to handle tall data with the modeling power of non-parametric inference. Unfortunately, the number of particles required to represent a model adequately grows exponentially with the dimensionality of the model. Stein mixtures \citep{nalisnick2017variational} alleviate the exponential growth in particles by letting each particle parameterize a distribution. However, the inference algorithm proposed by \cite{nalisnick2017variational} can be numerically unstable. We show that their algorithm corresponds to inference with the R\'enyi α-divergence for $\alpha=0$ and that using other values for α can lead to more stable inference. We empirically study the performance of Stein mixtures inferred with different α values on various real-world problems, demonstrating significantly improved results when using $\alpha=1$, which coincides with using the evidence lower bound (ELBO). We call this instance of our algorithm ELBO-within-Stein. A black-box version of the inference algorithm (for arbitrary $\alpha\in \sR$) is available in the deep probabilistic programming language NumPyro \citep{phan2019}.

Schedule-Robust Online Continual Learning

Ruohan Wang,Marco Ciccone,Giulia Luise,Andrew Yapp,massimiliano pontil,Carlo Ciliberto

A continual learning (CL) algorithm learns from a non-stationary data stream. The non-stationarity is modeled by some schedule that determines how data is presented over time. Most current methods make strong assumptions on the schedule and have unpredictable performance when such requirements are not met. A key challenge in CL is thus to design methods robust against arbitrary schedules over the same underlying data, since in real-world scenarios schedules are often unknown and dynamic. In this work, we introduce the notion of schedule-robustness for CL and a novel approach satisfying this desirable property in the challenging online class-incremental setting. We also present a new perspective on CL, as the process of learning a schedule-robust predictor, followed by adapting the predictor using only replay data. Empirically, we demonstrate that our approach outperforms existing methods on CL benchmarks for image classification by a large margin.

****

On the Usefulness of Embeddings, Clusters and Strings for Text Generation Evaluation

Tiago Pimentel,Clara Isabel Meister,Ryan Cotterell

A good automatic evaluation metric for language generation ideally correlates highly with human judgements of text quality. Yet, there is a dearth of such metrics, which inhibits the rapid and efficient progress of language generators. One exception is the recently proposed Mauve. In theory, Mauve measures an information-theoretic divergence between two probability distributions over strings: one representing the language generator under evaluation; the other representing the true natural language distribution. Mauve's authors argue that its success comes from the qualitative properties of their proposed divergence. Yet in practice, as this divergence is uncomputable, Mauve approximates it by measuring the divergence between multinomial distributions over clusters instead, where cluster assignments are attained by grouping strings based on a pretrained language model's embeddings. As we show, however, this is not a tight approximation---in either theory or practice. This begs the question: why does Mauve work so well? In this work, we show that \mauve was right for the wrong reasons, and that its newly proposed divergence is not necessary for its high performance. In fact, classical divergences paired with its proposed cluster-based approximation may actually serve as better evaluation metrics. We finish the paper with a probing analysis; this analysis leads us to conclude that---by encoding syntactic- and coherence-level features of text, while ignoring surface-level features---such cluster-based approximations to string distributions may simply be better for evaluating state-of-the-art language generators.

****

Attention Enables Zero Approximation Error

Zhiying Fang,Yidong Ouyang,Ding-Xuan Zhou,Guang Cheng

Attention-based architectures become the core backbone of many state-of-the-art models for various tasks, including language translation and image classification. However, theoretical properties of attention-based models are seldom considered. In this work, we show that with suitable adaptations, the single-head self-attention transformer with a fixed number of transformer encoder blocks and free parameters is able to generate any desired polynomial of the input with no error. The number of transformer encoder blocks is the same as the degree of the target polynomial. Even more exciting, we find that these transformer encoder blocks in this model do not need to be trained. As a direct consequence, we show that the single-head self-attention transformer with increasing numbers of free parameters is universal. Also, we show that our proposed model can avoid the classical trade-off between approximation error and sample error in the mean squared error analysis for the regression task if the target function is a polynomial. We conduct various experiments and ablation studies to verify our theoretical results.

Revisiting Activation Function Design for Improving Adversarial Robustness at Sc

ale
Cihang Xie,Mingxing Tan,Boqing Gong,Alan Yuille,Quoc V Le

Modern ConvNets typically use ReLU activation function. Recently smooth activation functions have been used to improve their accuracy. Here we study the role of smooth activation function from the perspective of adversarial robustness. We find that ReLU activation function significantly weakens adversarial training due to its non-smooth nature. Replacing ReLU with its smooth alternatives allows adversarial training to find harder adversarial training examples and to compute better gradient updates for network optimization.

We focus our study on the large-scale ImageNet dataset. On ResNet-50, switching from ReLU to the smooth activation function SILU improves adversarial robustness from 33.0% to 42.3%, while also improving accuracy by 0.9% on ImageNet. Smooth activation functions also scale well with larger networks: it helps EfficientNet-L1 to achieve 82.2% accuracy and 58.6% robustness, largely outperforming the previous state-of-the-art defense by 9.5% for accuracy and 11.6% for robustness. Models are available at https://rb.gy/qt8jya.

Contrastive Hierarchical Clustering
Micha■ Znale■niak,Przemys■aw Rola,Patryk Kaszuba,Jacek Tabor,Marek ■mieja

Deep clustering has been dominated by flat clustering models, which split a dataset into a predefined number of groups. Although recent methods achieve extremely high similarity with the ground truth on popular benchmarks, the information contained in the flat partition is limited. In this paper, we introduce CoHiClust, a Contrastive Hierarchical Clustering model based on deep neural networks, which can be applied to large-scale image data. By employing a self-supervised learning approach, CoHiClust distills the base network into a binary tree without access to any labeled data. The hierarchical clustering structure can be used to analyze the relationship between clusters as well as to measure the similarity between data points. Experiments performed on typical image benchmarks demonstrate that CoHiClust generates a reasonable structure of clusters, which is consistent with our intuition and image semantics. Moreover, by applying the proposed pruning strategy, we can restrict the hierarchy to the requested number of clusters (leaf nodes) and obtain the clustering accuracy comparable to the state-of-the-art flat clustering baselines.

****

Accurate Bayesian Meta-Learning by Accurate Task Posterior Inference
Michael Volpp,Philipp Dahlinger,Philipp Becker,Christian Daniel,Gerhard Neumann

Bayesian meta-learning (BML) enables fitting expressive generative models to small datasets by incorporating inductive priors learned from a set of related tasks. The Neural Process (NP) is a prominent deep neural network-based BML architecture, which has shown remarkable results in recent years. In its standard formulation, the NP encodes epistemic uncertainty in an amortized, factorized, Gaussian variational (VI) approximation to the BML task posterior (TP), using reparametrized gradients. Prior work studies a range of architectural modifications to boost performance, such as attentive computation paths or improved context aggregation schemes, while the influence of the VI scheme remains under-explored. We aim to bridge this gap by introducing GMM-NP, a novel BML model, which builds on recent work that enables highly accurate, full-covariance Gaussian mixture (GMM) TP approximations by combining VI with natural gradients and trust regions. We show that GMM-NP yields tighter evidence lower bounds, which increases the efficiency of marginal likelihood optimization, leading to improved epistemic uncertainty estimation and accuracy. GMM-NP does not require complex architectural modifications, resulting in a powerful, yet conceptually simple BML model, which outperforms the state of the art on a range of challenging experiments, highlighting its applicability to settings where data is scarce.

Learning to Decompose Visual Features with Latent Textual Prompts
Feng Wang,Manling Li,Xudong Lin,Hairong Lv,Alex Schwing,Heng Ji

Recent advances in pre-training vision-language models like CLIP have shown great potential in learning transferable visual representations. Nonetheless, for downstream inference, CLIP-like models suffer from either 1) degraded accuracy and robustness in the case of inaccurate text descriptions during retrieval-based inference (the challenge for zero-shot protocol); or 2) breaking the well-established vision-language alignment (the challenge for linear probing). To address them, we propose Decomposed Feature Prompting (DeFo). DeFo leverages a flexible number of learnable embeddings as textual input while maintaining the vision-language dual-model architecture, which enables the model to learn decomposed visual features with the help of feature-level textual prompts. We further use an additional linear layer to perform classification, allowing a scalable size of language inputs. Our empirical study shows DeFo's significance in improving the vision-language models. For example, DeFo obtains 73.2% test accuracy on ImageNet with a ResNet-50 backbone without tuning any pretrained weights of both the vision and language encoder, outperforming zero-shot CLIP by a large margin of 15.0%, and outperforming state-of-the-art vision-language prompt tuning method by 7.6%.

Skill Machines: Temporal Logic Composition in Reinforcement Learning

Geraud Nangue Tasse,Devon Jarvis,Steven James,Benjamin Rosman

A major challenge in reinforcement learning is specifying tasks in a manner that is both interpretable and verifiable. One common approach is to specify tasks through reward machines---finite state machines that encode the task to be solved. We introduce skill machines, a representation that can be learned directly from these reward machines that encode the solution to such tasks. We propose a framework where an agent first learns a set of base skills in a reward-free setting, and then combines these skills with the learned skill machine to produce composite behaviours specified by any regular language, such as linear temporal logics. This provides the agent with the ability to map from complex logical task specifications to near-optimal behaviours zero-shot. We demonstrate our approach in both a tabular and high-dimensional video game environment, where an agent is faced with several of these complex, long-horizon tasks. Our results indicate that the agent is capable of satisfying extremely complex task specifications, producing near optimal performance with no further learning. Finally, we demonstrate that the performance of skill machines can be improved with regular off-policy reinforcement learning algorithms when optimal behaviours are desired.

Surrogate Gradient Design for LIF networks

Luca Celotti,Jean Rouat

Spiking Neuromorphic Computing uses binary activity to improve Artificial Intelligence energy efficiency. However, the non-smoothness of binary ac■tivity requires approximate gradients, known as Surrogate Gradients (SG), to close the performance gap with Deep Learning. Several SG have been proposed in the literature, but it remains unclear how to determine the best SG for a given task and network. Good performance can be achieved with most SG shapes, after an extensive search of hyper-parameters that can be costly. Thus, we aim at experimentally and theoretically define the best SG across different stress tests, to reduce future need of grid search. Here we first show that the derivative of the fast sigmoid outperforms other SG across tasks and networks, for a wide range of learning rates. Secondly, we focus on the Leaky Integrate and Fire (LIF) spiking neural model, and we show that a SG with low dampening, high sharpness, and low tail fat■ness, systematically leads to higher accuracy. Thirdly, we observe that the Orthogonal initialization leads the LIF to higher accuracy with most SG. Fourthly, we note that high initial firing rates, combined with a sparsity encouraging loss term, can lead to better generalization, depending on the SG shape. Finally, we provide a theoretical solution, inspired by Glorot and He initializations, to reduce the need of extensive grid-search, to find an SG and initialization that experimentally result in improved accuracy.

Context-enriched molecule representations improve few-shot drug discovery

Johannes Schimunek,Philipp Seidl,Lukas Friedrich,Daniel Kuhn,Friedrich Rippmann, Sepp Hochreiter,Günter Klambauer

A central task in computational drug discovery is to construct models from known active molecules to find further promising molecules for subsequent screening. However, typically only very few active molecules are known. Therefore, few-shot learning methods have the potential to improve the effectiveness of this critical phase of the drug discovery process. We introduce a new method for few-shot drug discovery. Its main idea is to enrich a molecule representation by knowledge about known context or reference molecules. Our novel concept for molecule representation enrichment is to associate molecules from both the support set and the query set with a large set of reference (context) molecules through a modern Hopfield network. Intuitively, this enrichment step is analogous to a human expert who would associate a given molecule with familiar molecules whose properties are known. The enrichment step reinforces and amplifies the covariance structure of the data, while simultaneously removing spurious correlations arising from the decoration of molecules. Our approach is compared with other few-shot methods for drug discovery on the FS-Mol benchmark dataset. On FS-Mol, our approach outperforms all compared methods and therefore sets a new state-of-the art for few-shot learning in drug discovery. An ablation study shows that the enrichment step of our method is the key to improve the predictive quality. In a domain shift experiment, we further demonstrate the robustness of our method.

The Multiple Subnetwork Hypothesis: Enabling Multidomain Learning by Isolating Task-Specific Subnetworks in Feedforward Neural Networks

Jacob William Renn,Ian Sotnek,Benjamin Harvey,Brian Caffo

Neural networks have seen an explosion of usage and research in the past decade, particularly within the domains of computer vision and natural language processing. However, only recently have advancements in neural networks yielded performance improvements beyond narrow applications and translated to expanded multitask models capable of generalizing across multiple data types and modalities. Simultaneously, it has been shown that neural networks are overparameterized to a high degree, and pruning techniques have proved capable of significantly reducing the number of active weights within the network while largely preserving performance. In this work, we identify a methodology and network representational structure which allows a pruned network to employ previously unused weights to learn subsequent tasks. We employ these methodologies on well-known benchmarking datasets for testing purposes and show that networks trained using our approaches are able to learn multiple tasks, which may be related or unrelated, in parallel or in sequence without sacrificing performance on any task or exhibiting catastrophic forgetting.

Delving into the Openness of CLIP

Shuhuai Ren,Lei Li,Xuancheng Ren,Guangxiang Zhao,Xu Sun

Contrastive Language-Image Pre-training (CLIP) has demonstrated great potential in realizing open-vocabulary visual recognition in a matching style, due to its holistic use of natural language supervision that covers unconstrained real-world visual concepts. However, it is, in turn, also difficult to evaluate and analyze the openness of CLIP-like models, since they are in theory open to any vocabulary but the actual accuracy varies. To address the insufficiency of conventional studies on openness, we resort to an incremental perspective and define the extensibility, which essentially approximates the model's ability to deal with new visual concepts, by evaluating openness through vocabulary expansions. Our evaluation based on extensibility shows that CLIP-like models are hardly truly open and their performances degrade as the vocabulary expands to different degrees. Further analysis reveals that the over-estimation of openness is not because CLIP-like models fail to capture the general similarity of image and text features of novel visual concepts, but because of the confusion among competing text features, that is, they are not stable with respect to the vocabulary. In light of this, we propose to improve the openness of CLIP in feature space by enforcing the distinguishability of text features. Our method retrieves relevant texts from the pre-training corpus to enhance prompts for inference, which boosts the extens ibility and stability of CLIP even without fine-tuning.

****

Test-Time Adaptation via Self-Training with Nearest Neighbor Information

Minguk Jang,Sae-Young Chung,Hye Won Chung

Test-time adaptation (TTA) aims to adapt a trained classifier using online unlabeled test data only, without any information related to the training procedure. Most existing TTA methods adapt the trained classifier using the classifier's prediction on the test data as pseudo-label.

However, under test-time domain shift, accuracy of the pseudo labels cannot be guaranteed, and thus the TTA methods often encounter performance degradation at the adapted classifier. To overcome this limitation, we propose a novel test-time adaptation method, called Test-time Adaptation via Self-Training with nearest neighbor information (TAST), which is composed of the following procedures: (1) adds trainable adaptation modules on top of the trained feature extractor; (2) newly defines a pseudo-label distribution for the test data by using the nearest neighbor information; (3) trains these modules only a few times during test time to match the nearest neighbor-based pseudo label distribution and a prototype-based class distribution for the test data; and (4) predicts the label of test data using the average predicted class distribution from these modules. The pseudo-label generation is based on the basic intuition that a test data and its nearest neighbor in the embedding space are likely to share the same label under the domain shift. By utilizing multiple randomly initialized adaptation modules, TAST extracts useful information for the classification of the test data under the domain shift, using the nearest neighbor information. TAST showed better performance than the state-of-the-art TTA methods on two standard benchmark tasks, domain generalization, namely VLCS, PACS, OfficeHome, and TerraIncognita, and image corruption, particularly CIFAR-10/100C.

Learning to Counter: Stochastic Feature-based Learning for Diverse Counterfactual Explanations

Vy Vo,Trung Le,Van Nguyen,He Zhao,Edwin V. Bonilla,Reza Haf,Dinh Phung

Interpretable machine learning seeks to understand the reasoning process of complex black-box systems that are long notorious for lack of explainability. One growing interpreting approach is through counterfactual explanations, which go beyond why a system arrives at a certain decision to further provide suggestions on what a user can do to alter the outcome. A counterfactual example must be able to counter the original prediction from the black-box classifier, while also satisfying various constraints for practical applications. These constraints exist at trade-offs between one and another presenting radical challenges to existing works. To this end, we propose a stochastic learning-based framework that effectively balances the counterfactual trade-offs. The framework consists of a generation and a feature selection module with complementary roles: the former aims to model the distribution of valid counterfactuals whereas the latter serves to enforce additional constraints in a way that allows for differentiable training and amortized optimization. We demonstrate the effectiveness of our method in generating actionable and plausible counterfactuals that are more diverse than the existing methods and particularly in a more efficient manner than counterparts of the same capacity.

Accurate Neural Training with 4-bit Matrix Multiplications at Standard Formats

Brian Chmiel,Ron Banner,Elad Hoffer,Hilla Ben-Yaacov,Daniel Soudry

Quantization of the weights and activations is one of the main methods to reduce the computational footprint of Deep Neural Networks (DNNs) training. Current methods enable 4-bit quantization of the forward phase. However, this constitutes only a third of the training process. Reducing the computational footprint of the entire training process requires the quantization of the neural gradients, i.e., the loss gradients with respect to the outputs of intermediate neural layers.

Previous works separately showed that accurate 4-bit quantization of the neural gradients needs to (1) be unbiased and (2) have a log scale. However, no previous work aimed to combine both ideas, as we do in this work. Specifically, we examine the importance of having unbiased quantization in quantized neural network training, where to maintain it, and how to combine it with logarithmic quantization. Based on this, we suggest a $\textit{logarithmic unbiased quantization}$ (LUQ) method to quantize all both the forward and backward phase to 4-bit, achieving state-of-the-art results in 4-bit training without overhead. For example, in ResNet50 on ImageNet, we achieved a degradation of 1.1 %. We further improve this to degradation of only 0.32 % after three epochs of high precision fine-tunining, combined with a variance reduction method---where both these methods add overhead comparable to previously suggested methods.
A reference implementation is supplied in the supplementary material.

SWARM Parallelism: Training Large Models Can Be Surprisingly Communication-Efficient
Max Ryabinin,Tim Dettmers,Michael Diskin,Alexander Borzunov
Many deep learning applications benefit from using large models with billions of parameters. Training these models is notoriously expensive due to the need for specialized HPC clusters. In this work, we consider alternative setups for training large models: using cheap ``preemptible'' instances or pooling existing resources from multiple regions. We analyze the performance of existing model-parallel algorithms in these conditions and find configurations where training larger models becomes less communication-intensive. Based on these findings, we propose SWARM Parallelism (Stochastically Wired Adaptively Rebalanced Model Parallelism), a model-parallel training algorithm designed for poorly connected, heterogeneous and unreliable devices. SWARM creates temporary randomized pipelines between nodes that are rebalanced in case of failure. We empirically validate our findings and compare SWARM Parallelism with existing large-scale training approaches. Finally, we combine our insights with compression strategies to train a large Transformer language model with 1B shared parameters ($\approx$13B before sharing) on preemptible T4 GPUs with less than 200 Mb/s network.

Relative representations enable zero-shot latent space communication
Luca Moschella,Valentino Maiorca,Marco Fumero,Antonio Norelli,Francesco Locatello,Emanuele Rodolà
Neural networks embed the geometric structure of a data manifold lying in a high-dimensional space into latent representations. Ideally, the distribution of the data points in the latent space should depend only on the task, the data, the loss, and other architecture-specific constraints. However, factors such as the random weights initialization, training hyperparameters, or other sources of randomness in the training phase may induce incoherent latent spaces that hinder any form of reuse. Nevertheless, we empirically observe that, under the same data and modeling choices, the angles between the encodings within distinct latent spaces do not change. In this work, we propose the latent similarity between each sample and a fixed set of anchors as an alternative data representation, demonstrating that it can enforce the desired invariances without any additional training. We show how neural architectures can leverage these relative representations to guarantee, in practice, invariance to latent isometries and rescalings, effectively enabling latent space communication: from zero-shot model stitching to latent space comparison between diverse settings. We extensively validate the generalization capability of our approach on different datasets, spanning various modalities (images, text, graphs), tasks (e.g., classification, reconstruction) and architectures (e.g., CNNs, GCNs, transformers).

****

oViT: An Accurate Second-Order Pruning Framework for Vision Transformers
Denis Kuznedelev,Eldar Kurtic,Elias Frantar,Dan Alistarh
Models from the Vision Transformer (ViT) family have recently provided breakthrough results across image classification tasks such as ImageNet. Yet, they still face barriers to deployment, notably the fact that their accuracy can be severel

y impacted by compression techniques such as pruning. In this paper, we take a step towards addressing this issue by introducing \textit{Optimal ViT Surgeon (oViT)}, a new state-of-the-art method for the weight sparsification of Vision Transformers (ViT) models. At the technical level, oViT introduces a new weight pruning algorithm which leverages second-order information, specifically adapted to be both highly-accurate and efficient in the context of ViTs. We complement this accurate one-shot pruner with an in-depth investigation of gradual pruning, augmentation, and recovery schedules for ViTs, which we show to be critical for successful ViT compression. We validate our method via extensive experiments on classical ViT and DeiT models, as well as on newer variants, such as XCiT, EfficientFormer and Swin. Moreover, our results are even relevant to recently-proposed highly-accurate ResNets. Our results show for the first time that ViT-family models can in fact be pruned to high sparsity levels (e.g. $\geq 75\%$) with low impact on accuracy ($\leq 1\%$ relative drop), and that our approach outperforms prior methods by significant margins at high sparsities. In addition, we show that our method is compatible with structured pruning methods and quantization, and that it can lead to significant speedups on a sparsity-aware inference engine.

Learning Basic Interpretable Factors from Temporal Signals via Physics Symmetry
Xuanjie Liu,Daniel Chin,Yichen Huang,Gus Xia
We have recently seen great progress in learning interpretable music representations, ranging from basic factors, such as pitch and timbre, to high-level concepts, such as chord, texture and melody contour. However, most methods rely heavily on music domain knowledge and it remains an open question how to learn interpretable and disentangled representations using inductive biases that are more general. In this study, we use \textit{physical symmetry} as a self-consistency constraint on the latent space. Specifically, it requires the prior model that characterises the dynamics of the latent states to be \textit{equivariant} with respect to a certain group transformation (say, translation and rotation). We show that our model can learn \textit{linear} pitch factor (that agrees with human music perception) as well as pitch-timbre disentanglement from unlabelled monophonic music audio. In addition, the same methodology can be applied to computer vision, learning the 3D Cartesian space as well as space-colour disentanglement from a simple moving object shot by a single fix camera. Furthermore, applying physical symmetry to the prior model naturally leads to \textit{representation augmentation}, a new learning technique which helps improve sample efficiency.

Addressing High-dimensional Continuous Action Space via Decomposed Discrete Policy-Critic
Yechen Zhang,Jian Sun,Gang Wang,Jie Chen
Reinforcement learning (RL) methods for discrete action spaces like DQNs are being widely used in tasks such as Atari games. However, they encounter difficulties when addressing continuous control tasks, since discretizing continuous action space incurs the curse-of-dimensionality. To tackle continuous control tasks via discretized actions, we propose a decomposed discrete policy-critic (D2PC) architecture, which was inspired by multi-agent RL (MARL) and associates with each action dimension a discrete policy, while leveraging a single critic network to provide a shared evaluation. Building on D2PC, we advocate soft stochastic D2PC (SD2PC) and deterministic D2PC (D3PC) methods with a discrete stochastic or deterministic policy, which show comparable or superior training performances relative to even continuous actor-critic methods. Additionally, we design a mechanism that allows D3PC to interact with continuous actor-critic methods, contributing to the Q-policy-critic (QPC) algorithm, which inherits the training efficiency of discrete RL and the near-optimal final performance of continuous RL algorithms. Substantial experimental results on several continuous benchmark tasks validate our claims.

Unsupervised Manifold Alignment with Joint Multidimensional Scaling
Dexiong Chen,Bowen Fan,Carlos Oliver,Karsten Borgwardt

We introduce Joint Multidimensional Scaling, a novel approach for unsupervised manifold alignment, which maps datasets from two different domains, without any known correspondences between data instances across the datasets, to a common low-dimensional Euclidean space. Our approach integrates Multidimensional Scaling (MDS) and Wasserstein Procrustes analysis into a joint optimization problem to simultaneously generate isometric embeddings of data and learn correspondences between instances from two different datasets, while only requiring intra-dataset pairwise dissimilarities as input. This unique characteristic makes our approach applicable to datasets without access to the input features, such as solving the inexact graph matching problem. We propose an alternating optimization scheme to solve the problem that can fully benefit from the optimization techniques for MDS and Wasserstein Procrustes. We demonstrate the effectiveness of our approach in several applications, including joint visualization of two datasets, unsupervised heterogeneous domain adaptation, graph matching, and protein structure alignment. The implementation of our work is available at https://github.com/BorgwardtLab/JointMDS.

Can Single-Pass Contrastive Learning Work for Both Homophilic and Heterophilic Graph?

Haonan Wang,Jieyu Zhang,Qi Zhu,Wei Huang

Existing graph contrastive learning (GCL) typically requires two forward pass for a single instance to construct the contrastive loss. Despite its remarkable success, it is unclear whether such a dual-pass design is (theoretically) necessary. Besides, the empirical results are hitherto limited to the homophilic graph benchmarks. Then a natural question arises: Can we design a method that works for both homophilic and heterophilic graphs with a performance guarantee? To answer this, we theoretically analyze the concentration property of features obtained by neighborhood aggregation on both homophilic and heterophilic graphs, introduce the single-pass graph contrastive learning loss based on the property, and provide performance guarantees of the minimizer of the loss on downstream tasks. As a direct consequence of our theory, we introduce the Single-Pass Graph Contrastive Learning method (SP-GCL). Empirically, on 14 benchmark datasets with varying degrees of heterophily, the features learned by the SP-GCL can match or outperform existing strong baselines with significantly less computational overhead, and empirical results show the feasibility of conclusions derived by our analysis in real-world cases.

****

TOAST: Topological Algorithm for Singularity Tracking

Julius Von Rohrscheidt,Bastian Rieck

The manifold hypothesis, which assumes that data lie on or close to an unknown manifold of low intrinsic dimensionality, is a staple of modern machine learning research. However, recent work has shown that real-world data exhibit distinct non-manifold structures, which result in singularities that can lead to erroneous conclusions about the data. Detecting such singularities is therefore crucial as a precursor to interpolation and inference tasks. We address detecting singularities by developing (i) persistent local homology, a new topology-driven framework for quantifying the intrinsic dimension of a data set locally, and (ii) Euclidicity, a topology-based multi-scale measure for assessing the ‘manifoldness’ of individual points. We show that our approach can reliably identify singularities of complex spaces, while also capturing singular structures in real-world data sets.

Robust Manifold Estimation Approach for Evaluating Fidelity and Diversity

Pum Jun Kim,Yoojin Jang,Jisu Kim,Jaejun Yoo

We propose a robust and reliable evaluation metric for generative models by introducing topological and statistical treatments for a rigorous support manifold estimation. Existing metrics, such as Inception Score (IS), Frechet Inception Distance (FID), and the variants of Precision and Recall (P&R), heavily rely on support manifolds that are estimated from sample features. However, the reliability of their estimation has not been seriously discussed (and overlooked) even thou gh the quality of the evaluation entirely depends on it. In this paper, we propose Topological Precision and Recall (TopP&R, pronounced “topper”), which provides a systematic approach to estimating support manifolds, retaining only topologically and statistically important features with a certain level of confidence. This not only makes TopP&R strong for noisy features, but also provides statistical consistency. Our theoretical and experimental results show that TopP&R is robust to outliers and non-independent and identically distributed (Non-IID) perturbations, while accurately capturing the true trend of change in samples. To the best of our knowledge, this is the first evaluation metric focused on the robust estimation of the support manifold and provides its statistical consistency under noise.

Exploiting Certified Defences to Attack Randomised Smoothing

Andrew Craig Cullen,Paul Montague,Shijie Liu,Sarah Monazam Erfani,Benjamin I. P. Rubinstein

Certified guarantees of adversarial robustness play an important role in providing assurances regarding a models output, irrespective of the behaviour of an attacker. However, while the development of such guarantees has drawn upon an improved understanding of attacker behaviour, so too can certified guarantees be exploited in order to generate more efficient adversarial attacks. Within this work, we explore this heretofore undiscovered additional attack surface, while also considering how previously discovered attacks could be applied to models defended by randomised smoothing. In all bar one experiment our approach generates smaller adversarial perturbations for more than $70 \%$ of tested samples, reducing the average magnitude of the adversarial perturbation by $13 \%$.

****

Simple and Scalable Nearest Neighbor Machine Translation

Yuhan Dai,Zhirui Zhang,Qiuzhi Liu,Qu Cui,Weihua Li,Yichao Du,Tong Xu

$k$NN-MT is a straightforward yet powerful approach for fast domain adaptation, which directly plugs the pre-trained neural machine translation (NMT) models with domain-specific token-level $k$-nearest-neighbor ($k$NN) retrieval to achieve domain adaptation without retraining. Despite being conceptually attractive, $k$NN-MT is burdened with massive storage requirements and high computational complexity since it conducts nearest neighbor searches over the entire reference corpus. In this paper, we propose a simple and scalable nearest neighbor machine translation framework to drastically promote the decoding and storage efficiency of $k$NN-based models while maintaining the translation performance. To this end, we dynamically construct a extremely small datastore for each input via sentence-level retrieval to avoid searching the entire datastore in vanilla $k$NN-MT, based on which we further introduce a distance-aware adapter to adaptively incorporate the $k$NN retrieval results into the pre-trained NMT models. Experiments on machine translation in two general settings, static domain adaptation, and online learning, demonstrate that our proposed approach not only achieves almost 90% speed as the NMT model without performance degradation, but also significantly reduces the storage requirements of $k$NN-MT.

****

On the Effectiveness of Out-of-Distribution Data in Self-Supervised Long-Tail Learning.

Jianhong Bai,Zuozhu Liu,Hualiang Wang,Jin Hao,YANG FENG,Huanpeng Chu,Haoji Hu

Though Self-supervised learning (SSL) has been widely studied as a promising technique for representation learning, it doesn't generalize well on long-tailed datasets due to the majority classes dominating the feature space. Recent work shows that the long-tailed learning performance could be boosted by sampling extra in-domain (ID) data for self-supervised training, however, large-scale ID data which can rebalance the minority classes are expensive to collect. In this paper, we propose an alternative but easy-to-use and effective solution, \textbf{C}ontrastive with \textbf{O}ut-of-distribution (OOD) data for \textbf{L}ong-\textbf{T}ail learning (COLT), which can effectively exploit OOD data to dynamically re-balance the feature space. We empirically identify the counter-intuitive usefulness of OOD samples in SSL long-tailed learning and principally design a novel SSL

method. Concretely, we first localize the `\emph{head}' and `\emph{tail}' samples by assigning a tailness score to each OOD sample based on its neighborhoods in the feature space. Then, we propose an online OOD sampling strategy to dynamically re-balance the feature space. Finally, we enforce the model to be capable of distinguishing ID and OOD samples by a distribution-level supervised contrastive loss. Extensive experiments are conducted on various datasets and several state-of-the-art SSL frameworks to verify the effectiveness of the proposed method. The results show that our method significantly improves the performance of SSL on long-tailed datasets by a large margin, and even outperforms previous work which uses external ID data. Our code is available at \url{https://github.com/JianhongBai/COLT}.

Dynamic Update-to-Data Ratio: Minimizing World Model Overfitting
Nicolai Dorka,Tim Welschehold,Wolfram Burgard
Early stopping based on the validation set performance is a popular approach to find the right balance between under- and overfitting in the context of supervised learning. However, in reinforcement learning, even for supervised sub-problems such as world model learning, early stopping is not applicable as the dataset is continually evolving. As a solution, we propose a new general method that dynamically adjusts the update to data (UTD) ratio during training based on under- and overfitting detection on a small subset of the continuously collected experience not used for training. We apply our method to DreamerV2, a state-of-the-art model-based reinforcement learning algorithm, and evaluate it on the DeepMind Control Suite and the Atari 100k benchmark. The results demonstrate that one can better balance under- and overestimation by adjusting the UTD ratio with our approach compared to the default setting in DreamerV2 and that it is competitive with an extensive hyperparameter search which is not feasible for many applications. Our method eliminates the need to set the UTD hyperparameter by hand and even leads to a higher robustness with regard to other learning-related hyperparameters further reducing the amount of necessary tuning.

Uni-Mol: A Universal 3D Molecular Representation Learning Framework
Gengmo Zhou,Zhifeng Gao,Qiankun Ding,Hang Zheng,Hongteng Xu,Zhewei Wei,Linfeng Zhang,Guolin Ke
Molecular representation learning (MRL) has gained tremendous attention due to its critical role in learning from limited supervised data for applications like drug design. In most MRL methods, molecules are treated as 1D sequential tokens or 2D topology graphs, limiting their ability to incorporate 3D information for downstream tasks and, in particular, making it almost impossible for 3D geometry prediction/generation. In this paper, we propose a universal 3D MRL framework, called Uni-Mol, that significantly enlarges the representation ability and application scope of MRL schemes. Uni-Mol contains two pretrained models with the same SE(3) Transformer architecture: a molecular model pretrained by 209M molecular conformations; a pocket model pretrained by 3M candidate protein pocket data. Besides, Uni-Mol contains several finetuning strategies to apply the pretrained models to various downstream tasks. By properly incorporating 3D information, Uni-Mol outperforms SOTA in 14/15 molecular property prediction tasks. Moreover, Uni-Mol achieves superior performance in 3D spatial tasks, including protein-ligand binding pose prediction, molecular conformation generation, etc. The code, model, and data are made publicly available at https://github.com/dptech-corp/Uni-Mol.

CAPE: Channel-Attention-Based PDE Parameter Embeddings for SciML
Makoto Takamoto,Francesco Alesiani,Mathias Niepert
Scientific Machine Learning (SciML) designs machine learning methods that predict physical systems governed by partial differential equations (PDE). These ML-based surrogate models substitute inefficient and often non-differentiable numerical simulation algorithms and find multiple applications such as weather forecasting, molecular dynamics, and medical applications.
While a number of ML-based methods for approximating the solutions of PDEs have

been proposed in recent years, they typically do not consider the parameters of the PDEs, making it difficult for the ML surrogate models to generalize to PDE parameters not seen during training.

We propose a new channel-attention-based parameter embedding (CAPE) component for scientific machine learning models and a simple and effective curriculum learning strategy. The CAPE module can be combined with any kind of ML surrogate model, which can adapt to changing PDE parameters without harming the original model's ability to find approximate solutions to PDEs. The curriculum learning strategy provides a seamless transition between teacher-forcing and fully auto-regressive training.

We compare CAPE in conjunction with the curriculum learning strategy using a PDE benchmark and obtain consistent and significant improvements over the base models. The experiments also show several advantages of CAPE, such as its increased ability to generalize to unseen PDE parameters without substantially increasing inference time and parameter count.

An implementation of the method and experiments are available at \url{https://anonymous.4open.science/r/CAPE-ML4Sci-145B}.

Topic and Hyperbolic Transformer to Handle Multi-modal Dependencies

Noriaki Kawamae

As multi-modal search relies on jointly learning image-text representations and has been investigated in the literature,

our innovation is to develop Chimera, a framework in which to learn their representations and similarities.

Because the core of multi-modal search is learning the modalities in a shared semantic space and measuring their similarities,

search quality depends on which expressive space is utilized in learning.

This motivates us to identify the space that can elucidate their semantic and complex relationships with small information loss.

Novelty is assured by introducing the topic and hyperbolic as spaces,

and performing contrastive/metric learning tasks to ensure the cooperation of these spaces with Transformer.

Experiments show that Chimera empowers pre-trained models for multi-modal search tasks and demonstrate the ability of the layers it introduces.

Variance Covariance Regularization Enforces Pairwise Independence in Self-Supervised Representations

Grégoire Mialon,Randall Balestriero,Yann LeCun

Self-Supervised Learning (SSL) methods such as VICReg, Barlow Twins or W-MSE avoid collapse of their joint embedding architectures by constraining or regularizing the covariance matrix of their projector’s output. This study highlights important properties of such strategy, which we coin Variance-Covariance regularization (VCReg). More precisely, we show that VCReg enforces pairwise independence between the features of the learned representation. This result emerges by bridging VCReg applied on the projector’s output to kernel independence criteria applied on the projector’s input. This provides the first theoretical motivations and explanations of VCReg. We empirically validate our findings where (i) we put in evidence which projector’s characteristics favor pairwise independence, (ii) we use these findings to obtain nontrivial performance gains for VICReg, (iii) we demonstrate that the scope of VCReg goes beyond SSL by using it to solve Independent Component Analysis. We hope that our findings will support the adoption of VCReg in SSL and beyond.

DEP-RL: Embodied Exploration for Reinforcement Learning in Overactuated and Musculoskeletal Systems

Pierre Schumacher,Daniel Haeufle,Dieter Büchler,Syn Schmitt,Georg Martius

Muscle-actuated organisms are capable of learning an unparalleled diversity of dexterous movements despite their vast amount of muscles.

Reinforcement learning (RL) on large musculoskeletal models, however, has not be

en able to show similar performance.
We conjecture that ineffective exploration in large overactuated action spaces is a key problem.
This is supported by the finding that common exploration noise strategies are inadequate in synthetic examples of overactuated systems.
We identify differential extrinsic plasticity (DEP), a method from the domain of self-organization, as being able to induce state-space covering exploration within seconds of interaction.
By integrating DEP into RL, we achieve fast learning of reaching and locomotion in musculoskeletal systems, outperforming current approaches in all considered tasks in sample efficiency and robustness.
****

Restricted Generative Projection for One-Class Classification and Anomaly detection
Feng Xiao,Ruoyu Sun,Jicong Fan
We present a novel framework for one-class classification and anomaly detection. The core idea is to learn a mapping to transform the unknown distribution of training (normal) data to a known distribution that is supposed to be different from the transformed distribution of unknown abnormal data. Crucially, the target distribution of training data should be sufficiently simple, compact, and informative. The simplicity is to ensure that we can sample from the distribution easily, the compactness is to ensure that the decision boundary between normal data and abnormal data is clear and reliable, and the informativeness is to ensure that the transformed data preserve the important information of the original data. Therefore, we propose to use truncated Gaussian, uniform in hyperball, uniform on hypersphere, or uniform between hyperspheres, as the target distribution. We then minimize the distance between the transformed data distribution and the target distribution while keeping the reconstruction error for the original data small enough. Our model is simple and easy to train especially compared with those based on generative models. Comparative studies on a few benchmark datasets verify the effectiveness of our method in comparison to baselines.

Name Your Colour For the Task: Artificially Discover Colour Naming via Colour Quantisation Transformer
Shenghan Su,Lin Gu,Ziteng Cui,Yue Yang,Jingjing Shen,Hiroaki Yamane,Zenghui Zhang,Tatsuya Harada
The long-standing theory that a colour-naming system evolves under the dual pressure of efficient communication and perceptual mechanism is supported by more and more linguistic studies including the analysis of four decades’ diachronic data from the Nafaanra language. This inspires us to explore whether artificial intelligence could evolve and discover a similar colour-naming system via optimising the communication efficiency represented by high-level recognition performance. Here, we propose a novel colour quantisation transformer, CQFormer, that quantises colour space while maintaining the accuracy of machine recognition on the quantised image. Given an RGB image, the annotation branch maps it into an index map before generating the quantised image with a colour palette, meanwhile the palette branch utilises a key-point detection way to find proper colours in palette among whole colour space. By interacting with colour annotation, CQFormer is able to balance both the machine vision accuracy and colour perceptual structure such as distinct and stable colour distribution for discovered colour system. Very interestingly, we even observe the consistent evolution pattern between our artificial colour system and basic colour terms across human languages. Besides, our colour quantisation method also offers an efficient quantisation method that effectively compresses the image storage while maintaining a high performance in high-level recognition tasks such as classification and detection. Extensive experiments demonstrate the superior performance of our method with extremely low bit-rate colours. We will release the source code upon acceptance.

The Symmetric Generalized Eigenvalue Problem as a Nash Equilibrium
Ian Gemp,Charlie Chen,Brian McWilliams

The symmetric generalized eigenvalue problem (SGEP) is a fundamental concept in numerical linear algebra. It captures the solution of many classical machine learning problems such as canonical correlation analysis, independent components analysis, partial least squares, linear discriminant analysis, principal components and others. Despite this, most general solvers are prohibitively expensive when dealing with *streaming data sets* (i.e., minibatches) and research has instead concentrated on finding efficient solutions to specific problem instances. In this work, we develop a game-theoretic formulation of the top-k SGEP whose Nash equilibrium is the set of generalized eigenvectors. We also present a parallelizable algorithm with guaranteed asymptotic convergence to the Nash. Current state-of-the-art methods require $\mathcal{O}(d^2k)$ runtime complexity per iteration which is prohibitively expensive when the number of dimensions (d) is large. We show how to modify this parallel approach to achieve $\mathcal{O}(dk)$ runtime complexity. Empirically we demonstrate that this resulting algorithm is able to solve a variety of SGEP problem instances including a large-scale analysis of neural network activations.

Learning with Auxiliary Activation for Memory-Efficient Training

Sunghyeon Woo,Dongsuk Jeon

While deep learning has achieved great success in various fields, a large amount of memory is necessary to train deep neural networks, which hinders the development of massive state-of-the-art models. The reason is the conventional learning rule, backpropagation, should temporarily store input activations of all the layers in the network. To overcome this, recent studies suggested various memory-efficient implementations of backpropagation. However, those approaches incur computational overhead due to the recomputation of activations, slowing down neural network training. In this work, we propose a new learning rule which significantly reduces memory requirements while closely matching the performance of backpropagation. The algorithm combines auxiliary activation with output activation during forward propagation, while only auxiliary activation is used during backward propagation instead of actual input activation to reduce the amount of data to be temporarily stored. We mathematically show that our learning rule can reliably train the networks whose loss landscape is convex if the auxiliary activation satisfies certain conditions. Based on this observation, we suggest candidates of auxiliary activation that satisfy those conditions. Experimental results confirm that the proposed learning rule achieves competitive performance compared to backpropagation in various models such as ResNet, Transformer, BERT, ViT, and MLP-Mixer.

Equivariant 3D-Conditional Diffusion Models for Molecular Linker Design

Ilia Igashov,Hannes Stärk,Clement Vignac,Victor Garcia Satorras,Pascal Frossard,Max Welling,Michael M. Bronstein,Bruno Correia

Fragment-based drug discovery has been an effective paradigm in early-stage drug development. An open challenge in this area is designing linkers between disconnected molecular fragments of interest to obtain chemically-relevant candidate drug molecules. In this work, we propose DiffLinker, an E(3)-equivariant 3D-conditional diffusion model for molecular linker design. Given a set of disconnected fragments, our model places missing atoms in between and designs a molecule incorporating all the initial fragments. Unlike previous approaches that are only able to connect pairs of molecular fragments, our method can link an arbitrary number of fragments. Additionally, the model automatically determines the number of atoms in the linker and its attachment points to the input fragments. We demonstrate that DiffLinker outperforms other methods on the standard datasets generating more diverse and synthetically-accessible molecules. Besides, we experimentally test our method in real-world applications, showing that it can successfully generate valid linkers conditioned on target protein pockets.

Language Modelling with Pixels

Phillip Rust,Jonas F. Lotz,Emanuele Bugliarello,Elizabeth Salesky,Miryam de Lhoneux,Desmond Elliott

Language models are defined over a finite set of inputs, which creates a vocabulary bottleneck when we attempt to scale the number of supported languages. Tackling this bottleneck results in a trade-off between what can be represented in the embedding matrix and computational issues in the output layer. This paper introduces PIXEL, the Pixel-based Encoder of Language, which suffers from neither of these issues. PIXEL is a pretrained language model that renders text as images, making it possible to transfer representations across languages based on orthographic similarity or the co-activation of pixels. PIXEL is trained to reconstruct the pixels of masked patches instead of predicting a distribution over tokens. We pretrain the 86M parameter PIXEL model on the same English data as BERT and evaluate on syntactic and semantic tasks in typologically diverse languages, including various non-Latin scripts. We find that PIXEL substantially outperforms BERT on syntactic and semantic processing tasks on scripts that are not found in the pretraining data, but PIXEL is slightly weaker than BERT when working with Latin scripts. Furthermore, we find that PIXEL is more robust than BERT to orthographic attacks and linguistic code-switching, further confirming the benefits of modelling language with pixels.

Sinkhorn Discrepancy for Counterfactual Generalization
Hao Wang,Quanyu Dai,Jiajun Fan,Weiming Liu,Zhichao Chen,Tianqiao Liu,Yichao Wang,Zhenhua Dong,Ruiming Tang

Estimating individual treatment effects from observational data is very challenging due to the existence of treatment selection bias.

Most existing representation-based methods mitigate this issue by aligning distributions of different treatment groups in the representation space. However, they still suffer from two critical problems: (1) Mini-batch Sampling Effects (MSE), where the alignment easily fails due to the outcome imbalance or outliers in the batch; (2) Unobserved Confounder Effects (UCE), where the unobserved confounders damage the correct alignment. To tackle these problems, we propose a principled approach named Entire Space CounterFactual Regression (ESCFR) based on a generalized sinkhorn discrepancy for distribution alignment within the stochastic optimal transport framework. Based on the framework, we propose a relaxed mass preserving regularizer to address the MSE issue and design a proximal factual outcome regularizer to handle the UCE issue. Extensive experiments demonstrate that our proposed ESCFR can successfully tackle the treatment selection bias and achieve significantly better performance than state-of-the-art methods.

Massively Scaling Heteroscedastic Classifiers
Mark Collier,Rodolphe Jenatton,Basil Mustafa,Neil Houlsby,Jesse Berent,Effrosyni Kokiopoulou

Heteroscedastic classifiers, which learn a multivariate Gaussian distribution over prediction logits, have been shown to perform well on image classification problems with hundreds to thousands of classes. However, compared to standard classifiers, they introduce extra parameters that scale linearly with the number of classes. This makes them infeasible to apply to larger-scale problems. In addition heteroscedastic classifiers introduce a critical temperature hyperparameter which must be tuned. We propose HET-XL, a heteroscedastic classifier whose parameter count when compared to a standard classifier scales independently of the number of classes. In our large-scale settings, we show that we can remove the need to tune the temperature hyperparameter, by directly learning it on the training data. On large image classification datasets with up to 4B images and 30k classes our method requires 14X fewer additional parameters, does not require tuning the temperature on a held-out set and performs consistently better than the baseline heteroscedastic classifier. HET-XL improves ImageNet 0-shot classification in a multimodal contrastive learning setup which can be viewed as a 3.5 billion class classification problem.

Vera Verto: Multimodal Hijacking Attack
Minxing Zhang,Ahmed Salem,Michael Backes,Yang Zhang

The increasing cost of training machine learning (ML) models has led to the incl

usion of new parties to the training pipeline, such as users who contribute training data and companies that provide computing resources. This involvement of such new parties in the ML training process has introduced new attack surfaces for an adversary to exploit. A recent attack in this domain is the model hijacking attack, whereby an adversary hijacks a victim model to implement their own -- possibly malicious -- hijacking tasks. However, the scope of the model hijacking attack is so far limited to computer vision-related tasks. In this paper, we transform the model hijacking attack into a more general multimodal setting, where the hijacking and original tasks are performed on data of different modalities. Specifically, we focus on the setting where an adversary implements a natural language processing (NLP) hijacking task into an image classification model. To mount the attack, we propose a novel encoder-decoder based framework, namely the Blender, which relies on advanced image and language models. Experimental results show that our modal hijacking attack achieves strong performances in different settings. For instance, our attack achieves 94%, 94%, and 95% attack success rate when using the Sogou news dataset to hijack STL10, CIFAR-10, and MNIST classifiers.

Joint Attention-Driven Domain Fusion and Noise-Tolerant Learning for Multi-Source Domain Adaptation

Tong Xu,Lin Wang,Wu Ning,Chunyan Lyu,Kejun Wang

Multi-source Unsupervised Domain Adaptation (MUDA) transfers knowledge from multiple source domains with labeled data to an unlabeled target domain.

Recently, endeavours have been made in establishing connections among different domains to enable feature interaction. However, these approaches essentially enhance category information and thus lack the transfer of the domain-specific information. Moreover, few research has explored the connection between pseudo-label generation and the framework’s learning capabilities, crucial for ensuring robust MUDA. In this paper, we propose a novel framework, which significantly reduces the domain discrepancy and demonstrates new state-of-the-art performance. In particular, we first propose a Contrary Attention-based Domain Merge (CADM) module to enable the interaction among the features so as to achieve the mixture of domain-specific information instead of focusing on the category information. Secondly, to enable the network to correct the pseudo labels during training, we propose an adaptive and reverse cross-entropy loss, which can adaptively impose constraints on the pseudo-label generation process. We conduct experiments on four benchmark datasets, showing that our approach can efficiently fuse all domains for MUDA while showing much better performance than the prior methods.

EA-HAS-Bench: Energy-aware Hyperparameter and Architecture Search Benchmark

Shuguang Dou,XINYANG JIANG,Cai Rong Zhao,Dongsheng Li

The energy consumption for training deep learning models is increasing at an alarming rate due to the growth of training data and model scale, resulting in a negative impact on carbon neutrality. Energy consumption is an especially pressing issue for AutoML algorithms because it usually requires repeatedly training large numbers of computationally intensive deep models to search for optimal configurations. This paper takes one of the most essential steps in developing energy-aware (EA) NAS methods, by providing a benchmark that makes EA-NAS research more reproducible and accessible. Specifically, we present the first large-scale energy-aware benchmark that allows studying AutoML methods to achieve better trade-offs between performance and search energy consumption, named EA-HAS-Bench. EA-HAS-Bench provides a large-scale architecture/hyperparameter joint search space, covering diversified configurations related to energy consumption. Furthermore, we propose a novel surrogate model specially designed for large joint search space, which proposes a Bezier curve-based model to predict learning curves with unlimited shape and length. Based on the proposed dataset, we new energy-aware AutoML method that arms existing AutoML algorithms to consider the search energy consumption, and our experiments show that the modified energy-aware AutoML methods achieve a better trade-off between energy consumption and model performance.

Breaking the Curse of Dimensionality for Parametric Elliptic PDEs
Marius Zeinhofer,Alex Kaltenbach

Motivated by recent empirical success, we examine how neural network-based ansatz classes can break the curse of dimensionality for high-dimensional, non-linear elliptic partial differential equations (PDEs) with variational structure. The high-dimensionality of the PDEs can either be induced through a high-dimensional physical domain or a high-dimensional parameter space. The latter include parametric right-hand sides, parametric domains, and material constants. Our main result shows that any scheme, that computes neural network based $W^{1,p}$-approximations, leverages the extraordinary approximation capabilities of neural networks and, thus, is able to beat the curse of dimensionality if the ground truth solution is smooth or possesses Barron regularity. Popular examples of $W^{1,p}$-convergent schemes include, e.g., the Deep Ritz Method and physics-informed neural networks. We present numerical experiments supporting our theoretical findings.

UniFormerV2: Spatiotemporal Learning by Arming Image ViTs with Video UniFormer
Kunchang Li,Yali Wang,Yinan He,Yizhuo Li,Yi Wang,Limin Wang,Yu Qiao

Learning discriminative spatiotemporal representation is the key problem of video understanding. Recently, Vision Transformers (ViTs) have shown their power in learning long-term video dependency with self-attention. Unfortunately, they exhibit limitations in tackling local video redundancy, due to the blind global comparison among tokens. UniFormer has successfully alleviated this issue, by unifying convolution and self-attention as a relation aggregator in the transformer format. However, this model has to require a tiresome and complicated image-pretraining phrase, before being finetuned on videos. This blocks its wide usage in practice. On the contrary, open-sourced ViTs are readily available and well-pretrained with rich image supervision. Based on these observations, we propose a generic paradigm to build a powerful family of video networks, by arming the pretrained ViTs with efficient UniFormer designs. We call this family UniFormerV2, since it inherits the concise style of the UniFormer block. But it contains brand-new local and global relation aggregators, which allow for preferable accuracy-computation balance by seamlessly integrating advantages from both ViTs and UniFormer. Without any bells and whistles, our UniFormerV2 gets the state-of-the-art recognition performance on 8 popular video benchmarks, including scene-related Kinetics-400/600/700 and Moments in Time, temporal-related Something-Something V1/V2, untrimmed ActivityNet and HACS. In particular, it is the first model to achieve 90% top-1 accuracy on Kinetics-400, to our best knowledge. The models will be released afterward.

Dynamical Equations With Bottom-up Self-Organizing Properties Learn Accurate Dynamical Hierarchies Without Any Loss Function
Danilo Vasconcellos Vargas,Tham Yik Foong,Heng Zhang

Self-organization is ubiquitous in nature and mind. However, machine learning and theories of cognition still barely touch the subject. The hurdle is that general patterns are difficult to define in terms of dynamical equations and designing a system that could learn by reordering itself is still to be seen. Here, we propose a learning system, where patterns are defined within the realm of nonlinear dynamics with positive and negative feedback loops, allowing attractor-repeller pairs to emerge for each pattern observed. Experiments reveal that such a system can map temporal to spatial correlation, enabling hierarchical structures to be learned from sequential data. The results are accurate enough to surpass state-of-the-art unsupervised learning algorithms in seven out of eight experiments as well as two real-world problems. Interestingly, the dynamic nature of the system makes it inherently adaptive, giving rise to phenomena similar to phase transitions in chemistry/thermodynamics when the input structure changes. Thus, the work here sheds light on how self-organization can allow for pattern recognition and hints at how intelligent behavior might emerge from simple dynamic equations without an objective/loss function.

Multi-Label Knowledge Distillation

Peng-Hui Yang,Ming-Kun Xie,Chen-Chen Zong,Lei Feng,Gang Niu,Masashi Sugiyama,Sheng-Jun Huang

Existing knowledge distillation methods typically work by enforcing the consistency of output logits or intermediate feature maps between the teacher network and student network. Unfortunately, these methods can hardly be extended to the multi-label learning scenario. Because each instance is associated with multiple semantic labels, neither the prediction logits nor the feature maps obtained from the whole example can accurately transfer knowledge for each label. In this paper, we propose a novel multi-label knowledge distillation method. On one hand, it exploits the informative semantic knowledge from the logits by label decoupling with the one-versus-all reduction strategy; on the other hand, it enhances the distinctiveness of the learned feature representations by leveraging the structural information of label-wise embeddings. Experimental results on multiple benchmark datasets validate that the proposed method can avoid knowledge counteraction among labels, and achieve superior performance against diverse comparing methods.

ADVERSARY-AWARE PARTIAL LABEL LEARNING WITH LABEL DISTILLATION

Cheng Chen,Yueming Lyu,Ivor Tsang

To ensure that the data collected from human subjects is entrusted with a secret, rival labels are introduced to conceal the information provided by the participants on purpose. The corresponding learning task can be formulated as a noisy partial-label learning problem. However, conventional partial-label learning (PLL) methods are still vulnerable to the high ratio of noisy partial labels, especially in a large labelling space. To learn a more robust model, we present Adversary-Aware Partial Label Learning and introduce the $\textit{rival}$, a set of noisy labels, to the collection of candidate labels for each instance. By introducing the rival label, the predictive distribution of PLL is factorised such that a reasonably good predictive label is achieved with less uncertainty coming from the transition matrix, assuming its generation process is known. Nonetheless, the predictive accuracy is still insufficient to produce an adequately good set of positive samples to minimise the loss function. Moreover, the inclusion of rivals also brings an inconsistency issue for the classifier and risk function due to the intractability of the transition matrix. Consequently, the immature teacher within momentum (ITWM) disambiguation algorithm is proposed to cope with the situation. We utilise the confidence score mapping from the instance space to approximate the intractable term, allowing us to obtain a provably consistent classifier and risk function. Extensive experiments demonstrate that our method achieves promising results on the CIFAR10, CIFAR100 and CUB200 datasets.

Structural Privacy in Graphs

Rucha Bhalchandra Joshi,Subhankar Mishra

Graph Neural Networks (GNNs) gained popularity to address the tasks over the graph-structured data that best represent many real-world systems. The privacy of the participants of these systems is at risk if the GNNs are not carefully designed. Existing works in privacy-preserving GNNs primarily ensure the privacy of features and labels of a node. In order to ensure complete privacy related to graph data, its structure also needs to be privatized. We provide a method SPGraph to privatize the graph structure by adding noise to the neighborhood data of the node. Our method addresses two challenges in introducing structural privacy in graphs. Applying randomization on the set of actual neighbors to introduce noise leads to a reduction in the degree of a node, which is undesirable. To overcome this first challenge, we introduce λ-selector that samples nodes to be added to the set of neighbors. The second challenge is to denoise the neighborhood so that the noise added in the neighborhood does not significantly impact the accuracy. In this view, we use p-hop neighborhood to compensate for the loss of actual neighbors in the randomization. We continue to use the node and label privacy as implemented in the previous methods for privacy in GNNs. We conduct extensive experiments over real-world datasets to show the impact of perturbation in the graph structure.

KnowDA: All-in-One Knowledge Mixture Model for Data Augmentation in Low-Resource NLP

Yufei Wang,Jiayi Zheng,Can Xu,Xiubo Geng,Tao Shen,Chongyang Tao,Daxin Jiang

This paper focuses on data augmentation for low-resource NLP tasks where the training set is limited. The existing solutions either leverage task-independent heuristic rules (e.g., Synonym Replacement) or fine-tune general-purpose pre-trained language models (e.g., GPT2) using the limited training instances to produce new synthetic data. Consequently, they have trivial task-specific knowledge and are limited to yielding low-quality synthetic data. To combat this issue, we propose Knowledge Mixture Data Augmentation Model (KnowDA), a Seq2Seq language model pretrained on a mixture of diverse NLP tasks under a novel framework of Knowledge Mixture Training (KoMT). The goal of KoMT is to condense diverse NLP task-specific knowledge into the single KnowDA model (i.e., all-in-one). The resulting KnowDA could utilize these knowledge to quickly grasp the inherent synthesis law of the target task through limited training instances. Specifically, KoMT reformulates input examples from various heterogeneous NLP tasks into a unified text-to-text format and employs denoising training objectives in different granularity to learn to reconstruct partial or complete samples. To the best of our knowledge, we are the first to attempt to apply 100+ NLP multi-task training for data augmentation. Extensive experiments show that i) the synthetic data produced by KnowDA successfully improves the performance of the strong pre-trained language models (i.e., Bert, ALBert and Deberta) by a large margin on the low-resource NLP benchmark FewGLUE, CoNLL’03 and WikiAnn; ii) KnowDA successful transfer the task knowledge to NLP tasks whose types are seen and unseen in KoMT.

Learning Graph Neural Network Topologies

Avishkar Saha,Oscar Mendez Maldonado,Chris Russell,Richard Bowden

Graph convolutional networks (GCNs) enable end-to-end learning on graph structured data. However, many works begin by assuming a given graph structure. As the ideal graph structure is often unknown, this limits applicability. To address this, we present a novel end-to-end differentiable graph-generator which builds the graph topology on the fly. Our module can be readily integrated into existing pipelines involving graph convolution operations, replacing the predetermined or existing adjacency matrix with one that is learned, and optimised, as part of the general objective. As such it is applicable to any GCN. We show that integrating our module into both node classification and trajectory prediction pipelines improves accuracy across a range of datasets and backbones.

Finding the Global Semantic Representation in GAN through Fréchet Mean

Jaewoong Choi,Geonho Hwang,Hyunsoo Cho,Myungjoo Kang

The ideally disentangled latent space in GAN involves the global representation of latent space using semantic attribute coordinates. In other words, in this disentangled space, there exists the global semantic basis as a vector space where each basis component describes one attribute of generated images. In this paper, we propose an unsupervised method for finding this global semantic basis in the intermediate latent space in GANs. This semantic basis represents sample-independent meaningful perturbations that change the same semantic attribute of an image on the entire latent space. The proposed global basis, called Fréchet basis, is derived by introducing Fréchet mean to the local semantic perturbations in a latent space. Fréchet basis is discovered in two stages. First, the global semantic subspace is discovered by the Fréchet mean in the Grassmannian manifold of the local semantic subspaces. Second, Fréchet basis is found by optimizing a basis of the semantic subspace via the Fréchet mean in the Special Orthogonal Group. Experimental results demonstrate that Fréchet basis provides better semantic factorization and robustness compared to the previous methods. Moreover, we suggest the basis refinement scheme for the previous methods. The quantitative experiments show that the refined basis achieves better semantic factorization while constrained on the same semantic subspace given by the previous method.

****

Identical Initialization: A Universal Approach to Fast and Stable Training of Neural Networks

Yu Pan,Zekai Wu,Chaozheng Wang,Qifan Wang,Min Zhang,Zenglin Xu

A well-conditioned initialization is beneficial for training deep neural networks. However, existing initialization approaches do not simultaneously show robustness and universality. Specifically, even though the widely-used Xavier and Kaiming initialization approaches can generally fit a variety of networks, they fail to train residual networks without Batch Normalization for calculating an inappropriate scale on data-flow. On the other hand, some literature design stable initialization (e.g., Fixup and ReZero) based on dynamical isometry, an efficient learning mechanism. Nonetheless, these methods are specifically designed for either a non-residual structure or a residual block only, and even include extra auxiliary components, limiting their applicable range. Intriguingly, we find that the identity matrix is a feasible and universal solution to the aforementioned problems, as it adheres to dynamical isometry while remaining applicable to a wide range of models. Motivated by this, we develop Identical Initialization (IDInit), a sufficiently robust, universal, and fast-converging approach on the identity matrix. Empirical results on a variety of benchmarks show that IDInit is universal to various network types, and practically useful with good performance and fast convergence.

****

Addressing Parameter Choice Issues in Unsupervised Domain Adaptation by Aggregation

Marius-Constantin Dinu,Markus Holzleitner,Maximilian Beck,Hoan Duc Nguyen,Andrea Huber,Hamid Eghbal-zadeh,Bernhard A. Moser,Sergei Pereverzyev,Sepp Hochreiter,Werner Zellinger

We study the problem of choosing algorithm hyper-parameters in unsupervised domain adaptation, i.e., with labeled data in a source domain and unlabeled data in a target domain, drawn from a different input distribution. We follow the strategy to compute several models using different hyper-parameters, and, to subsequently compute a linear aggregation of the models. While several heuristics exist that follow this strategy, methods are still missing that rely on thorough theories for bounding the target error. In this turn, we propose a method that extends weighted least squares to vector-valued functions, e.g., deep neural networks. We show that the target error of the proposed algorithm is asymptotically not worse than twice the error of the unknown optimal aggregation. We also perform a large scale empirical comparative study on several datasets, including text, images, electroencephalogram, body sensor signals and signals from mobile phones. Our method outperforms deep embedded validation (DEV) and importance weighted validation (IWV) on all datasets, setting a new state-of-the-art performance for solving parameter choice issues in unsupervised domain adaptation with theoretical error guarantees. We further study several competitive heuristics, all outperforming IWV and DEV on at least five datasets. However, our method outperforms each heuristic on at least five of seven datasets.

****

MARS: Meta-learning as Score Matching in the Function Space

Krunoslav Lehman Pavasovic,Jonas Rothfuss,Andreas Krause

Meta-learning aims to extract useful inductive biases from a set of related datasets. In Bayesian meta-learning, this is typically achieved by constructing a prior distribution over neural network parameters. However, specifying families of computationally viable prior distributions over the high-dimensional neural network parameters is difficult. As a result, existing approaches resort to meta-learning restrictive diagonal Gaussian priors, severely limiting their expressiveness and performance. To circumvent these issues, we approach meta-learning through the lens of functional Bayesian neural network inference which views the prior as a stochastic process and performs inference in the function space. Specifically, we view the meta-training tasks as samples from the data-generating process and formalize meta-learning as empirically estimating the law of this stochastic process. Our approach can seamlessly acquire and represent complex prior know ledge by meta-learning the score function of the data-generating process marginals instead of parameter space priors. In a comprehensive benchmark, we demonstrate that our method achieves state-of-the-art performance in terms of predictive accuracy and substantial improvements in the quality of uncertainty estimates.

****

Faster Gradient-Free Methods for Escaping Saddle Points

Hualin Zhang,Bin Gu

Escaping from saddle points has become an important research topic in non-convex optimization. In this paper, we study the case when calculations of explicit gradients are expensive or even infeasible, and only function values are accessible.

Currently, there have two types of gradient-free (zeroth-order) methods based on random perturbation and negative curvature finding proposed to escape saddle points efficiently and converge to an ϵ-approximate second-order stationary point.

Nesterov's accelerated gradient descent (AGD) method can escape saddle points faster than gradient descent (GD) which have been verified in first-order algorithms. However, whether AGD could accelerate the gradient-free methods is still unstudied. To unfold this mystery, in this paper, we propose two accelerated variants for the two types of gradient-free methods of escaping saddle points. We show that our algorithms can find an ϵ-approximate second-order stationary point with $\tilde{\mathcal{O}}(1/\epsilon^{1.75})$ iteration complexity and $\tilde{\mathcal{O}}(d/\epsilon^{1.75})$ oracle complexity, where d is the problem dimension. Thus, our methods achieve a comparable convergence rate to their first-order counterparts and have fewer oracle complexity compared to prior derivative-free methods for finding second-order stationary points.

****

Symmetrical SyncMap for Imbalanced General Chunking Problems

Heng Zhang,Danilo Vasconcellos Vargas

Recently, SyncMap (2021) pioneered an approach to learn complex structures from sequences as well as adapt to any changes in underlying structures. Such approach, inspired by neuron group behaviors, is achieved by using self-organizing dynamical equations without any loss functions. Here we propose Symmetrical SyncMap that goes beyond the original work to show how to create dynamical equations and attractor-repeller points which are stable over the long run, even dealing with imbalanced continual general chunking problems (CGCPs). The main idea is to apply equal updates from positive and negative feedback loops by symmetrical activation. We then introduce the concept of memory window to allow for more positive updates. Our algorithm surpasses or ties other unsupervised state-of-the-art baselines in all 12 imbalanced CGCPs with various difficulties, including dynamical ones. To verify its performance in real-world scenarios, we conduct experiments on several well-studied structure learning problems. The proposed method surpasses substantially other methods in all scenarios, suggesting that symmetrical activation plays a critical role in uncovering topological structures and even hierarchies encoded in temporal data.

Solving Partial Label Learning Problem with Multi-Agent Reinforcement Learning

Xinyi Zhang,Xingdong Feng,Fan Zhou

Partial label learning (PLL) deals with classifications when a set of candidate labels instead of the true one is given for each training instance. As a weakly supervised learning problem, the main target of PLL is to discover latent relationships within training samples, and utilize such information to disambiguate noisy labels. Many existing methods choose nearest neighbors of each partially-labeled instance in an unsupervised way such that the obtained instance similarities can be empirically non-optimal and unrelated to the downstream classification task. To address this issue, we propose a novel multi-agent reinforcement learning (MARL) framework which models the connection between each pair of training samples as a reinforcement learning (RL) agent. We use attention-based graph neural network (GNN) to learn the instance similarity, and adaptively refine it using a deterministic policy gradient approach until some pre-defined scoring functio n is optimized. Different from those two-stage and alternative optimization algorithms whose training procedures are not end-to-end, our RL-based approach directly optimizes the objective function and estimates the instance similarities more precisely. The experimental results show that our method outperforms state-of-the-art competitors with a higher classification accuracy in both synthetic and real examples.

Uncovering the Effectiveness of Calibration on Open Intent Classification

Hyejin Won,Kyung Ho Park

Open intent classification aims to simultaneously identify known and unknown intents, and it is one of the challenging tasks in modern dialogue systems. While prior approaches are based on known intent classifiers trained under the cross-entropy loss, we presume this loss function yields a representation overly biased to the known intents; thus, it negatively impacts identifying unknown intents. In this study, we propose a novel open intent classification approach that utilizes model calibration into the previously-proposed state-of-the-art. We empirically examine that simply changing a learning objective in a more calibrated manner outperforms the past state-of-the-art. We further excavate that the underlying reason behind calibrated classifier's supremacy derives from the high-level layers of the deep neural networks. We also discover that our approach is robust to harsh settings where few training samples per class exist. Consequentially, we expect our findings and takeaways to exhibit practical guidelines of open intent classification, thus helping to inform future model design choices.

****

PMixUp: Simultaneous Utilization of Part-of-Speech Replacement and Feature Space Interpolation for Text Data Augmentation

Hyeon Soo Kim,Hyejin Won,Kyung Ho Park

Data augmentation has become a de facto technique in various NLP tasks to overcome the lack of a large-scale, qualified training set. The previous studies presented several data augmentation methods, such as replacing tokens with synonyms or interpolating feature space of given text input. While they are known to be convenient and promising, several limits exist. First, prior studies simply treated topic classification and sentiment analysis under the same category of text classification while we presume they have distinct characteristics. Second, previously-proposed replacement-based methods bear several improvement avenues as they utilize heuristics or statistical approaches for choosing synonyms. Lastly, while the feature space interpolation method achieved current state-of-the-art, prior studies have not comprehensively utilized it with replacement-based methods. To mitigate these drawbacks, we first analyzed which POS tags are important in each text classification task, and resulted that nouns are essential to topic classification, while sentiment analysis regards verbs and adjectives as important POS information. Contrary to the aforementioned analysis, we discover that augmenting verbs and adjective tokens commonly improves text classification performance regardless of its type. Lastly, we propose PMixUp, a novel data augmentation strategy that simultaneously utilizes replacement-based and feature space interpolation methods. We examine that they are new state-of-the-art in nine public benchmark settings, especially under the few training samples.

****

SDT: Specific Domain Training in Domain Generalization

Saeed Karimi,Hamdi Dibeklioglu

Domain generalization (DG) methods aim to achieve generalizability to an unseen target domain by using only training data from the source domains. Although there has been a growing interest to learn from multiple training domains by applying different types of invariance across those domains, the improvements compared to empirical risk minimization (ERM) are almost negligible under controlled evaluation protocols. In this paper, we demonstrate that the disentanglement of spurious and invariant features is a tough task in standard training, since ERM simply minimize the loss and does not exploit invariance among domains. To address the issue, we introduce a simple yet effective method called specific domain training (SDT), which intensifies the trace of spurious features and make them more

discernible and exploit masking strategy to decrease their effect. We provide a theoretical and experimental evidence to show the effectiveness of SDT for out-of-distribution generalization. Notably, SDT outperforms previous state of the art \citet{cha2021swad} in DomainNet benchmarks 0.2pp in average. Furthermore, SDT improves accuracy of some domains such as Sketch in PACS, SUN09 in VLCS and L100 in TerraIncognita by clear margins 2.5pp, 3.4pp, and 5.4pp respectively.

Lossy Compression with Gaussian Diffusion
Lucas Theis,Tim Salimans,Matthew Douglas Hoffman,Fabian Mentzer

We consider a novel lossy compression approach based on unconditional diffusion generative models, which we call DiffC. Unlike modern compression schemes which rely on transform coding and quantization to restrict the transmitted information, DiffC relies on the efficient communication of pixels corrupted by Gaussian noise. We implement a proof of concept and find that it works surprisingly well despite the lack of an encoder transform, outperforming the state-of-the-art generative compression method HiFiC on ImageNet 64x64. DiffC only uses a single model to encode and denoise corrupted pixels at arbitrary bitrates. The approach further provides support for progressive coding, that is, decoding from partial bit streams. We perform a rate-distortion analysis to gain a deeper understanding of its performance, providing analytical results for multivariate Gaussian data as well as theoretic bounds for general distributions. Furthermore, we prove that a flow-based reconstruction achieves a 3 dB gain over ancestral sampling at high bitrates.

Score-Based Graph Generative Modeling with Self-Guided Latent Diffusion
Ling Yang,Zhilong Zhang,Wentao Zhang,Shenda Hong

Graph generation is a fundamental task in machine learning, and it is critical for numerous real-world applications, biomedical discovery and social science. Existing diffusion-based graph generation methods have two limitations: (i) they conduct diffusion process directly in complex graph space (i.e., node feature, adjacency matrix, or both), resulting in hard optimization with network evaluations; (ii) they usually neglect to sufficiently cover the whole distribution of target unlabeled graph set and thus fail to make semantic controllable generation. In this paper, we first propose a unified latent-based graph generative framework, Score-Based Graph Generative Model (SGGM), powered by Self-Guided Latent Diffusion (SLD) to address both limitations. Specifically, we pretrain a variational graph autoencoder to map raw graph of high-dimensional discrete space to low-dimensional topology-injected latent space, and apply score-based generative model there, yielding a smoother, faster and more expressive graph generation procedure. To sufficiently cover the whole semantical distribution of unlabeled graph set, we propose SLD to make controllable self-guidance of the sample generation with gradients from the designed assigning function towards the hierarchical pseudo label, produced by iteratively clustering on the latent embeddings. In addition, we conduct periodic update on the pseudo label in training process to achieve mutual adaptation between self-guidance and score-based generation. Experiments show that our SGGM powered by SLD outperforms previous graph generation baselines on both generic and molecular graph datasets, demonstrating the generality and extensibility along with further theoretical proofs.

Gradient-Informed Quality Diversity for the Illumination of Discrete Spaces
Guillaume Richard,Raphael Boige,Jérémie DONA,Antoine Cully,Thomas PIERROT

Quality Diversity (QD) algorithms have been proposed to search for a large collection of both diverse and high-performing solutions instead of a single set of local optima. While early QD algorithms view the objective and descriptor functions as black-box functions, novel tools have been introduced to use gradient information to accelerate the search and improve overall performance of those algorithms over continuous input spaces. However a broad range of applications involve discrete spaces, such as drug discovery or image generation. Exploring those spaces is challenging as they are combinatorially large and gradients cannot be used in the same manner as in continuous spaces. We introduce MAP-Elites with a Gr adient-Informed Discrete Emitter (ME-GIDE), which extends QD optimisation with differentiable functions over discrete search spaces. ME-GIDE leverages the gradient information of the objective and descriptor functions with respect to its discrete inputs to propose gradient-informed updates that guide the search towards a diverse set of high quality solutions. We evaluate our method on challenging benchmarks including protein design and discrete latent space illumination and find that our method outperforms state-of-the-art QD algorithms in all benchmarks.

Deep Generative Wasserstein Gradient Flows
Alvin Heng,Abdul Fatir Ansari,Harold Soh

Deep generative modeling is a rapidly-advancing field with a wealth of modeling choices developed in the past decades. Amongst them, Wasserstein gradient flows (WGF) are a powerful and theoretically rich class of methods.

However, their applications to high-dimensional distributions remain relatively underexplored. In this paper, we present Deep Generative Wasserstein Gradient Flows (DGGF), which constructs a WGF between two distributions by minimizing the entropy-regularized f-divergence. We demonstrate how to train a deep density ratio estimator that is required for the WGF and apply it to the task of generative modeling. Experiments demonstrate that DGGF is able to synthesize high-fidelity images of resolutions up to 128×128, directly in data space. We demonstrate that DGGF has an interpretable diagnostic of sample quality by naturally estimating the KL divergence throughout the gradient flow. Finally, we show DGGF's modularity by composition with external density ratio estimators for conditional generation, as well as for unpaired image-to-image translation with no modifications to the framework.

Linear Scalarization for Byzantine-Robust Learning on non-IID data
Latifa Errami,El houcine Bergou

In this work we study the problem of Byzantine-robust learning when data among clients is heterogeneous. We focus on poisoning attacks targeting the convergence of SGD. Although this problem has received great attention; the main Byzantine defenses rely on the IID assumption causing them to fail when data distribution is non-IID even with no attack.

We propose the use of Linear Scalarization (LS) as an enhancing method to enable current defenses to circumvent Byzantine attacks in the non-IID setting. The LS method is based on the incorporation of a trade-off vector that penalizes the suspected malicious clients.

Empirical analysis corroborates that the proposed LS variants are viable in the IID setting. For mild to strong non-IID data splits, LS is either comparable or outperforming current approaches under state-of-the-art Byzantine attack scenarios.

Where to Go Next for Recommender Systems? ID- vs. Modality-based recommender models revisited
Zheng Yuan,Fajie Yuan,Yu Song,youhua Li,Fei Yang,Yunzhu Pan

Recommender models that utilize unique identities (IDs for short) to represent distinct users and items have been the state-of-the-arts and dominating the recommender system (RS) literature for over a decade. In parallel, the pre-trained modality encoders, such as BERT and ResNet, are becoming increasingly powerful in modeling raw modality features, e.g., text and images. In light of this, a natural question arises: whether the modality (a.k.a, content) only based recommender models (MoRec) can exceed or be on par with the ID-only based models (IDRec) when item modality features are available? In fact, this question had been answered once a decade ago, when IDRec beat MoRec with strong advantages in terms of both recommendation accuracy and efficiency.

We aim to revisit this `old' question and systematically study MoRec from several aspects. Specifically, we study several sub-questions: (i) which recommender paradigm, MoRec or IDRec, performs best in various practical scenarios, including regular, cold and new item scenarios? does this hold for items with different modality features? (ii) will MoRec benefit from the latest technical advances in corresponding communities, for example, natural language processing and computer vision? (iii) what is an effective way to leverage item modality representations, freezing them or adapting them by fine-tuning on new data? (iv) are there any other factors that affect the efficacy of MoRec. To answer these questions, we conduct rigorous experiments for item recommendations with two popular modalities, i.e., text and vision. We provide empirical evidence that MoRec with standard end-to-end training is highly competitive and even exceeds IDRec in some cases. Many of our observations imply that the dominance of IDRec in terms of recommendation accuracy does not hold well when items' raw modality features are available. We promise to release all related codes & datasets upon acceptance.

Optimising 2D Pose Representation: Improving Accuracy, Stability and Generalisability inUnsupervised 2D-3D Human Pose Estimation
Peter Timothy David Hardy,Srinandan Dasmahapatra,Hansung Kim
This paper addresses the problem of 2D pose representation during unsupervised 2D to 3D pose lifting to improve the accuracy, stability and generalisability of 3D human pose estimation (HPE) models. All unsupervised 2D-3D HPE approaches provide the entire 2D kinematic skeleton to a model during training. We argue that this is sub-optimal and disruptive as long-range correlations are induced between independent 2D key points and predicted 3D ordinates during training. To this end, we conduct the following study. With a maximum architecture capacity of 6 residual blocks, we evaluate the performance of 5 models which each represent a 2D pose differently during the adversarial unsupervised 2D-3D HPE process. Additionally, we show the correlations between 2D key points which are learned during the training process, highlighting the unintuitive correlations induced when an entire 2D pose is provided to a lifting model. Our results show that the most optimal representation of a 2D pose is that of two independent segments, the torso and legs, with no shared features between each lifting network. This approach decreased the average error by 20% on the Human3.6M dataset when compared to a model with a near identical parameter count trained on the entire 2D kinematic skeleton. Furthermore, due to the complex nature of adversarial learning, we show how this representation can also improve convergence during training allowing for an optimum result to be obtained more often.

Model Obfuscation for Securing Deployed Neural Networks
Mingyi Zhou,Xiang Gao,Jing Wu,John C. Grundy,Xiao Chen,Chunyang Chen,Li Li
More and more edge devices and mobile apps are leveraging deep learning (DL) capabilities. Deploying such models on devices -- referred to as on-device models -- rather than as remote cloud-hosted services, has gained popularity as it avoids transmitting user's data off of the device and for high response time. However, on-device models can be easily attacked, as they can be accessed by unpacking corresponding apps and the model is fully exposed to attackers. Recent studies show that adversaries can easily generate white-box-like attacks for an on-device model or even inverse its training data. To protect on-device models from white-box attacks, we propose a novel technique called model obfuscation. Specifically, model obfuscation hides and obfuscates the key information -- structure, parameters and attributes -- of models by renaming, parameter encapsulation, neural structure obfuscation, shortcut injection, and extra layer injection. We have developed a prototype tool ModelObfuscator to automatically obfuscate on-device TF Lite models. Our experiments show that this proposed approach can dramatically improve model security by significantly increasing the overhead of extracting models' inner information, without increasing the latency of DL models. Our proposed on-device model obfuscation has the potential to be a fundamental technique for on-device model deployment. Our prototype tool is publicly available at https://github.com/AnonymousAuthor000/Code2536.

ESP: Exponential Smoothing on Perturbations for Increasing Robustness to Data Corruptions

Weebum Yoo,Hwanjo Yu,Sung Whan Yoon

Despite the great advances in the machine learning field over the past decade, deep learning algorithms are often vulnerable to data corruption in real-world environments. We propose a simple yet efficient data augmentation method named Exponential Smoothing on Perturbations (ESP) that imposes perturbations on training data to enhance a model’s robustness to unforeseen data corruptions. With the perturbation on the input side, the target label of a sample is smoothed with an exponentially decaying confidence level with respect to the size of the perturbation. ESP enforces a contour-like decision boundary that smoothly encompasses the region around inter-class samples. We theoretically show that perturbations in input space can encourage a model to find a flat minimum on the parameter space, which makes a model robust to domain shifts. In the extensive evaluation on common corruption benchmarks including MNIST-C, CIFAR-10/100-C, and Tiny-ImageNet-C, our method improves the robustness of a model both as a standalone method and in conjunction with the previous state-of-the-art augmentation-based methods. ESP is a model-agnostic algorithm in the sense that it is neither model-specific nor data-specific.

MultiViz: Towards Visualizing and Understanding Multimodal Models

Paul Pu Liang,Yiwei Lyu,Gunjan Chhablani,Nihal Jain,Zihao Deng,Xingbo Wang,Louis-Philippe Morency,Ruslan Salakhutdinov

The promise of multimodal models for real-world applications has inspired research in visualizing and understanding their internal mechanics with the end goal of empowering stakeholders to visualize model behavior, perform model debugging, and promote trust in machine learning models. However, modern multimodal models are typically black-box neural networks, which makes it challenging to understand their internal mechanics. How can we visualize the internal modeling of multimodal interactions in these models? Our paper aims to fill this gap by proposing MultiViz, a method for analyzing the behavior of multimodal models by scaffolding the problem of interpretability into 4 stages: (1) unimodal importance: how each modality contributes towards downstream modeling and prediction, (2) cross-modal interactions: how different modalities relate with each other, (3) multimodal representations: how unimodal and cross-modal interactions are represented in decision-level features, and (4) multimodal prediction: how decision-level features are composed to make a prediction. MultiViz is designed to operate on diverse modalities, models, tasks, and research areas. Through experiments on 8 trained models across 6 real-world tasks, we show that the complementary stages in MultiViz together enable users to (1) simulate model predictions, (2) assign interpretable concepts to features, (3) perform error analysis on model misclassifications, and (4) use insights from error analysis to debug models. MultiViz is publicly available, will be regularly updated with new interpretation tools and metrics, and welcomes inputs from the community.

How Informative is the Approximation Error from Tensor Decomposition for Neural Network Compression?

Jetze Schuurmans,kim batselier,Julian Kooij

Tensor decompositions have been successfully applied to compress neural networks. The compression algorithms using tensor decompositions commonly minimize the approximation error on the weights. Recent work assumes the approximation error on the weights is a proxy for the performance of the model to compress multiple layers and fine-tune the compressed model. Surprisingly, little research has systematically evaluated which approximation errors can be used to make choices regarding the layer, tensor decomposition method, and level of compression. To close this gap, we perform an experimental study to test if this assumption holds across different layers and types of decompositions, and what the effect of fine-tuning is. We include the approximation error on the features resulting from a compressed layer in our analysis to test if this provides a better proxy, as it exp

licitly takes the data into account. We find the approximation error on the weights has a positive correlation with the performance error, before as well as after fine-tuning. Basing the approximation error on the features does not improve the correlation significantly. While scaling the approximation error commonly is used to account for the different sizes of layers, the average correlation across layers is smaller than across all choices (i.e. layers, decompositions, and level of compression) before fine-tuning. When calculating the correlation across the different decompositions, the average rank correlation is larger than across all choices. This means multiple decompositions can be considered for compression and the approximation error can be used to choose between them.

DISCO-DANCE: Learning to Discover Skills with Guidance
Hyunseung Kim,Byungkun Lee,Sejik Park,Hojoon Lee,Dongyoon Hwang,Kyushik Min,Jaegul Choo

Unsupervised skill discovery (USD) allows agents to learn diverse and discriminable skills without access to pre-defined rewards,
by maximizing the mutual information (MI) between skills and states reached by each skill.
The most common problem of MI-based skill discovery is insufficient exploration, because each skill is heavily penalized when it deviates from its initial settlement. Recent works introduced an auxiliary reward to encourage the exploration of the agent via maximizing the state's epistemic uncertainty or entropy.
However, we have discovered that the performance of these auxiliary rewards decreases as the environment becomes more challenging. Therefore, we introduce a new unsupervised skill discovery algorithm, skill discovery with guidance (DISCO-DANCE), which (1) selects the guide skill which has the highest potential to reach the unexplored states, (2) guide other skills to follow the guide skill, then (3) the guided skills are diffused to maximize their discriminability in the unexplored states. Empirically, DISCO-DANCE substantially outperforms other USD baselines on challenging environments including two navigation benchmarks and a continuous control benchmark.

Architecture-Agnostic Masked Image Modeling -- From ViT back to CNN
Siyuan Li,Di Wu,Fang Wu,Zelin Zang,Lei Shang,Baigui Sun,Xuansong Xie,Stan Z. Li

Masked image modeling (MIM), an emerging self-supervised pre-training method, has shown impressive success across numerous downstream vision tasks with Vision transformers (ViTs). Its underlying idea is simple: a portion of the input image is randomly masked out and then reconstructed via the pre-text task. However, the working principle behind MIM is not well explained, and previous studies insist that MIM primarily works for the Transformer family but is incompatible with CNNs. In this paper, we first study interactions among patches to understand what knowledge is learned and how it is acquired via the MIM task. We observe that MIM essentially teaches the model to learn better middle-order interactions among patches and extract more generalized features. Based on this fact, we propose an Architecture-Agnostic Masked Image Modeling framework (A^{2}MIM), which is compatible with both Transformers and CNNs in a unified way. Extensive experiments on popular benchmarks show that our A^{2}MIM learns better representations without explicit design and endows the backbone model with the stronger capability to transfer to various downstream tasks for both Transformers and CNNs.
****

Blurring Diffusion Models
Emiel Hoogeboom,Tim Salimans

Recently, Rissanen et al., (2022) have presented a new type of diffusion process for generative modeling based on heat dissipation, or blurring, as an alternative to isotropic Gaussian diffusion. Here, we show that blurring can equivalently be defined through a Gaussian diffusion process with non-isotropic noise. In making this connection, we bridge the gap between inverse heat dissipation and denoising diffusion, and we shed light on the inductive bias that results from this modeling choice. Finally, we propose a generalized class of diffusion models that offers the best of both standard Gaussian denoising diffusion and inverse hea t dissipation, which we call Blurring Diffusion Models.

BrGANs: Stabilizing GANs' Training Process with Brownian Motion Control

Tianjiao Luo,Ziyu Zhu,Gabriele Oliaro,Jun Zhu,Zhidong Deng

The training process of generative adversarial networks (GANs) is unstable and does not converge globally. In this paper, we propose a universal higher order noise based control called Brownian Motion Control (BMC) that is invariant to GANs frameworks so that the training process of GANs is exponential stable almost surely. Specifically, starting with the prototypical case of Dirac-GANs, we design a BMC and propose Dirac-BrGANs that retrieve exactly the same but reachable optimal equilibrium regardless of GANs' framework. The optimal equilibrium of our Dirac-BrGANs' training system is globally unique and always exists. Furthermore, the training process of Dirac-BrGANs achieve exponentially stability almost surely for any arbitrary initial value. Then we extend our BMC to normal GANs' settings and propose BrGANs. We provide numerical experiments showing that our BrGANs effectively stabilizes GANs's training process and obtains state-of-the art performance compared to other stabilizing methods.

Hyperbolic Self-paced Learning for Self-supervised Skeleton-based Action Representations

Luca Franco,Paolo Mandica,Bharti Munjal,Fabio Galasso

Self-paced learning has been beneficial for tasks where some initial knowledge is available, such as weakly supervised learning and domain adaptation, to select and order the training sample sequence, from easy to complex. However its applicability remains unexplored in unsupervised learning, whereby the knowledge of the task matures during training.

We propose a novel HYperbolic Self-Paced model (HYSP) for learning skeletonbased action representations. HYSP adopts self-supervision: it uses data augmentations to generate two views of the same sample, and it learns by matching one (named online) to the other (the target). We propose to use hyperbolic uncertainty to determine the algorithmic learning pace, under the assumption that less uncertain samples should be more strongly driving the training, with a larger weight and pace. Hyperbolic uncertainty is a by-product of the adopted hyperbolic neural networks, it matures during training and it comes with no extra cost, compared to the established Euclidean SSL framework counterparts.

When tested on three established skeleton-based action recognition datasets, HYSP outperforms the state-of-the-art on PKU-MMD I, as well as on 2 out of 3 downstream tasks on NTU-60 and NTU-120. Additionally, HYSP only uses positive pairs and bypasses therefore the complex and computationally-demanding mining procedures required for the negatives in contrastive techniques.

Code is available at https://github.com/paolomandica/HYSP.

Unfair geometries: exactly solvable data model with fairness implications

Stefano Sarao Mannelli,Federica Gerace,Negar Rostamzadeh,Luca Saglietti

Machine learning (ML) may be oblivious to human bias but it is not immune to its perpetuation. Marginalisation and iniquitous group representation are often traceable in the very data used for training, and may be reflected or even enhanced by the learning models.

In the present work, we aim at clarifying the role played by data geometry in the emergence of ML bias. We introduce an exactly solvable high-dimensional model of data imbalance, where parametric control over the many bias-inducing factors allows for an extensive exploration of the bias inheritance mechanism.Through the tools of statistical physics, we analytically characterise the typical properties of learning models trained in this synthetic framework and obtain exact predictions for the observables that are commonly employed for fairness assessment.

Despite the simplicity of the data model, we retrace and unpack typical unfairness behaviour observed on real-world datasets.

We also obtain a detailed analytical characterisation of a class of bias mitigation strategies. We first consider a basic loss-reweighing scheme, which allows for an implicit minimisation of different unfairness metrics, and quantify the in compatibilities between some existing fairness criteria. Then, we consider a novel mitigation strategy based on a matched inference approach, consisting in the introduction of coupled learning models. Our theoretical analysis of this approach shows that the coupled strategy can strike superior fairness-accuracy trade-offs.

Understanding Adversarial Transferability in Federated Learning

Yijiang Li,ying gao,Dawn Song,Haohan Wang

With the promises Federated Learning (FL) delivers, various topics regarding its robustness and security issues have been widely studied in recent years: such as the possibility to conduct adversarial attacks (or transferable adversarial attacks) in a while-box setting with full knowledge of the model (or the entire data), or the possibility to conduct poisoning/backdoor attacks during the training process as a malicious client. In this paper, we investigate the robustness and security issues from a different, simpler, but practical setting: a group of malicious clients has impacted the model during training by disguising their identities and acting as benign clients, and only revealing their adversary position after the training to conduct transferable adversarial attacks with their data, which is usually a subset of the data that FL system is trained with. Our aim is to offer a full understanding of the challenges the FL system faces in this setting across a spectrum of configurations. We notice that such an attack is possible, but the federated model is more robust compared with its centralized counterpart when the accuracy on clean images is comparable. Through our study, we hypothesized the robustness is from two factors: the decentralized training on distributed data and the averaging operation. Our work has implications for understanding the robustness of federated learning systems and poses a practical question for federated learning applications.

Efficient Offline Policy Optimization with a Learned Model

Zichen Liu,Siyi Li,Wee Sun Lee,Shuicheng YAN,Zhongwen Xu

MuZero Unplugged presents a promising approach for offline policy learning from logged data. It conducts Monte-Carlo Tree Search (MCTS) with a learned model and leverages Reanalyze algorithm to learn purely from offline data. For good performance, MCTS requires accurate learned models and a large number of simulations, thus costing huge computing time. This paper investigates a few hypotheses where MuZero Unplugged may not work well under the offline RL settings, including 1) learning with limited data coverage; 2) learning from offline data of stochastic environments; 3) improperly parameterized models given the offline data; 4) with a low compute budget. We propose to use a regularized one-step look-ahead approach to tackle the above issues. Instead of planning with the expensive MCTS, we use the learned model to construct an advantage estimation based on a one-step rollout. Policy improvements are towards the direction that maximizes the estimated advantage with regularization of the dataset. We conduct extensive empirical studies with BSuite environments to verify the hypotheses and then run our algorithm on the RL Unplugged Atari benchmark. Experimental results show that our proposed approach achieves stable performance even with an inaccurate learned model. On the large-scale Atari benchmark, the proposed method outperforms MuZero Unplugged by 43%. Most significantly, it uses only 5.6% wall-clock time (i.e., 1 hour) compared to MuZero Unplugged (i.e., 17.8 hours) to achieve a 150% IQM normalized score with the same hardware and software stacks. Our implementation is open-sourced at https://github.com/sail-sg/rosmo.

New Insights for the Stability-Plasticity Dilemma in Online Continual Learning

Dahuin Jung,Dongjin Lee,Sunwon Hong,Hyemi Jang,Ho Bae,Sungroh Yoon

The aim of continual learning is to learn new tasks continuously (i.e., plasticity) without forgetting previously learned knowledge from old tasks (i.e., stability). In the scenario of online continual learning, wherein data comes strictly in a streaming manner, the plasticity of online continual learning is more vulnerable than offline continual learning because the training signal that can be obtained from a single data point is limited. To overcome the stability-plasticity dilemma in online continual learning, we propose an online continual learning framework named multi-scale feature adaptation network (MuFAN) that utilizes a richer context encoding extracted from different levels of a pre-trained network. Additionally, we introduce a novel structure-wise distillation loss and replace the commonly used batch normalization layer with a newly proposed stability-plasticity normalization module to train MuFAN that simultaneously maintains high plasticity and stability. MuFAN outperforms other state-of-the-art continual learning methods on the SVHN, CIFAR100, miniImageNet, and CORe50 datasets. Extensive experiments and ablation studies validate the significance and scalability of each proposed component: 1) multi-scale feature maps from a pre-trained encoder, 2) the structure-wise distillation loss, and 3) the stability-plasticity normalization module in MuFAN. Code is publicly available at https://github.com/whitesnowdrop/MuFAN.

MixPro: Data Augmentation with MaskMix and Progressive Attention Labeling for Vision Transformer

Qihao Zhao,Yangyu Huang,Wei Hu,Fan Zhang,Jun Liu

The recently proposed data augmentation TransMix employs attention labels to help visual transformers (ViT) achieve better robustness and performance. However, TransMix is deficient in two aspects: 1) The image cropping method of TransMix may not be suitable for vision transformer. 2) At the early stage of training, the model produces unreliable attention maps. TransMix uses unreliable attention maps to compute mixed attention labels that can affect the model. To address the aforementioned issues, we propose MaskMix and Progressive Attention Labeling (PAL) in image and label space, respectively. In detail, from the perspective of image space, we design MaskMix, which mixes two images based on a patch-like grid mask. In particular, the size of each mask patch is adjustable and is a multiple of the image patch size, which ensures each image patch comes from only one image and contains more global contents. From the perspective of label space, we design PAL, which utilizes a progressive factor to dynamically re-weight the attention weights of the mixed attention label. Finally, we combine MaskMix and Progressive Attention Labeling as our new data augmentation method, named MixPro. The experimental results show that our method can improve various ViT-based models at scales on ImageNet classification (73.8% top-1 accuracy based on DeiT-T for 300 epochs). After being pre-trained with MixPro on ImageNet, the ViT-based models also demonstrate better transferability to semantic segmentation, object detection, and instance segmentation. Furthermore, compared to TransMix, MixPro also shows stronger robustness on several benchmarks.

****

StyleMorph: Disentangled 3D-Aware Image Synthesis with a 3D Morphable StyleGAN

Eric-Tuan Le,Edward Bartrum,Iasonas Kokkinos

We introduce StyleMorph, a 3D-aware generative model that disentangles 3D shape, camera pose, object appearance, and background appearance for high quality image synthesis. We account for shape variability by morphing a canonical 3D object template, effectively learning a 3D morphable model in an entirely unsupervised manner through backprop. We chain 3D morphable modelling with deferred neural rendering by performing an implicit surface rendering of “Template Object Coordinates” (TOCS), which can be understood as an unsupervised counterpart to UV maps. This provides a detailed 2D TOCS map signal that reflects the compounded geometric effects of non-rigid shape variation, camera pose, and perspective projection. We combine 2D TOCS maps with an independent appearance code to condition a StyleGAN-based deferred neural rendering (DNR) network for foreground image (object) synthesis; we use a separate code for background synthesis and do late fusion to deliver the final result. We show competitive synthesis results on 4 datasets (FFHQ faces, AFHQ Cats, Dogs, Wild), while achieving the joint disentanglement of shape, pose, object and background texture.

****

Accelerated Riemannian Optimization: Handling Constraints to Bound Geometric Penalties

David Martínez-Rubio,Sebastian Pokutta

We propose a globally-accelerated, first-order method for the optimization of smooth and (strongly or not) geodesically-convex functions in Hadamard manifolds. Our algorithm enjoys the same convergence rates as Nesterov's accelerated gradient descent, up to a multiplicative geometric penalty and log factors.

Crucially, we can enforce our method to stay within a compact set we define. Prior fully accelerated works resort to assuming that the iterates of their algorithms stay in some pre-specified compact set, except for two previous methods, whose applicability is limited to local optimization and to spaces of constant curvature, respectively. Achieving global and general Riemannian acceleration without iterates assumptively staying in the feasible set was asked as an open question in (Kim & Yang, 2022), which we solve for Hadamard manifolds.

In our solution, we show that we can use a linearly convergent algorithm for constrained strongly g-convex smooth problems to implement a Riemannian inexact proximal point operator that we use as a subroutine, which is of independent interest.

Searching Lottery Tickets in Graph Neural Networks: A Dual Perspective

Kun Wang,Yuxuan Liang,Pengkun Wang,Xu Wang,Pengfei Gu,Junfeng Fang,Yang Wang

Graph Neural Networks (GNNs) have shown great promise in various graph learning tasks. However, the computational overheads of fitting GNNs to large-scale graphs grow rapidly, posing obstacles to GNNs from scaling up to real-world applications. To tackle this issue, Graph Lottery Ticket (GLT) hypothesis articulates that there always exists a sparse subnetwork/subgraph with admirable performance in GNNs with random initialization. Such a pair of core subgraph and sparse subnetwork (called graph lottery tickets) can be uncovered by iteratively applying a novel sparsification method. While GLT provides new insights for GNN compression, it requires a full pretraining process to obtain graph lottery tickets, which is not universal and friendly to real-world applications. Moreover, the graph sparsification in GLT utilizes sampling techniques, which may result in massive information loss and aggregation failure. In this paper, we explore the searching of graph lottery tickets from a complementary perspective -- transforming a random ticket into a graph lottery ticket, which allows us to more comprehensively explore the relationships between the original network/graph and their sparse counterpart. To achieve this, we propose regularization-based network pruning and hierarchical graph sparsification, leading to our Dual Graph Lottery Ticket (DGLT) framework for a joint sparsification of network and graph. Compared to GLT, our DGLT helps achieve a triple-win situation of graph lottery tickets with high sparsity, admirable performance, and good explainability. More importantly, we rigorously prove that our model can eliminate noise and maintain reliable information in substructures using the graph information bottleneck theory. Extensive experimental results on various graph-related tasks validate the effectiveness of our framework.

Video Scene Graph Generation from Single-Frame Weak Supervision

Siqi Chen,Jun Xiao,Long Chen

Video scene graph generation (VidSGG) aims to generate a sequence of graph-structure representations for the given video. However, all existing VidSGG methods are fully-supervised, i.e., they need dense and costly manual annotations. In this paper, we propose the first weakly-supervised VidSGG task with only single-frame weak supervision: SF-VidSGG. By ``weakly-supervised", we mean that SF-VidSGG relaxes the training supervision from two different levels: 1) It only provides single-frame annotations instead of all-frame annotations. 2) The single-frame ground-truth annotation is still a weak image SGG annotation, i.e., an unlocalized scene graph. To solve this new task, we also propose a novel Pseudo Label Assignment based method, dubbed as PLA. PLA is a two-stage method, which generates pseudo visual relation annotations for the given video at the first stage, and then trains a fully-supervised VidSGG model with these pseudo labels. Specifically, PLA consists of three modules: an object PLA module, a predicate PLA module, and a future predicate prediction (FPP) module. Firstly, in the object PLA, we localize all objects for every frame. Then, in the predicate PLA, we design two di fferent teachers to assign pseudo predicate labels. Lastly, in the FPP module, we fusion these two predicate pseudo labels by the regularity of relation transition in videos. Extensive ablations and results on the benchmark Action Genome have demonstrated the effectiveness of our PLA.

Planning With Uncertainty: Deep Exploration in Model-Based Reinforcement Learning

Yaniv Oren,Matthijs T. J. Spaan,Wendelin Boehmer

Deep model-based reinforcement learning has shown super-human performance in many challenging domains. Low sample efficiency and limited exploration remain however as leading obstacles in the field. In this paper, we demonstrate deep exploration in model-based RL by incorporating epistemic uncertainty into planning trees, circumventing the standard approach of propagating uncertainty through value learning. We evaluate this approach with the state of the art model-based RL algorithm MuZero, and extend its training process to stabilize learning from explicitly-exploratory decisions. Our results demonstrate that planning with uncertainty is able to achieve effective deep exploration with standard uncertainty estimation mechanisms, and with it significant gains in sample efficiency.

Unsupervised visualization of image datasets using contrastive learning

Niklas Böhm,Philipp Berens,Dmitry Kobak

Visualization methods based on the nearest neighbor graph, such as t-SNE or UMAP, are widely used for visualizing high-dimensional data. Yet, these approaches only produce meaningful results if the nearest neighbors themselves are meaningful. For images represented in pixel space this is not the case, as distances in pixel space are often not capturing our sense of similarity and therefore neighbors are not semantically close. This problem can be circumvented by self-supervised approaches based on contrastive learning, such as SimCLR, relying on data augmentation to generate implicit neighbors, but these methods do not produce two-dimensional embeddings suitable for visualization. Here, we present a new method, called t-SimCNE, for unsupervised visualization of image data. T-SimCNE combines ideas from contrastive learning and neighbor embeddings, and trains a parametric mapping from the high-dimensional pixel space into two dimensions. We show that the resulting 2D embeddings achieve classification accuracy comparable to the state-of-the-art high-dimensional SimCLR representations, thus faithfully capturing semantic relationships. Using t-SimCNE, we obtain informative visualizations of the CIFAR-10 and CIFAR-100 datasets, showing rich cluster structure and highlighting artifacts and outliers.

Contrastive Consistent Representation Distillation

Shipeng Fu,haoran Yang,Xiaomin Yang

The combination of knowledge distillation with contrastive learning has great potential to distill structural knowledge. Most of the contrastive-learning-based distillation methods treat the entire training dataset as the memory bank and maintain two memory banks, one for the student and one for the teacher. Besides, the representations in the two memory banks are updated in a momentum manner, leading to representation inconsistency. In this work, we propose Contrastive Consistent Representation Distillation (CoCoRD) to provide consistent representations for efficient contrastive-learning-based distillation. Instead of momentum-updating the cached representations, CoCoRD updates the encoders in a momentum manner. Specifically, the teacher is equipped with a momentum-updated projection head to generate consistent representations. These teacher representations are cached in a fixed-size queue which serves as the only memory bank in CoCoRD and is significantly smaller than the entire training dataset. Additionally, a slow-moving student, implemented as a momentum-based moving average of the student, is built to facilitate contrastive learning. CoCoRD, which utilizes only one memory bank and much fewer negative keys, provides highly competitive results under typical teacher-student settings. On ImageNet, CoCoRD-distilled ResNet50 outperforms the teacher ResNet101 by 0.2% top-1 accuracy. Furthermore, in PASCAL VOC and COCO detection, the detectors whose backbones are initialized by CoCoRD-distilled m odels exhibit considerable performance improvements.

PowerQuant: Automorphism Search for Non-Uniform Quantization

Edouard YVINEC,Arnaud Dapogny,Matthieu Cord,Kevin Bailly

Deep neural networks (DNNs) are nowadays ubiquitous in many domains such as computer vision. However, due to their high latency, the deployment of DNNs hinges on the development of compression techniques such as quantization which consists in lowering the number of bits used to encode the weights and activations. Growing concerns for privacy and security have motivated the development of data-free techniques, at the expanse of accuracy. In this paper, we identity the uniformity of the quantization operator as a limitation of existing approaches, and propose a data-free non-uniform method. More specifically, we argue that to be readily usable without dedicated hardware and implementation, non-uniform quantization shall not change the nature of the mathematical operations performed by the DNN. This leads to search among the continuous automorphisms of $(\mathbb{R}_+^*,\times)$, which boils down to the power functions defined by their exponent. To find this parameter, we propose to optimize the reconstruction error of each layer: in particular, we show that this procedure is locally convex and admits a unique solution. At inference time, we show that our approach, dubbed PowerQuant, only require simple modifications in the quantized DNN activation functions. As such, with only negligible overhead, it significantly outperforms existing methods in a variety of configurations.

CLEEGN: A Convolutional Neural Network for Plug-and-Play Automatic EEG Reconstruction

Pin-Hua Lai,Wei-Chun Yang,Hsiang-Chieh Tsou,Chun-Shu Wei

Human electroencephalography (EEG) is a brain monitoring modality that senses cortical neuroelectrophysiological activity in high-temporal resolution. One of the greatest challenges posed in applications of EEG is the unstable signal quality susceptible to inevitable artifacts during recordings. To date, most existing techniques for EEG artifact removal and reconstruction are applicable to offline analysis solely, or require individualized training data to facilitate online reconstruction. We have proposed CLEEGN, a novel convolutional neural network for plug-and-play automatic EEG reconstruction. CLEEGN is based on a subject-independent pre-trained model using existing data and can operate on a new user without any further calibration. The performance of CLEEGN was validated using multiple evaluations including waveform observation, reconstruction error assessment, and decoding accuracy on well-studied labeled datasets. The results of simulated online validation suggest that, even without any calibration, CLEEGN can largely preserve inherent brain activity and outperforms leading online/offline artifact removal methods in the decoding accuracy of reconstructed EEG data. In addition, visualization of model parameters and latent features exhibit the model behavior and reveal explainable insights related to existing knowledge of neuroscience. We foresee pervasive applications of CLEEGN in prospective works of online plug-and-play EEG decoding and analysis.

On Uni-modal Feature Learning in Multi-modal Learning

Chenzhuang Du,Jiaye Teng,Tingle Li,Yichen Liu,Tianyuan Yuan,Yue Wang,Yang Yuan,Hang Zhao

We abstract the features of multi-modal data into 1) uni-modal features, which can be learned from uni-modal training, and 2) paired features, which can only be learned from cross-modal interaction. Multi-modal joint training is expected to benefit from cross-modal interaction on the basis of ensuring uni-modal feature learning. However, recent late-fusion training approaches still suffer from insufficient learning of uni-modal features on each modality and we prove that this phenomenon does hurt the model's generalization ability.

Given a multi-modal task, we propose to choose targeted late-fusion learning method from Uni-Modal Ensemble (UME) and the proposed Uni-Modal Teacher (UMT), according to the distribution of uni-modal and paired features. We demonstrate that, under a simple guiding strategy, we can achieve comparable results to other com

plex late-fusion or intermediate-fusion methods on multi-modal datasets, including VGG-Sound, Kinetics-400, UCF101, and ModelNet40.

Unified neural representation model for physical and conceptual spaces
Tatsuya Haga,Yohei Oseki,Tomoki Fukai

The spatial processing system of the brain uses grid-like neural representations (grid cells) for supporting vector-based navigation. Experiments also suggest that neural representations for concepts (concept cells) exist in the human brain, and conceptual inference relies on navigation in conceptual spaces. We propose a unified model called ``disentangled successor information (DSI)'' that explains neural representations for both physical and conceptual spaces. DSI generates grid-like representations in a 2-dimensional space that highly resemble those observed in the brain. Moreover, the same model creates concept-specific representations from linguistic inputs, corresponding to concept cells. Mathematically, DSI vectors approximate value functions for navigation and word vectors obtained by word embedding methods, thus enabling both spatial navigation and conceptual inference based on vector-based calculation. Our results suggest that a single principle can explain computation of physical and conceptual spaces in the human brain.

Symbolic Physics Learner: Discovering governing equations via Monte Carlo tree search
Fangzheng Sun,Yang Liu,Jian-Xun Wang,Hao Sun

Nonlinear dynamics is ubiquitous in nature and commonly seen in various science and engineering disciplines. Distilling analytical expressions that govern nonlinear dynamics from limited data remains vital but challenging. To tackle this fundamental issue, we propose a novel Symbolic Physics Learner (SPL) machine to discover the mathematical structure of nonlinear dynamics. The key concept is to interpret mathematical operations and system state variables by computational rules and symbols, establish symbolic reasoning of mathematical formulas via expression trees, and employ a Monte Carlo tree search (MCTS) agent to explore optimal expression trees based on measurement data. The MCTS agent obtains an optimistic selection policy through the traversal of expression trees, featuring the one that maps to the arithmetic expression of underlying physics. Salient features of the proposed framework include search flexibility and enforcement of parsimony for discovered equations. The efficacy and superiority of the SPL machine are demonstrated by numerical examples, compared with state-of-the-art baselines.

The Dynamic of Consensus in Deep Networks and the Identification of Noisy Labels
Daniel Shwartz,Uri Stern,Daphna Weinshall

Deep neural networks have incredible capacity and expressibility, and can seemingly memorize any training set. This introduces a problem when training in the presence of noisy labels, as the noisy examples cannot be distinguished from clean examples by the end of training. Recent research has dealt with this challenge by utilizing the fact that deep networks seem to memorize clean examples much earlier than noisy examples. Here we report a new empirical result: for each example, when looking at the time it has been memorized by each model in an ensemble of networks, the diversity seen in noisy examples is much larger than the clean examples. We use this observation to develop a new method for noisy labels filtration. The method is based on a statistics of the data, which captures the differences in ensemble learning dynamics between clean and noisy data. We test our method on three tasks: (i) noise amount estimation; (ii) noise filtration; (iii) supervised classification. We show that our method improves over existing baselines in all three tasks using a variety of datasets, noise models, and noise levels. Aside from its improved performance, our method has two other advantages. (i) Simplicity, which implies that no additional hyperparameters are introduced. (ii) Our method is modular: it does not work in an end-to-end fashion, and can therefore be used to clean a dataset for any other future usage.

Efficient block contrastive learning via parameter-free meta-node approximation

Gayan K Kulatilleke,Marius Portmann,Shekhar S. Chandra

Contrastive learning has recently achieved remarkable success in many domains including graphs. However contrastive loss, especially for graphs, requires a large number of negative samples which is unscalable and computationally prohibitive with a quadratic time complexity. Sub-sampling is not optimal and incorrect negative sampling leads to sampling bias. In this work, we propose a meta-node based approximation technique that can (a) proxy all negative combinations (b) in quadratic cluster size time complexity, (c) at graph level, not node level, and (d) exploit graph sparsity. By replacing node-pairs with additive cluster-pairs, we compute the negatives in cluster-time at graph level. The resulting Proxy approximated meta-node Contrastive (PamC) loss, based on simple optimized GPU operations, captures the full set of negatives, yet is efficient with a linear time complexity. By avoiding sampling, we effectively eliminate sample bias. We meet the criterion for larger number of samples, thus achieving block-contrastiveness, which is proven to outperform pair-wise losses. We use learnt soft cluster assignments for the meta-node constriction, and avoid possible heterophily and noise added during edge creation. Theoretically, we show that real world graphs easily satisfy conditions necessary for our approximation. Empirically, we show promising accuracy gains over state-of-the-art graph clustering on 6 benchmarks. Importantly, we gain substantially in efficiency; up to 3x in training time, 1.8x in inference time and over 5x in GPU memory reduction.

Attribute Alignment and Enhancement for Generalized Zero-Shot Learning

Nannan Lu,MingKai Qiu

Generalized zero-shot learning (GZSL) aims to recognize both seen and unseen classes, which challenges the generalization ability of a model. In this paper, we propose a novel approach to fully utilize attributes information, referred to as attribute alignment and enhancement (A3E) network. It contains two modules. First, attribute localization (AL) module utilizes the supervision of class attribute vectors to guide visual localization for attributes through the implicit localization capability within the feature extractor, and the visual features corresponding to the attributes (attribute-visual features) are obtained. Second, enhanced attribute scoring (EAS) module employs the supervision of the attribute word vectors (attribute semantics) to project input attribute visual features to attribute semantic space using Graph Attention Network (GAT). Based on the constructed attribute relation graph (ARG), EAS module generates enhanced representation of attributes. Experiments on standard datasets demonstrate that the enhanced attribute representation greatly improves the classification performance, which helps A3E to achieve state-of-the-art performances in both ZSL and GZSL tasks.

BAYES RISK CTC: CONTROLLABLE CTC ALIGNMENT IN SEQUENCE-TO-SEQUENCE TASKS

Jinchuan Tian,Brian Yan,Jianwei Yu,CHAO WENG,Dong Yu,Shinji Watanabe

Sequence-to-Sequence (seq2seq) tasks transcribe the input sequence to a target sequence. The Connectionist Temporal Classification (CTC) criterion is widely used in multiple seq2seq tasks. Besides predicting the target sequence, a side product of CTC is to predict the alignment, which is the most probable input-long sequence that specifies a hard aligning relationship between the input and target units. As there are multiple potential aligning sequences (called paths) that are equally considered in CTC formulation, the choice of which path will be most probable and become the predicted alignment is always uncertain. In addition, it is usually observed that the alignment predicted by vanilla CTC will drift compared with its reference and rarely provides practical functionalities. Thus, the motivation of this work is to make the CTC alignment prediction controllable and thus equip CTC with extra functionalities. The Bayes risk CTC (BRCTC) criterion is then proposed in this work, in which a customizable Bayes risk function is adopted to enforce the desired characteristics of the predicted alignment. With the risk function, the BRCTC is a general framework to adopt some customizable preference over the paths in order to concentrate the posterior into a particular subset of the paths. In applications, we explore one particular preference which yields models with the down-sampling ability and reduced inference costs. By using BRCTC with another preference for early emissions, we obtain an improved performance-latency trade-off for online models. Experimentally, the proposed BRCTC reduces the inference cost of offline models by up to 47% without performance degradation and cuts down the overall latency of online systems to an unseen level.

A Convergent Single-Loop Algorithm for Relaxation of Gromov-Wasserstein in Graph Data

Jiajin Li,Jianheng Tang,Lemin Kong,Huikang Liu,Jia Li,Anthony Man-Cho So,Jose Blanchet

In this work, we present the Bregman Alternating Projected Gradient (BAPG) method, a single-loop algorithm that offers an approximate solution to the Gromov-Wasserstein (GW) distance.

We introduce a novel relaxation technique that balances accuracy and computational efficiency, albeit with some compromises in the feasibility of the coupling map. Our analysis is based on the observation that the GW problem satisfies the Luo-Tseng error bound condition, which relates to estimating the distance of a point to the critical point set of the GW problem based on the optimality residual.

This observation allows us to provide an approximation bound for the distance between the fixed-point set of BAPG and the critical point set of GW. Moreover, under a mild technical assumption, we can show that BAPG converges to its fixed point set.

The effectiveness of BAPG has been validated through comprehensive numerical experiments in graph alignment and partition tasks, where it outperforms existing methods in terms of both solution quality and wall-clock time.

A Hierarchical Hyper-rectangle Mass Model for Fine-grained Entity Typing

SHING HU,Chunyu Li,Bibo Hao

Fine-grained entity typing is the task of detecting types of entities inside a given language text. Entity typing models typically transform entities into vectors in high-dimensional space, hyperbolic space, or add additional context information. However, such spaces or feature transformations are not compatible with modeling types' inter-dependencies and diverse scenarios. We study the ability of the hierarchical hyper-rectangle mass model(hRMM), which represents mentions and types into hyper-rectangle mass(hRM) and thus captures the relationships of ontology into a geometric mass view. Natural language contexts are fed into the encoder and then projected to hyper-rectangle mass embedding(hRME). We find that hRM perfectly depicts features of mentions and types. With further research in hypervolume indicators and adaptive thresholds, performance achieves additional improvement. Experiments show that our approach achieves better performance on several entity typing benchmarks and attains state-of-the-art results on two benchmark datasets.

Semi-supervised learning with a principled likelihood from a generative model of data curation

Stoil Krasimirov Ganev,Laurence Aitchison

We currently do not have an understanding of semi-supervised learning (SSL) objectives such as pseudo-labelling and entropy minimization as log-likelihoods, which precludes the development of e.g. Bayesian SSL. Here, we note that benchmark image datasets such as CIFAR-10 are carefully curated, and we formulate SSL objectives as a log-likelihood in a generative model of data curation. We show that SSL objectives, from entropy minimization and pseudo-labelling, to state-of-the-art techniques similar to FixMatch can be understood as lower-bounds on our principled log-likelihood. We are thus able to introduce a Bayesian extension of SSL, which gives considerable improvements over standard SSL in the setting of 40 labelled points on CIFAR-10, with performance of $92.2\pm 0.3\%$ vs 88.6% in the original FixMatch paper. Finally, our theory suggests that SSL is effective in part due to the statistical patterns induced by data curation. This provides a n explanation of past results which show SSL performs better on clean datasets without any ``out of distribution'' examples. Confirming these results we find that SSL gave much larger performance improvements on curated than on uncurated data, using matched curated and uncurated datasets based on Galaxy Zoo 2.

Ti-MAE: Self-Supervised Masked Time Series Autoencoders

Zhe Li,Pengyun Wang,Zhongwen Rao,Lujia Pan,Zenglin Xu

Multivariate Time Series forecasting has been an increasingly popular topic in various applications and scenarios. Recently, contrastive learning and Transformer-based models have achieved good performance in many long-term series forecasting tasks. However, there are still several issues in existing methods. First, the training paradigm of contrastive learning and downstream prediction tasks are inconsistent, leading the accuracy of prediction not good enough. Second, existing Transformer-based models which learn similar patterns in historical time series data to predict future values always induces severe distribution shift problems, and does not fully leverage the sequence information compared to self-supervised methods. To address these issues, we propose a novel framework named Ti-MAE, in which the input time series are assumed to follow an integrate distribution. In detail, Ti-MAE randomly masks out embedded time series data and learns an autoencoder to reconstruct them at the point-level. Ti-MAE adopts mask modeling as the auxiliary task rather than contrastive learning and bridges the connection between existing representation learning and generative Transformer-based methods, reducing the difference between upstream and downstream forecasting tasks while maintaining the utilization of original time series data. Experiments on several public real-world datasets demonstrate that our framework of masked autoencoding could learn strong representations directly from the raw data, yielding better performance in time series forecasting and classification tasks. The code will be made public after this paper is accepted.

E3Bind: An End-to-End Equivariant Network for Protein-Ligand Docking

Yangtian Zhang,Huiyu Cai,Chence Shi,Jian Tang

In silico prediction of the ligand binding pose to a given protein target is a crucial but challenging task in drug discovery.

This work focuses on blind flexible self-docking, where we aim to predict the positions, orientations and conformations of docked molecules. Traditional physics-based methods usually suffer from inaccurate scoring functions and high inference cost. Recently, data-driven methods based on deep learning techniques are attracting growing interest thanks to their efficiency during inference and promising performance. These methods usually either adopt a two-stage approach by first predicting the distances between proteins and ligands and then generating the final coordinates based on the predicted distances, or directly predicting the global roto-translation of ligands. In this paper, we take a different route. Inspired by the resounding success of AlphaFold2 for protein structure prediction, we propose E3Bind, an end-to-end equivariant network that iteratively updates the ligand pose. E3Bind models the protein-ligand interaction through careful consideration of the geometric constraints in docking and the local context of the binding site. Experiments on standard benchmark datasets demonstrate the superior performance of our end-to-end trainable model compared to traditional and recently-proposed deep learning methods.

Improving Model Consistency of Decentralized Federated Learning via Sharpness Aware Minimization and Multiple Gossip Approaches

Yifan Shi,Li Shen,Kang Wei,Yan Sun,Bo Yuan,Xueqian Wang,Dacheng Tao

To mitigate the privacy leakages and reduce the communication burden of Federated Learning (FL), decentralized FL (DFL) discards the central server and each client only communicates with its neighbors in the decentralized communication network. However, existing DFL algorithms tend to feature high inconsistency among local models, which results in severe distribution shifts across clients and inferior performance compared with centralized FL (CFL), especially on heterogeneous data or with sparse connectivity of communication topology.

To alleviate this challenge, we propose two DFL algorithms named DFedSAM and DFedSAM-MGS to improve the performance.
Specifically, DFedSAM leverages gradient perturbation to generate local flatness models via Sharpness Aware Minimization (SAM), which searches for model parameters with uniformly low loss function values.
In addition, DFedSAM-MGS further boosts DFedSAM by adopting the technique of Multiple Gossip Steps (MGS) for a better model consistency, which accelerates the aggregation of local flatness models and better balances the communication complexity and learning performance.
In the theoretical perspective, we present the improved convergence rates $\small \mathcal{O}\big(\frac{1}{T}+\frac{1}{T^2(1-\lambda)^2}\big)$ and $\small \mathcal{O}\big(\frac{1}{T}+\frac{\lambda^Q+1}{T^2(1-\lambda^Q)^2}\big)$ in the stochastic non-convex setting for DFedSAM and DFedSAM-MGS, respectively, where $1-\lambda$ is the spectral gap of the gossip matrix W and Q is the gossip steps in MGS. Meanwhile, we empirically confirm that our methods can achieve competitive performance compared with CFL baselines and outperform existing DFL baselines.

VA-DepthNet: A Variational Approach to Single Image Depth Prediction
Ce Liu,Suryansh Kumar,Shuhang Gu,Radu Timofte,Luc Van Gool
We introduce VA-DepthNet, a simple, effective, and accurate deep neural network approach for the single-image depth prediction (SIDP) problem. The proposed approach advocates using classical first-order variational constraints for this problem. While state-of-the-art deep neural network methods for SIDP learn the scene depth from images in a supervised setting, they often overlook the invaluable invariances and priors in the rigid scene space, such as the regularity of the scene. The paper's main contribution is to reveal the benefit of classical and well-founded variational constraints in the neural network design for the SIDP task. It is shown that imposing first-order variational constraints in the scene space together with popular encoder-decoder-based network architecture design provides excellent results for the supervised SIDP task. The imposed first-order variational constraint makes the network aware of the depth gradient in the scene space, i.e., regularity. The paper demonstrates the usefulness of the proposed approach via extensive evaluation and ablation analysis over several benchmark datasets, such as KITTI, NYU Depth V2, and SUN RGB-D. The VA-DepthNet at test time shows considerable improvements in depth prediction accuracy compared to the prior art and is accurate also at high-frequency regions in the scene space. At the time of writing this paper, our method---labeled as VA-DepthNet, when tested on the KITTI depth-prediction evaluation set benchmarks, shows state-of-the-art results, and is the top-performing published approach.

Prompt-to-Prompt Image Editing with Cross-Attention Control
Amir Hertz,Ron Mokady,Jay Tenenbaum,Kfir Aberman,Yael Pritch,Daniel Cohen-or
Recent large-scale text-driven synthesis diffusion models have attracted much attention thanks to their remarkable capabilities of generating highly diverse images that follow given text prompts. Therefore, it is only natural to build upon these synthesis models to provide text-driven image editing capabilities. However, Editing is challenging for these generative models, since an innate property of an editing technique is to preserve some content from the original image, while in the text-based models, even a small modification of the text prompt often leads to a completely different outcome. State-of-the-art methods mitigate this by requiring the users to provide a spatial mask to localize the edit, hence, ignoring the original structure and content within the masked region. In this paper, we pursue an intuitive prompt-to-prompt editing framework, where the edits are controlled by text only. We analyze a text-conditioned model in depth and observe that the cross-attention layers are the key to controlling the relation between the spatial layout of the image to each word in the prompt. With this observation, we propose to control the attention maps along the diffusion process. Our approach enables us to monitor the synthesis process by editing the textual prompt only, paving the way to a myriad of caption-based editing applications such

as localized editing by replacing a word, global editing by adding a specification, and even controlling the extent to which a word is reflected in the image. We present our results over diverse images and prompts with different text-to-image models, demonstrating high-quality synthesis and fidelity to the edited prompts.

Re-weighting Based Group Fairness Regularization via Classwise Robust Optimization

Sangwon Jung,Taeeon Park,Sanghyuk Chun,Taesup Moon

Many existing group fairness-aware training methods aim to achieve the group fairness by either re-weighting underrepresented groups based on certain rules or using weakly approximated surrogates for the fairness metrics in the objective as regularization terms. Although each of the learning schemes has its own strength in terms of applicability or performance, respectively, it is difficult for any method in the either category to be considered as a gold standard since their successful performances are typically limited to specific cases. To that end, we propose a principled method, dubbed as FairDRO, which unifies the two learning schemes by incorporating a well-justified group fairness metric into the training objective using a classwise distributionally robust optimization (DRO) framework. We then develop an iterative optimization algorithm that minimizes the resulting objective by automatically producing the correct re-weights for each group. Our experiments show that FairDRO is scalable and easily adaptable to diverse applications, and consistently achieves the state-of-the-art performance on several benchmark datasets in terms of the accuracy-fairness trade-off, compared to recent strong baselines.

****

DiffEdit: Diffusion-based semantic image editing with mask guidance

Guillaume Couairon,Jakob Verbeek,Holger Schwenk,Matthieu Cord

Image generation has recently seen tremendous advances, with diffusion models allowing to synthesize convincing images for a large variety of text prompts. In this article, we propose DiffEdit, a method to take advantage of text-conditioned diffusion models for the task of semantic image editing, where the goal is to edit an image based on a text query. Semantic image editing is an extension of image generation, with the additional constraint that the generated image should be as similar as possible to a given input image.

Current editing methods based on diffusion models usually require to provide a mask, making the task much easier by treating it as a conditional inpainting task. In contrast, our main contribution is able to automatically generate a mask highlighting regions of the input image that need to be edited, by contrasting predictions of a diffusion model conditioned on different text prompts. Moreover, we rely on latent inference to preserve content in those regions of interest and show excellent synergies with mask-based diffusion.

DiffEdit achieves state-of-the-art editing performance on ImageNet. In addition, we evaluate semantic image editing in more challenging settings, using images from the COCO dataset as well as text-based generated images.

****

Are More Layers Beneficial to Graph Transformers?

Haiteng Zhao,Shuming Ma,Dongdong Zhang,Zhi-Hong Deng,Furu Wei

Despite that going deep has proven successful in many neural architectures, the existing graph transformers are relatively shallow. In this work, we explore whether more layers are beneficial to graph transformers, and find that current graph transformers suffer from the bottleneck of improving performance by increasing depth. Our further analysis reveals the reason is that deep graph transformers are limited by the vanishing capacity of global attention, restricting the graph transformer from focusing on the critical substructure and obtaining expressive features. To this end, we propose a novel graph transformer model named DeepGraph that explicitly employs substructure tokens in the encoded representation, and applies local attention on related nodes to obtain substructure based attention encoding. Our model enhances the ability of the global attention to focus on substructures and promotes the expressiveness of the representations, addressing

the limitation of self-attention as the graph transformer deepens. Experiments show that our method unblocks the depth limitation of graph transformers and results in state-of-the-art performance across various graph benchmarks with deeper models.
****

Learning Combinatorial Node Labeling Algorithms
Lukas Gianinazzi,Maximilian Fries,Nikoli Dryden,Tal Ben-Nun,Maciej Besta,Torsten Hoefler
We present the combinatorial node labeling framework, which generalizes many prior approaches to solving hard graph optimization problems by supporting problems where solutions consist of arbitrarily many node labels, such as graph coloring. We then introduce a neural network architecture to implement this framework. Our architecture builds on a graph attention network with several inductive biases to improve solution quality and is trained using policy gradient reinforcement learning. We demonstrate our approach on both graph coloring and minimum vertex cover. Our learned heuristics match or outperform classical hand-crafted greedy heuristics and machine learning approaches while taking only seconds on large graphs. We conduct a detailed analysis of the learned heuristics and architecture choices and show that they successfully adapt to different graph structures.
****

Simplicial Hopfield networks
Thomas F Burns,Tomoki Fukai
Hopfield networks are artificial neural networks which store memory patterns on the states of their neurons by choosing recurrent connection weights and update rules such that the energy landscape of the network forms attractors around the memories. How many stable, sufficiently-attracting memory patterns can we store in such a network using N neurons? The answer depends on the choice of weights and update rule. Inspired by setwise connectivity in biology, we extend Hopfield networks by adding setwise connections and embedding these connections in a simplicial complex. Simplicial complexes are higher dimensional analogues of graphs which naturally represent collections of pairwise and setwise relationships. We show that our simplicial Hopfield networks increase memory storage capacity. Surprisingly, even when connections are limited to a small random subset of equivalent size to an all-pairwise network, our networks still outperform their pairwise counterparts. Such scenarios include non-trivial simplicial topology. We also test analogous modern continuous Hopfield networks, offering a potentially promising avenue for improving the attention mechanism in Transformer models.
****

Versatile Neural Processes for Learning Implicit Neural Representations
Zongyu Guo,Cuiling Lan,Zhizheng Zhang,Yan Lu,Zhibo Chen
Representing a signal as a continuous function parameterized by neural network (a.k.a. Implicit Neural Representations, INRs) has attracted increasing attention in recent years. Neural Processes (NPs), which model the distributions over functions conditioned on partial observations (context set), provide a practical solution for fast inference of continuous functions. However, existing NP architectures suffer from inferior modeling capability for complex signals. In this paper, we propose an efficient NP framework dubbed Versatile Neural Processes (VNP), which largely increases the capability of approximating functions. Specifically, we introduce a bottleneck encoder that produces fewer and informative context tokens, relieving the high computational cost while providing high modeling capability. At the decoder side, we hierarchically learn multiple global latent variables that jointly model the global structure and the uncertainty of a function, enabling our model to capture the distribution of complex signals. We demonstrate the effectiveness of the proposed VNP on a variety of tasks involving 1D, 2D and 3D signals. Particularly, our method shows promise in learning accurate INRs w.r.t. a 3D scene without further finetuning.
****

DEEP ACCURATE SOLVER FOR THE GEODESIC PROBLEM
Saar Huberman,Ron Kimmel
A high order accurate deep learning method for computing geodesic distances on s

urfaces is introduced. The proposed method exploits a dynamic programming principle which lends itself to a scheme with quasi-linear computational complexity. We consider two main components for computing distances on surfaces; A numerical solver that locally approximates the distance function and an efficient causal ordering scheme by which points are updated. The quality of the distance approximation is determined by the local solver and is the main focus of this paper. A common approach to compute distances on continuous surfaces is by considering a discretized polygonal mesh approximating the surface, and estimating distances on the polygon. With such an approximation, the exact geodesic distances restricted to the polygon are at most second order accurate with respect to the distances on the corresponding continuous surface. Here, by order of accuracy we refer to the rate of convergence as a function of the average distance between sampled points. To improve the rate of convergence, we consider a neural network based local solver which implicitly approximates the structure of the continuous surface. The proposed solver circumvents the polyhedral representation, by directly consuming sampled mesh vertices for approximation of distances on the sampled continuous surfaces. We provide numerical evidence that the proposed update scheme, with appropriate local numerical support, provides better accuracy compared to the best possible polyhedral approximations and previous learning based methods. We introduce a trained solver which is third order accurate, with quasi-linear complexity in the number of sampled points.
****

PBFormer: Capturing Complex Scene Text Shape with Polynomial Band Transformer
Ruijin Liu,Ning Lu,Dapeng Chen,Cheng LI,Zejian Yuan,Wei Peng
We present PBFormer, an efficient yet powerful scene text detector that unifies the transformer with a novel text shape representation Polynomial Band (PB). The representation has four polynomial curves to fit a text's top, bottom, left, and right sides, which can capture a text with a complex shape by varying polynomial coefficients. PB has appealing features compared with conventional representations: 1) It can model different curvatures with a fixed number of parameters, while polygon-points-based methods need to utilize a different number of points. 2) It can distinguish adjacent or overlapping texts as they have apparent different curve coefficients, while segmentation-based methods suffer from adhesive spatial positions. PBFormer combines the PB with the transformer, which can directly generate smooth text contours sampled from predicted curves without interpolation. To leverage the advantage of PB, PBFormer has a parameter-free cross-scale pixel attention module. The module can enlarge text features and suppress irrelevant areas to benefit from detecting texts with diverse scale variations. Furthermore, PBFormer is trained with a shape-contained loss, which not only enforces the piecewise alignment between the ground truth and the predicted curves but also makes curves' position and shapes consistent with each other. Without bells and whistles about text pre-training, our method is superior to the previous state-of-the-art text detectors on the arbitrary-shaped CTW1500 and Total-Text datasets. Codes will be public.

Classically Approximating Variational Quantum Machine Learning with Random Fourier Features
Jonas Landman,Slimane Thabet,Constantin Dalyac,Hela Mhiri,Elham Kashefi
Many applications of quantum computing in the near term rely on variational quantum circuits (VQCs). They have been showcased as a promising model for reaching a quantum advantage in machine learning with current noisy intermediate scale quantum computers (NISQ). It is often believed that the power of VQCs relies on their exponentially large feature space, and extensive works have explored the expressiveness and trainability of VQCs in that regard. In our work, we propose a classical sampling method that can closely approximate most VQCs with Hamiltonian encoding, given only the description of their architecture. It uses the seminal proposal of Random Fourier Features (RFF) and the fact that VQCs can be seen as large Fourier series. We show theoretically and experimentally that models built from exponentially large quantum feature space can be classically reproduced by sampling a few frequencies to build an equivalent low dimensional kernel. Prec

isely, we show that the number of required samples grows favourably with the size of the quantum spectrum. This tool therefore questions the hope for quantum advantage from VQCs in many cases, but conversely helps to narrow the conditions for their potential success. We expect VQCs with various and complex encoding Hamiltonians, or with large input dimension, to become more robust to classical approximations.

Distributional Meta-Gradient Reinforcement Learning

Haiyan Yin,Shuicheng YAN,Zhongwen Xu

Meta-gradient reinforcement learning (RL) algorithms have substantially boosted the performance of RL agents by learning an adaptive return. All the existing algorithms adhere to the same reward learning principle, where the adaptive return is simply formulated in the form of expected cumulative rewards, upon which the policy and critic update rules are specified under well-adopted distance metrics. In this paper, we present a novel algorithm that builds on the success of meta-gradient RL algorithms and effectively improves such algorithms by following a simple recipe, i.e., going beyond the expected return to formulate and learn the return in a more expressive form, value distributions. To this end, we first formulate a distributional return that could effectively capture bootstrapping and discounting behaviors over distributions, to form an informative distributional return target in value update. Then we derive an efficient meta update rule to learn the adaptive distributional return with meta-gradients. For empirical evaluation, we first present an illustrative example on a toy two-color grid-world domain, which validates the benefit of learning distributional return over expectation; then we conduct extensive comparisons on a large-scale RL benchmark Atari 2600, where we confirm that our proposed method with distributional return works seamlessly well with the actor-critic framework and leads to state-of-the-art median human normalized score among meta-gradient RL literature.

Towards A Unified Policy Abstraction Theory and Representation Learning Approach in Markov Decision Processes

Min Zhang,Hongyao Tang,Jianye HAO,YAN ZHENG

Lying on the heart of intelligent decision-making systems, how policy is represented and optimized is a fundamental problem. The root challenge in this problem is the large scale and the high complexity of policy space, which exacerbates the difficulty of policy learning especially in real-world scenarios. Towards a desirable surrogate policy space, recently policy representation in a low-dimensional latent space has shown its potential in improving both the evaluation and optimization of policy. The key question involved in these studies is by what criterion we should abstract the policy space for desired compression and generalization. However, both the theory on policy abstraction and the methodology on policy representation learning are less studied in the literature. In this work, we make very first efforts to fill up the vacancy. First, we propose a unified policy abstraction theory, containing three types of policy abstraction associated to policy features at different levels. Then, we generalize them to three policy metrics that quantify the distance (i.e., similarity) of policies, for more convenient use in learning policy representation. Further, we propose a policy representation learning approach based on deep metric learning. For the empirical study, we investigate the efficacy of the proposed policy metrics and representations, in characterizing policy difference and conveying policy generalization respectively. Our experiments are conducted in both policy optimization and evaluation problems, containing trust-region policy optimization (TRPO), diversity-guided evolution strategy (DGES) and off-policy evaluation (OPE). Somewhat naturally, the experimental results indicate that there is no a universally optimal abstraction for all downstream learning problems; while the influence-irrelevance policy abstraction can be a generally preferred choice.

CENTROID-BASED JOINT REPRESENTATION FOR HUMAN POSE ESTIMATION AND INSTANCE SEGMENTATION

Niaz Ahmad,Jawad Khan,Jeremy Yuhyun Kim,Youngmoon Lee

Joint pose estimation and instance segmentation combines keypoint heatmaps with segmentation masks for multi-person pose and instance-level segmentation. Unlike easy cases with explicit heatmap activation, hard cases with implicit heatmap due to multi-person entanglement, overlap, and occlusions requires joint representation with a segmentation mask in end-to-end training. This paper presents a new centroid-based joint representation method called CENTERFOCUS. It follows a bottom-up paradigm to generate Strong Keypoint Feature Maps for both soft and hard keypoints and improve keypoints detection accuracy as well as the confidence score by introducing KeyCentroids and a Body Heat Map. CENTERFOCUS then uses the high-resolution representation of keypoint as a center of attraction for the pixels in the embedding space to generate MaskCentroid to cluster the pixels to a particular human instance to whom it belongs, even if 70% of the body is occluded. Finally, we propose a new PoseSeg algorithm that collects the feature representation of a 2D human pose and segmentation for the joint structure of the pose and instance segmentation. We then experimentally demonstrate the effectiveness and generalization ability of our system on challenging scenarios such as occlusions, entangled limbs, and overlapping people. The experimental results show the effectiveness of CENTERFOCUS outperforms representative models on the challenging MS COCO and OCHuman benchmarks in terms of both accuracy and runtime performance, Ablation experiments analyze the impact of each component of the system. The code will be released publicly.

Pairwise Confidence Difference on Unlabeled Data is Sufficient for Binary Classification

Wei Wang,Lei Feng,Gang Niu,Min-Ling Zhang,Masashi Sugiyama

Learning with confidence labels is an emerging weakly supervised learning paradigm, where training data are equipped with confidence labels instead of exact labels. Positive-confidence (Pconf) classification is a typical learning problem in this context, where we are given only positive data equipped with confidence. However, pointwise confidence may not be accessible in real-world scenarios. In this paper, we dive into a novel weakly supervised learning problem called confidence-difference (ConfDiff) classification. Instead of pointwise confidence, we are given only unlabeled data pairs equipped with confidence difference specifying the difference in the probabilities of being positive. An unbiased risk estimator is derived to tackle the problem, and we show that the estimation error bound achieves the optimal convergence rate. Extensive experiments on benchmark data sets validate the effectiveness of our proposed approaches in leveraging the supervision information of the confidence difference.

Emergent Communication with Attention

Ryokan Ri,Ryo Ueda,Jason Naradowsky

To develop computational agents that can better communicate with others using their own emergent language, we endow the agents with an ability to focus their attention on particular concepts in the environment. Humans often understand a thing or scene as a composite of concepts and those concepts are further mapped onto words. We implement this intuition as attention mechanisms in Speaker and Listener agents in a referential game and show attention leads to more compositional and interpretable emergent language. We also demonstrate how attention helps us understand the learned communication protocol by investigating the attention weights associated with each message symbol and the alignment of attention weights between Speaker and Listener agents. Overall, our results suggest that attention is a promising mechanism for developing more human-like emergent language.

Discovering Bugs in Vision Models using Off-the-shelf Image Generation and Captioning

Olivia Wiles,Isabela Albuquerque,Sven Gowal

Automatically discovering failures in vision models under real-world settings remains an open challenge. This work shows how off-the-shelf, large-scale, image-to-text and text-to-image models, trained on vast amounts of data, can be leveraged to automatically find such failures. In essence, a conditional text-to-image generative model is used to generate large amounts of synthetic, yet realistic, inputs given a ground-truth label. A captioning model is used to describe misclassified inputs. Descriptions are used in turn to generate more inputs, thereby assessing whether specific descriptions induce more failures than expected. As failures are grounded to natural language, we automatically obtain a high-level, human-interpretable explanation of each failure. We use this pipeline to demonstrate that we can effectively interrogate classifiers trained on ImageNet to find specific failure cases and discover spurious correlations. We also show that we can scale the approach to generate adversarial datasets targeting specific classifier architectures. This work demonstrates the utility of large-scale generative models to automatically discover bugs in vision models in an open-ended manner. We also describe a number of limitations and pitfalls related to this approach.

MetaFS: An Effective Wrapper Feature Selection via Meta Learning

Zheyi Pan,Chunyang Li,Songyu Ke,Haoran Xu,Junbo Zhang,Ye Yuan,Yu Zheng

Feature selection is of great importance and applies in lots of fields, such as medical and commercial. Wrapper methods, directly comparing the performance of different feature combinations, are widely used in real-world applications. However, selecting effective features meets the following two main challenges: 1) feature combinations are distributed in a huge discrete space; and 2) efficient and precise combinations evaluation is hard. To tackle these challenges, we propose a novel deep meta-learning-based feature selection framework, termed MetaFS, containing a Feature Subset Sampler (FSS) and a Meta Feature Estimator (MetaFE), which transforms the discrete search space into continuous and adopts meta-learning technique for effective feature selection. Specifically, FSS parameterizes the distribution of discrete search space and applies gradient-based methods to optimize. MetaFE learns the representations of different feature combinations, and dynamically generates unique models without retraining for efficient and precise combination evaluation. We adopt a bi-level optimization strategy to optimize the MetaFS. After optimization, we evaluate multiple feature combinations sampled from the converged distribution (i.e., the condensed search space) and select the optimal one. Finally, we conduct extensive experiments on two datasets, illustrating the superiority of MetaFS over 7 state-of-the-art methods.

Same Pre-training Loss, Better Downstream: Implicit Bias Matters for Language Models

Hong Liu,Sang Michael Xie,Zhiyuan Li,Tengyu Ma

Language modeling on large-scale datasets leads to impressive performance gains on various downstream language tasks. The (validation) pre-training loss (or perplexity in autoregressive language modeling) is often used as the evaluation metric when developing language models since the pre-training loss tends to be well-correlated with downstream performance (which is itself difficult to evaluate comprehensively). Contrary to this conventional wisdom, this paper shows that 1) pre-training loss cannot fully explain downstream performance and 2) flatness of the model is well-correlated with downstream performance where pre-training loss is not. On simplified datasets, we identify three ways to produce models with the same (statistically optimal) pre-training loss but different downstream performance: continue pre-training after convergence, increasing the model size, and changing the training algorithm. These experiments demonstrate the existence of implicit bias of pre-training algorithms/optimizers---among models with the same minimal pre-training loss, they implicitly prefer more transferable ones. Toward understanding this implicit bias, we prove that SGD with standard mini-batch noise implicitly prefers flatter minima in language models, and empirically observe a strong correlation between flatness and downstream performance among models with the same minimal pre-training loss. We also prove in a synthetic langua

ge setting that among the models with the minimal pre-training loss, the flattest model transfers to downstream tasks.

Signal to Sequence Attention-Based Multiple Instance Network for Segmentation Free Inference of RNA Modifications
Christopher Hendra,Alexandre H. Thiery,Jonathan Goeke
Direct RNA sequencing technology works by allowing long RNA molecules to pass through tiny pores, generating electrical current, called squiggle, that are interpreted as a series of RNA nucleotides through the use of Deep Learning algorithms. The platform has also facilitated computational detection of RNA modifications via machine learning and statistical approaches as they cause detectable shift in the current generated as the modified nucleotides pass through the pores. Nevertheless, since modifications only occur in a handful of positions along the molecules, existing techniques require segmentation of the long squiggle in order to filter off irrelevant signals and this step produces large computational and storage overhead. Inspired by the recent work in vector similarity search, we introduce a segmentation-free approach by utilizing scaled-dot product attention to perform implicit segmentation and feature extraction of raw signals that correspond to sites of interest. We further demonstrate the feasibility of our approach by achieving significant speedup while maintaining competitive performance in m6A detection against existing state-of-the-art methods.
****
Interval-based Offline Policy Evaluation without Sufficient Exploration or Realizability
Kohei Miyaguchi,Hiroshi Kajino
We study the problem of offline policy evaluation (OPE),
where the goal is to estimate the value of given decision-making policy without interacting with the actual environment.
In particular, we consider the interval-based OPE, where the output is an interval rather than a point, indicating the uncertainty of the evaluation.
The interval-based estimation is especially important in OPE since,
when the data coverage is insufficient relative to the complexity of the environmental model,
any OPE method can be biased even with infinite sample size.
In this paper, we characterize the worst case of such irreducible bias, called the *minimax bias*, in terms of the discrepancy between the target policy and the data-sampling distribution,
and show that the marginal-importance-sampling (MIS) estimator achieves the minimax bias with an appropriate importance-weight function.
Motivated with this result, we then propose a new interval-based MIS estimator that asymptotically achieves the minimax bias.
****
A Differential Geometric View and Explainability of GNN on Evolving Graphs
Yazheng Liu,Xi Zhang,Sihong Xie
Graphs are ubiquitous in social networks and biochemistry, where Graph Neural Networks (GNN) are the state-of-the-art models for prediction. Graphs can be evolving and it is vital to formally model and understand how a trained GNN responds to graph evolution. We propose a smooth parameterization of the GNN predicted distributions using axiomatic attribution, where the distributions are on a low dimensional manifold within a high-dimensional embedding space. We exploit the differential geometric viewpoint to model distributional evolution as smooth curves on the manifold. We reparameterize families of curves on the manifold and design a convex optimization problem to find a unique curve that concisely approximates the distributional evolution for human interpretation. Extensive experiments on node classification, link prediction, and graph classification tasks with evolving graphs demonstrate the better sparsity, faithfulness, and intuitiveness of the proposed method over the state-of-the-art methods.
****
$\rm A^2Q$: Aggregation-Aware Quantization for Graph Neural Networks
Zeyu Zhu,Fanrong Li,Zitao Mo,Qinghao Hu,Gang Li,Zejian Liu,Xiaoyao Liang,Jian Ch

eng

As graph data size increases, the vast latency and memory consumption during inference pose a significant challenge to the real-world deployment of Graph Neural Networks (GNNs). While quantization is a powerful approach to reducing GNNs complexity, most previous works on GNNs quantization fail to exploit the unique characteristics of GNNs, suffering from severe accuracy degradation. Through an in-depth analysis of the topology of GNNs, we observe that the topology of the graph leads to significant differences between nodes, and most of the nodes in a graph appear to have a small aggregation value. Motivated by this, in this paper, we propose the Aggregation-Aware mixed-precision Quantization ($\rm A^2Q$) for GNNs, where an appropriate bitwidth is automatically learned and assigned to each node in the graph. To mitigate the vanishing gradient problem caused by sparse connections between nodes, we propose a Local Gradient method to serve the quantization error of the node features as the supervision during training. We also develop a Nearest Neighbor Strategy to deal with the generalization on unseen graphs. Extensive experiments on eight public node-level and graph-level datasets demonstrate the generality and robustness of our proposed method. Compared to the FP32 models, our method can achieve up to $18.8\times$ (i.e., 1.70bits) compression ratio with negligible accuracy degradation. Moreover, compared to the state-of-the-art quantization method, our method can achieve up to 11.4% and 9.5% accuracy improvements on the node-level and graph-level tasks, respectively, and up to $2\times$ speedup on a dedicated hardware accelerator.

Multi-Prompt Alignment for Multi-source Unsupervised Domain Adaptation

Haoran Chen,Zuxuan Wu,Yu-Gang Jiang

Most existing methods for multi-source unsupervised domain adaptation (UDA) rely on a common feature encoder to extract domain-invariant features. However, learning such an encoder involves updating the parameters of the entire network, which makes the optimization computationally expensive, particularly when coupled with min-max objectives. Inspired by recent advances in prompt learning that adapts high-capacity deep models for downstream tasks in a computationally economic way, we introduce Multi-Prompt Alignment (MPA), a simple yet efficient two-stage framework for multi-source UDA. Given a source and target domain pair, MPA first trains an individual prompt to minimize the domain gap through a contrastive loss, while tuning only a small set of parameters. Then, MPA derives a low-dimensional latent space through an auto-encoding process that maximizes the agreement of multiple learned prompts. The resulting embedding further facilitates generalization to unseen domains. Extensive experiments show that our method achieves state-of-the-art results on popular benchmark datasets while requiring substantially fewer tunable parameters. To the best of our knowledge, we are the first to apply prompt learning to the multi-source UDA problem and our method achieves the highest reported average accuracy of 54.1% on DomainNet, the most challenging UDA dataset to date, with only 15.9M parameters trained. More importantly, we demonstrate that the learned embedding space can be easily adapted to novel unseen domains.

Clean-image Backdoor: Attacking Multi-label Models with Poisoned Labels Only

Kangjie Chen,Xiaoxuan Lou,Guowen Xu,Jiwei Li,Tianwei Zhang

Multi-label models have been widely used in various applications including image annotation and object detection. The fly in the ointment is its inherent vulnerability to backdoor attacks due to the adoption of deep learning techniques. However, all existing backdoor attacks exclusively require to modify training inputs (e.g., images), which may be impractical in real-world applications. In this paper, we aim to break this wall and propose the first clean-image backdoor attack, which only poisons the training labels without touching the training samples. Our key insight is that in a multi-label learning task, the adversary can just manipulate the annotations of training samples consisting of a specific set of classes to activate the backdoor. We design a novel trigger exploration method to find convert and effective triggers to enhance the attack performance. We also propose three target label selection strategies to achieve different goals. Expe rimental results indicate that our clean-image backdoor can achieve a 98% attack success rate while preserving the model's functionality on the benign inputs. Besides, the proposed clean-image backdoor can evade existing state-of-the-art defenses.

Dense Correlation Fields for Motion Modeling in Action Recognition

Yichen Qian,Junyan Wang,Xiuyu Sun

The challenge of action recognition is to capture reasoning motion information. Compared to spatial convolution for appearance, the temporal component provides an additional (and important) clue for motion modeling, as a number of actions can be reliably recognized based on the motion information. In this paper, we present an effective and interpretable module, Dense Correlation Fields (DCF), which builds up dense visual correlation volumes at the feature level to model different motion patterns explicitly. To achieve this goal, we rely on a spatially hierarchical architecture that preserves both fine local information provided in the lower layer and the high-level semantic information from the deeper layer. Our method fuses spatial hierarchical correlation and temporal long-term correlation, which is better suited for small objects and large displacements. This module is extensible and can be plugged into many backbone architectures to accurately predict object interactions in the video. DCF shows consistent improvements over 2D CNNs and 3D CNNs baseline networks with 3.7% and 3.0% gains respectively on the standard video action benchmark of SSV1.

Variance Reduction is an Antidote to Byzantines: Better Rates, Weaker Assumptions and Communication Compression as a Cherry on the Top

Eduard Gorbunov,Samuel Horváth,Peter Richtárik,Gauthier Gidel

Byzantine-robustness has been gaining a lot of attention due to the growth of the interest in collaborative and federated learning. However, many fruitful directions, such as the usage of variance reduction for achieving robustness and communication compression for reducing communication costs, remain weakly explored in the field. This work addresses this gap and proposes Byz-VR-MARINA -- a new Byzantine-tolerant method with variance reduction and compression. A key message of our paper is that variance reduction is key to fighting Byzantine workers more effectively. At the same time, communication compression is a bonus that makes the process more communication efficient. We derive theoretical convergence guarantees for Byz-VR-MARINA outperforming previous state-of-the-art for general non-convex and Polyak-Lojasiewicz loss functions. Unlike the concurrent Byzantine-robust methods with variance reduction and/or compression, our complexity results are tight and do not rely on restrictive assumptions such as boundedness of the gradients or limited compression. Moreover, we provide the first analysis of a Byzantine-tolerant method supporting non-uniform sampling of stochastic gradients. Numerical experiments corroborate our theoretical findings.

What's Behind the Mask: Estimating Uncertainty in Image-to-Image Problems

Gilad Kutiel,Regev Cohen,Michael Elad,Daniel Freedman

Estimating uncertainty in image-to-image networks is an important task, particularly as such networks are being increasingly deployed in the biological and medical imaging realms. In this paper, we introduce a new approach to this problem based on masking. Given an existing image-to-image network, our approach computes a mask such that the distance between the masked reconstructed image and the masked true image is guaranteed to be less than a specified threshold, with high probability. The mask thus identifies the more certain regions of the reconstructed image. Our approach is agnostic to the underlying image-to-image network, and only requires triples of the input (degraded), reconstructed and true images for training. Furthermore, our method is agnostic to the distance metric used. As a result, one can use L_p-style distances or perceptual distances like LPIPS, which contrasts with interval-based approaches to uncertainty. Our theoretical guarantees derive from a conformal calibration procedure. We evaluate our mask-based approach to uncertainty on image colorization, image completion, and super-resolution tasks, demonstrating high quality performance on each.

A Time-Consistency Curriculum for Learning from Instance-Dependent Noisy Labels
Songhua Wu,Tianyi Zhou,Yuxuan Du,Jun Yu,Bo Han,Tongliang Liu

Many machine learning algorithms are known to be fragile on simple instance-independent noisy labels. However, noisy labels in real-world data are more devastating since they are produced by more complicated mechanisms in an instance-dependent manner. In this paper, we target this practical challenge of \textit{Instance-Dependent Noisy Labels} by jointly training
(1) a model reversely engineering the noise generating mechanism, which produces an \textit{instance-dependent mapping} between the clean label posterior and the observed noisy label; and (2) a robust classifier that produces clean label posteriors. Compared to previous methods, the former model is novel and enables end-to-end learning of the latter directly from noisy labels. An extensive empirical study indicates that the time-consistency of data is critical to the success of training both models and motivates us to develop a curriculum selecting training data based on their dynamics on the two models' outputs over the course of training. We show that the curriculum-selected data provide both clean labels and high-quality input-output pairs for training the two models. Therefore, it leads to promising and robust classification performance even in notably challenging settings of instance-dependent noisy labels where many SoTA methods could easily fail. Extensive experimental comparisons and ablation studies further demonstrate the advantages and significance of the time-consistency curriculum in learning from instance-dependent noisy labels on multiple benchmark datasets.

Efficient Personalized Federated Learning via Sparse Model-Adaptation
Daoyuan Chen,Liuyi Yao,Dawei Gao,Bolin Ding,Yaliang Li

Federated Learning (FL) aims to train machine learning models for multiple clients without sharing their own private data. Due to the heterogeneity of clients' local data distribution, recent studies explore the personalized FL that learns and deploys distinct local models with the help of auxiliary global models. However, the clients can be heterogeneous in terms of not only local data distribution, but also their computation and communication resources. The capacity and efficiency of personalized models are restricted by the lowest-resource clients, leading to sub-optimal performance and limited practicality of personalized FL. To overcome these challenges, we propose a novel approach named pFedGate for efficient personalized FL by adaptively and efficiently learning sparse local models. With a lightweight trainable gating layer, pFedGate enables clients to reach their full potential in model capacity by generating different sparse models accounting for both the heterogeneous data distributions and resource constraints. Meanwhile, the computation and communication efficiency are both improved thanks to the adaptability between the model sparsity and clients' resources. Further, we theoretically show that the proposed pFedGate has superior complexity with guaranteed convergence and generalization error. Extensive experiments show that pFedGate achieves superior global accuracy, individual accuracy and efficiency simultaneously over state-of-the-art methods, by up to 4.53\% accuracy improvement and 12x smaller model size. We also demonstrate that pFedGate performs better than competitors in the novel clients participation and partial clients participation scenarios, and can learn meaningful sparse local models adapted to different data distributions.

Momentum Tracking: Momentum Acceleration for Decentralized Deep Learning on Heterogeneous Data
Yuki Takezawa,Han Bao,Kenta Niwa,Ryoma Sato,Makoto Yamada

SGD with momentum acceleration is one of the key components for improving the performance of neural networks. For decentralized learning, a straightforward approach using momentum acceleration is Distributed SGD (DSGD) with momentum acceleration (DSGDm). However, DSGDm performs worse than DSGD when the data distributions are statistically heterogeneous. Recently, several studies have addressed this issue and proposed methods with momentum acceleration that are more robust to data heterogeneity than DSGDm, although their convergence rates remain dependent on data heterogeneity and decrease when the data distributions are heterogeneous. In this study, we propose Momentum Tracking, which is a method with momentum acceleration whose convergence rate is proven to be independent of data heterogeneity. More specifically, we analyze the convergence rate of Momentum Tracking in the standard deep learning setting, where the objective function is non-convex and the stochastic gradient is used. Then, we identify that it is independent of data heterogeneity for any momentum coefficient $\beta \in [0, 1)$. Through image classification tasks, we demonstrate that Momentum Tracking is more robust to data heterogeneity than the existing decentralized learning methods with momentum acceleration and can consistently outperform these existing methods when the data distributions are heterogeneous.

Deep Graph-Level Orthogonal Hypersphere Compression for Anomaly Detection

Yunhe Zhang,Yan Sun,Jinyu Cai,Jicong Fan

Graph-level anomaly detection aims to identify abnormal samples of a set of graphs in an unsupervised manner. It is non-trivial to find a reasonable decision boundary between normal data and anomalous data without using any anomalous data in the training stage, especially for data in graphs. This paper first proposes a novel deep graph-level anomaly detection model, which learns the graph representation with maximum mutual information between substructure features and global structure features while exploring a hypersphere anomaly decision boundary. The deep orthogonal projection layer is adopted to keep the training data distribution consistent with the decision hypersphere thus avoiding erroneous evaluations. We further propose projecting the normal data into the interval region between two co-centered hyperspheres, which makes the normal data distribution more compact and effectively overcomes the issue of outliers falling close to the center of the hypersphere. The numerical and visualization results on a few graph datasets demonstrate the effectiveness and superiority of our methods in comparison to many baselines and state-of-the-art.

****

Gradient Deconfliction via Orthogonal Projections onto Subspaces For Multi-task Learning

Shijie Zhu,Hui Zhao,Pengjie Wang,Hongbo Deng,Jian Xu,Bo Zheng

Although multi-task learning (MTL) has been a preferred approach and successfully applied in many real-world scenarios, MTL models are not guaranteed to outperform single-task models on all tasks mainly due to the negative effects of conflicting gradients among the tasks. In this paper, we fully examine the influence of conflicting gradients and further emphasize the importance and advantages of achieving non-conflicting gradients which allows simple but effective trade-off strategies among the tasks with stable performance. Base on our findings, we propose the Gradient Deconfliction via Orthogonal Projections onto Subspaces (GradOPS) spanned by other task-specific gradients. Our method not only solves all conflicts among the tasks, but can also effectively search for diverse solutions towards different trade-off preferences among the tasks. Theoretical analysis on convergence is provided, and performance of our algorithm is fully testified on multiple benchmarks in various domains. Results demonstrate that our method can effectively find multiple state-of-the-art solutions with different trade-off strategies among the tasks on multiple datasets.

Pareto Optimization for Active Learning under Out-of-Distribution Data Scenarios

Xueying Zhan,Zeyu Dai,Qingzhong Wang,Haoyi Xiong,Dejing Dou,Qing Li,Antoni B. Chan

Pool-based Active Learning (AL) has achieved great success in minimizing labeling costs by sequentially selecting the most informative unlabeled samples from a large unlabeled data pool and querying their labels from oracle/annotators. However, existing AL sampling schemes might not work well under out-of-distribution (OOD) data scenarios, where the unlabeled data pool contains data samples that do not belong to the pre-defined categories of the target task. Achieving good AL performance under OOD data scenarios is a challenging task due to the natural conflict between AL sampling strategies and OOD sample detection -- both more inf ormative in-distribution (ID) data and OOD data in unlabeled data pool may be assigned high informativeness scores (e.g., high entropy) during AL processes. In this paper, we propose a sampling scheme, Monte-Carlo Pareto Optimization for Active Learning (POAL), which selects optimal subsets of unlabeled samples with \emph{fixed batch size} from the unlabeled data pool. We cast the AL sampling task as a multi-objective optimization problem and utilize Pareto optimization based on two conflicting objectives: (1) the typical AL sampling scheme (e.g., maximum entropy), and (2) the confidence of not being an OOD data sample. Experimental results show the effectiveness of our POAL on classical Machine Learning (ML) and Deep Learning (DL) tasks.

Self-Consistent Learning: Cooperation between Generators and Discriminators
Tong Wu,Hao Wang,Zhongshen Zeng,Wei Wang,Hai-Tao Zheng,Jiaxing Zhang

Using generated data to improve the performance of downstream discriminative models has recently gained popularity due to the great development of pre-trained language models. In most previous studies, generative models and discriminative models are trained separately and thus could not adapt to any changes in each other. As a result, the generated samples can easily deviate from the real data distribution, while the improvement of the discriminative model quickly reaches saturation. Generative adversarial networks (GANs) train generative models via an adversarial process with discriminative models to achieve joint training. However, the training of standard GANs is notoriously unstable and often falls short of convergence. In this paper, to address these issues, we propose a $\textit{self-consistent learning}$ framework, in which a discriminator and a generator are cooperatively trained in a closed-loop form. The discriminator and the generator enhance each other during multiple rounds of alternating training until a scoring consensus is reached. This framework proves to be easy to train and free from instabilities such as mode collapse and non-convergence. Extensive experiments on sentence semantic matching demonstrate the effectiveness of the proposed framework: the discriminator achieves 10+ AP of improvement on the zero-shot setting and new state-of-the-art performance on the full-data setting.

****

Learning Dynamical Characteristics with Neural Operators for Data Assimilation
Yi Xiao,Wei Xue

Data assimilation refers to a group of algorithms that combines numerical models with observations to obtain an optimal estimation of the system's states. In areas like earth science, numerical models are usually formulated by differential equations, also known as the prior dynamics. It is a great challenge for neural networks to properly exploit the dynamical characteristics for data assimilation, because first, it is difficult to represent complicated dynamical characteristics in neural networks, and second, the dynamics are likely to be biased. The state-of-the-art neural networks borrow from the traditional method to introduce dynamical characteristics by optimizing the 4D-Var objective function in which the dynamics are inherently quantified, but the iterative optimization process leads to high computational cost. In this paper, we develop a novel deep learning framework with neural operators for data assimilation. The key novelty of our proposed approach is that we design a so-called flow operator through self-supervised learning to explicitly learn dynamical characteristics for reconstructed states. Numerical experiments on the Lorenz-63 and Lorenz-96 systems, which are the standard benchmarks for data assimilation performance evaluation, show that the proposed method is at least three times faster than state-of-the-art neural networks, and reduces the dynamic loss by two orders of magnitude. It is also demonstrated that our method is well-adapted to biases in the prior dynamics.

****

Lost Domain Generalization Is a Natural Consequence of Lack of Training Domains
Yimu Wang,Hongyang Zhang

We show a hardness result for the number of training domains required to achieve a small population error in the test domain. Although many domain generalization algorithms have been developed under various domain-invariance assumptions, there is significant evidence to indicate that out-of-distribution (o.o.d.) test a ccuracy of state-of-the-art o.o.d. algorithms is on par with empirical risk minimization and random guess on the domain generalization benchmarks such as DomainBed. In this work, we analyze its cause and attribute the lost domain generalization to the lack of training domains. We show that, in a minimax lower bound fashion, \emph{any} learning algorithm that outputs a classifier with an ϵ excess error to the Bayes optimal classifier requires at least $\mathrm{poly}(1/\epsilon)$ number of training domains, even though the number of training data sampled from each training domain is large. Experiments on the DomainBed benchmark demonstrate that o.o.d. test accuracy is monotonically increasing as the number of training domains increases. Our result sheds light on the intrinsic hardness of domain generalization and suggests benchmarking o.o.d. algorithms by the datasets with a sufficient number of training domains.

Graph Neural Networks for Link Prediction with Subgraph Sketching

Benjamin Paul Chamberlain,Sergey Shirobokov,Emanuele Rossi,Fabrizio Frasca,Thomas Markovich,Nils Yannick Hammerla,Michael M. Bronstein,Max Hansmire

Many Graph Neural Networks (GNNs) perform poorly compared to simple heuristics on Link Prediction (LP) tasks. This is due to limitations in expressive power such as the inability to count triangles (the backbone of most LP heuristics) and because they can not distinguish automorphic nodes (those having identical structural roles). Both expressiveness issues can be alleviated by learning link (rather than node) representations and incorporating structural features such as triangle counts. Since explicit link representations are often prohibitively expensive, recent works resorted to subgraph-based methods, which have achieved state-of-the-art performance for LP, but suffer from poor efficiency due to high levels of redundancy between subgraphs. We analyze the components of subgraph GNN (SGNN) methods for link prediction. Based on our analysis, we propose a novel full-graph GNN called ELPH (Efficient Link Prediction with Hashing) that passes subgraph sketches as messages to approximate the key components of SGNNs without explicit subgraph construction. ELPH is provably more expressive than Message Passing GNNs (MPNNs). It outperforms existing SGNN models on many standard LP benchmarks while being orders of magnitude faster. However, it shares the common GNN limitation that it is only efficient when the dataset fits in GPU memory. Accordingly, we develop a highly scalable model, called BUDDY, which uses feature precomputation to circumvent this limitation without sacrificing predictive performance. Our experiments show that BUDDY also outperforms SGNNs on standard LP benchmarks while being highly scalable and faster than ELPH.

Multitask Prompt Tuning Enables Parameter-Efficient Transfer Learning

Zhen Wang,Rameswar Panda,Leonid Karlinsky,Rogerio Feris,Huan Sun,Yoon Kim

Prompt tuning, in which a base pretrained model is adapted to each task via conditioning on learned prompt vectors, has emerged as a promising approach for efficiently adapting large language models to multiple downstream tasks. However, existing methods typically learn soft prompt vectors from scratch, and it has not been clear how to exploit the rich cross-task knowledge with prompt vectors in a multitask learning setting. We propose multitask prompt tuning (MPT), which first learns a single transferable prompt by distilling knowledge from multiple task-specific source prompts. We then learn multiplicative low rank updates to this shared prompt to efficiently adapt it to each downstream target task. Extensive experiments on 23 NLP datasets demonstrate that our proposed approach outperforms the state-of-the-art methods, including the full finetuning baseline in some cases, despite only tuning 0.035% as many task-specific parameters.

Personalized Federated Hypernetworks for Privacy Preservation in Multi-Task Reinforcement Learning

Doseok Jang,Larry Yan,Lucas Spangher,Selvaprabu Nadarajah,Costas Spanos

Multi-Agent Reinforcement Learning currently focuses on implementations where all data and training can be centralized to one machine. But what if local agents are split across multiple tasks, and need to keep data private between each? We develop the first application of Personalized Federated Hypernetworks (PFH) to R

einforcement Learning (RL). We then present a novel application of PFH to few-shot transfer, and demonstrate significant initial increases in learning. PFH has never been demonstrated beyond supervised learning benchmarks, so we apply PFH to an important domain: RL price-setting for energy demand response. We consider a general case across where agents are split across multiple microgrids, wherein energy consumption data must be kept private within each microgrid. Together, our work explores how the fields of personalized federated learning and RL can come together to make learning efficient across multiple tasks while keeping data secure.

CBLab: Scalable Traffic Simulation with Enriched Data Supporting
Chumeng Liang,Zherui Huang,Yicheng Liu,Zhanyu Liu,Guanjie Zheng,Hanyuan Shi,Yuhao Du,FULIANG LI,Zhenhui Li
Traffic simulation provides interactive data for the optimization of traffic policies. However, existing traffic simulators are limited by their lack of scalability and shortage in input data, which prevents them from generating interactive data from traffic simulation in the scenarios of real large-scale city road networks.

In this paper, we present \textbf{C}ity \textbf{B}rain \textbf{Lab}, a toolkit for scalable traffic simulation. CBLab is consist of three components: CBEngine, CBData, and CBScenario. CBEngine is a highly efficient simulator supporting large-scale traffic simulation. CBData includes a traffic dataset with road network data of 100 cities all around the world. We also develop a pipeline to conduct a one-click transformation from raw road networks to input data of our traffic simulation. Combining CBEngine and CBData allows researchers to run scalable traffic simulations in the road network of real large-scale cities. Based on that, CBScenario implements an interactive environment and several baseline methods for two scenarios of traffic policies respectively, with which traffic policies adaptable for large-scale urban traffic can be trained and tuned. To the best of our knowledge, CBLab is the first infrastructure supporting traffic policy optimization in large-scale urban scenarios. The code is available on GitHub:~\url{https://github.com/CityBrainLab/CityBrainLab.git}.

Personalized Decentralized Bilevel Optimization over Stochastic and Directed Networks
Naoyuki Terashita,Satoshi Hara
While personalization in distributed learning has been extensively studied, existing approaches employ dedicated algorithms to optimize their specific type of parameters (e.g., client clusters or model interpolation weights), making it difficult to simultaneously optimize different types of parameters to yield better performance.
Moreover, their algorithms require centralized or static undirected communication networks, which can be vulnerable to center-point failures or deadlocks.
This study proposes optimizing various types of parameters using a single algorithm that runs on more practical communication environments.
First, we propose a gradient-based bilevel optimization that reduces most personalization approaches to the optimization of client-wise hyperparameters.
Second, we propose a decentralized algorithm to estimate gradients with respect to the hyperparameters, which can run even on stochastic and directed communication networks.
Our empirical results demonstrated that the gradient-based bilevel optimization enabled combining existing personalization approaches which led to state-of-the-art performance, confirming it can perform on multiple simulated communication environments including a stochastic and directed network.

ContextSpeech: Expressive and Efficient Text-to-Speech for Paragraph Reading
Yujia Xiao,Shaofei Zhang,Xi Wang,Xu Tan,Lei He,Frank K. Soong,sheng zhao
Although Text-to-Speech (TTS) has made rapid progress in speech quality at sentence level, it still faces a lot of challenges in paragraph / long-form reading.

Synthesizing sentence by sentence in a paragraph and then concatenating them together will cause inconsistent issues that affect paragraph-level expressiveness. While directly modelling all the sentences in a paragraph will incur large computation / memory cost. In this paper, we develop a TTS system called ContextSpeech, which models the contextual information in a paragraph for coherence and expressiveness without largely increasing the computation or memory cost. On the one hand, we introduce a memory-cached recurrence mechanism to let the current sentence see more history information both on the text and speech sides. On the other hand, we construct text-based semantic information in a hierarchical structure, which can broaden the horizon and incorporate the future information. Additionally, we use a linearized self-attention with compatible relative-position encoding to reduce the computation / memory cost. Experiments show that ContextSpeech significantly improves the paragraph-level voice quality and prosody expressiveness in terms of both subjective and objective evaluation metrics. Furthermore, ContextSpeech achieves better model efficiency in both training and inference stage.

Learning Object Affordance with Contact and Grasp Generation

Haoming Li,Xinzhuo Lin,Yang Zhou,Xiang Li,Jiming Chen,Qi Ye

Understanding object affordance can help in designing better and more robust robotic grasping. Existing work in the computer vision community formulates the object affordance understanding as a grasping pose generation problem, which treats the problem as a black box by learning a mapping between objects and the distributions of possible grasping poses for the objects. On the other hand, in the robotics community, estimating object affordance represented by contact maps is of the most importance as localizing the positions of the possible affordance can help the planning of grasping actions. In this paper, we propose to formulate the object affordance understanding as both contacts and grasp poses generation. we factorize the learning task into two sequential stages, rather than the black-box strategy: (1) we first reason the contact maps by allowing multi-modal contact generation; (2) assuming that grasping poses are fully constrained given contact maps, we learn a one-to-one mapping from the contact maps to the grasping poses. Further, we propose a penetration-aware partial optimization from the intermediate contacts. It combines local and global optimization for the refinement of the partial poses of the generated grasps exhibiting penetration. Extensive validations on two public datasets show our method outperforms state-of-the-art methods regarding grasp generation on various metrics.

Deep Graph-Level Clustering Using Pseudo-Label-Guided Mutual Information Maximization Network

Jinyu Cai,Yi Han,Wenzhong Guo,Jicong Fan

In this work, we study the problem of partitioning a set of graphs into different groups such that the graphs in the same group are similar while the graphs in different groups are dissimilar. This problem was rarely studied previously, although there have been a lot of work on node clustering and graph classification. The problem is challenging because it is difficult to measure the similarity or distance between graphs. One feasible approach is using graph kernels to compute a similarity matrix for the graphs and then performing spectral clustering, but the effectiveness of existing graph kernels in measuring the similarity between graphs is very limited. To solve the problem, we propose a novel method called Deep Graph-Level Clustering (DGLC). DGLC utilizes a graph isomorphism network to learn graph-level representations by maximizing the mutual information between the representations of entire graphs and substructures, under the regularization of a clustering module that ensures discriminative representations via pseudo labels. DGLC achieves graph-level representation learning and graph-level clustering in an end-to-end manner. The experimental results on six benchmark datasets of graphs show that our DGLC has state-of-the-art performance in comparison to many baselines.

Deep Generative Model based Rate-Distortion for Image Downscaling Assessment

Yuanbang Liang,Bhavesh Garg,Paul L Rosin,Yipeng Qin

In this paper, we propose a novel measure, namely Image Downscaling Assessment by Rate-Distortion (IDA-RD), to quantitatively evaluate image downscaling algorithms. In contrast to image-based methods that measure the quality of downscaled images, ours is process-based that draws ideas from the rate-distortion theory to measure the distortion incurred during downscaling. Our main idea is that downscaling and super-resolution (SR) can be viewed as the encoding and decoding processes in the rate-distortion model, respectively, and that a downscaling algorithm that preserves more details in the resulting low-resolution (LR) images should lead to less distorted high-resolution (HR) images in SR. In other words, the distortion should increase as the downscaling algorithm deteriorates. However, it is non-trivial to measure this distortion as it requires the SR algorithm to be blind and stochastic. Our key insight is that such requirements can be met by recent SR algorithms based on deep generative models that can find all matching HR images for a given LR image on their learned image manifolds. Empirically, we first validate our IDA-RD measure with synthetic downscaling algorithms which simulate distortions by adding various types and levels of degradations to the downscaled images. We then test our measure on traditional downscaling algorithms such as bicubic, bilinear, nearest neighbor interpolation as well as state-of-the-art downscaling algorithms such as DPID, L0-regularized downscaling, and Perceptual downscaling. Experimental results show the effectiveness of our IDA-RD in evaluating image downscaling algorithms.

****

Selective Classifier Ensemble

Qiang Ding,Yixuan Cao,Ping Luo

Selective classification allows a machine learning model to abstain on some hard inputs and thus improve the safety of its predictions. In this paper, we study the ensemble of selective classifiers, i.e. selective classifier ensemble, which combines several weak selective classifiers to obtain a more powerful model. We prove that under some assumptions, the ensemble has a lower selective risk than the individual model under a range of coverage. This is nontrivial since the selective risk is a non-convex function of the model prediction. The assumptions and the theoretical result are supported by systematic experiments on both computer vision and natural language processing tasks. A surprising empirical result is that a simple selective classifier ensemble, namely, the ensemble model with maximum probability as confidence, is the state-of-the-art selective classifier. For instance, on CIFAR-10, using the same VGG-16 backbone model, this ensemble reduces the AURC (Area Under Risk-Coverage Curve) by about 24%, relative to the previous state-of-the-art method.

Better Generative Replay for Continual Federated Learning

Daiqing Qi,Handong Zhao,Sheng Li

Federated Learning (FL) aims to develop a centralized server that learns from distributed clients via communications without accessing the clients’ local data. However, existing works mainly focus on federated learning in a single task scenario with static data. In this paper, we introduce the continual federated learning (CFL) problem, where clients incrementally learn new tasks and history data can- not be stored due to certain reasons, such as limited storage and data retention policy 1. Generative replay (GR) based methods are effective for continual learning without storing history data. However, we fail when trying to intuitively adapt GR models for this setting. By analyzing the behaviors of clients during training, we find the unstable training process caused by distributed training on non-IID data leads to a notable performance degradation. To address this problem, we propose our FedCIL model with two simple but effective solutions: 1. model consolidation and 2. consistency enforcement. Experimental results on multiple benchmark datasets demonstrate that our method significantly outperforms baselines. Code is available at: https://github.com/daiqing98/FedCIL.

Enhancing the Transferability of Adversarial Examples via a Few Queries and Fuzzy Domain Eliminating

Xiangyuan Yang,Jie Lin,hanlin Zhang,Xinyu Yang,Peng Zhao

Due to the vulnerability of deep neural networks, the black-box attack has drawn great attention from the community. Though transferable priors decrease the query number of the black-box query attacks in recent efforts, the average number of queries is still larger than 100, which is easily affected by the number of queries limit policy. In this work, we propose a novel method called query prior-based method to enhance the attack transferability of the family of fast gradient sign methods by using a few queries. Specifically, for the untargeted attack, we find that the successful attacked adversarial examples prefer to be classified as the wrong categories with higher probability by the victim model. Therefore, the weighted augmented cross-entropy loss is proposed to reduce the gradient angle between the surrogate model and the victim model for enhancing the transferability of the adversarial examples. In addition, the fuzzy domain eliminating technique is proposed to avoid the generated adversarial examples getting stuck in the local optimum. Specifically, we define the fuzzy domain of the input example x in the ϵ-ball of x. Then, temperature scaling and fuzzy scaling are utilized to eliminate the fuzzy domain for enhancing the transferability of the generated adversarial examples. Theoretical analysis and extensive experiments demonstrate that our method could significantly improve the transferability of gradient-based adversarial attacks on CIFAR10/100 and ImageNet and outperform the black-box query attack with the same few queries.

Label-distribution-agnostic Ensemble Learning on Federated Long-tailed Data

Yaopei Zeng,Lei Liu,Baoyuan Wu,ShaoGuo Liu,Li Liu

Federated Learning (FL) is a distributed machine learning paradigm that enables devices to collaboratively train a shared model. However, the long-tailed distribution in nature deteriorates the performance of the global model, which is difficult to address due to data heterogeneity, e.g., local clients may exhibit diverse imbalanced class distributions. Moreover, existing re-balance strategies generally utilize label distribution as the class prior, which may conflict with the privacy requirement of FL. To this end, we propose a Label-Distribution-Agnostic Ensemble (LDAE) learning framework to integrate heterogeneous data distributions using multiple experts, which targets to optimize a balanced global objective under privacy protection. In particular, we derive a privacy-preserving proxy from the model updates of clients to guide the grouping and updating of multiple experts. Knowledge from clients can be aggregated via implicit interactions among different expert groups. We theoretically and experimentally demonstrate that (1) there is a global objective gap between global and local re-balance strategies\footnote{The local re-balance strategy means that each client utilizes re-balance methods based on the local label distribution, while the global re-balance strategy applies re-balance methods using global label distribution as the class-wise prior.} and (2) with protecting data privacy, the proxy can be used as an alternative to label distribution for existing class prior based re-balance strategies. Extensive experiments on long-tailed decentralized datasets demonstrate the effectiveness of our method, showing superior performance to state-of-the-art methods.

Generative Modelling with Inverse Heat Dissipation

Severi Rissanen,Markus Heinonen,Arno Solin

While diffusion models have shown great success in image generation, their noise-inverting generative process does not explicitly consider the structure of images, such as their inherent multi-scale nature. Inspired by diffusion models and the empirical success of coarse-to-fine modelling, we propose a new diffusion-like model that generates images through stochastically reversing the heat equation, a PDE that locally erases fine-scale information when run over the 2D plane of the image. We interpret the solution of the forward heat equation with constant additive noise as a variational approximation in the diffusion latent variable model. Our new model shows emergent qualitative properties not seen in standard diffusion models, such as disentanglement of overall colour and shape in images. Spectral analysis on natural images highlights connections to diffusion models and reveals an implicit coarse-to-fine inductive bias in them.

Self-supervision through Random Segments with Autoregressive Coding (RandSAC)

Tianyu Hua,Yonglong Tian,Sucheng Ren,Michalis Raptis,Hang Zhao,Leonid Sigal

Inspired by the success of self-supervised autoregressive representation learning in natural language (GPT and its variants), and advances in recent visual architecture design with Vision Transformers (ViTs), in this paper, we explore the effects various design choices have on the success of applying such training strategies for visual feature learning. Specifically, we introduce a novel strategy that we call Random Segments with Autoregressive Coding (RandSAC). In RandSAC, we group patch representations (image tokens) into hierarchically arranged segments; within each segment, tokens are predicted in parallel, similar to BERT, while across segment predictions are sequential, similar to GPT. We illustrate that randomized serialization of the segments significantly improves the performance and results in distribution over spatially-long (across-segments) and -short (within-segment) predictions which are effective for feature learning. We illustrate the pertinence of these design choices and explore alternatives on a number of datasets (e.g., CIFAR10, ImageNet). While our pre-training strategy works with vanilla Transformer, we also propose a conceptually simple, but highly effective, addition to the decoder that allows learnable skip-connections to encoder feature layers, which further improves the performance.

Rarity Score : A New Metric to Evaluate the Uncommonness of Synthesized Images

Jiyeon Han,Hwanil Choi,Yunjey Choi,Junho Kim,Jung-Woo Ha,Jaesik Choi

Evaluation metrics in image synthesis play a key role to measure performances of generative models. However, most metrics mainly focus on image fidelity. Existing diversity metrics are derived by comparing distributions, and thus they cannot quantify the diversity or rarity degree of each generated image. In this work, we propose a new evaluation metric, called `rarity score', to measure both image-wise uncommonness and model-wise diversified generation performance.

We first show empirical observation that typical samples are close to each other and distinctive samples are far from each other in nearest-neighbor distances on latent spaces represented by feature extractor networks such as VGG16. We then show that one can effectively filter typical or distinctive samples with the proposed metric. We also use our metric to demonstrate that the extent to which different generative models produce rare images can be effectively compared. Further, our metric can be used to compare rarities between datasets that share the same concept such as CelebA-HQ and FFHQ. Finally, we analyze the use of metrics in different designs of feature extractors to better understand the relationship between feature spaces and resulting high-rarity images. Code will be publicly available for the research community.

Benchmarking Approximate k-Nearest Neighbour Search for Big High Dimensional Dynamic Data

Ben Harwood,Amir Dezfouli,Iadine Chades

Approximate k-Nearest Neighbour (ANN) methods are commonly used for mining information from big high-dimensional datasets. For each application the high-level dataset properties and run-time requirements determine which method will provide the most suitable tradeoffs. However, due to a significant lack of comprehensive benchmarking, judicious method selection is not currently possible for ANN applications that involve frequent online changes to datasets. Here we address this issue by building upon existing benchmarks for static search problems to provide a new benchmarking framework for big high dimensional dynamic data. We apply our framework to dynamic scenarios modelled after common real world applications. In all cases we are able to identify a suitable recall-runtime tradeoff to improve upon a worst-case exhaustive search. Our framework provides a flexible solution to accelerate future ANN research and enable researchers in other online data-rich domains to find suitable methods for handling their ANN searches.

Semi-Supervised Offline Reinforcement Learning with Action-Free Trajectories

Qinqing Zheng,Mikael Henaff,Brandon Amos,Aditya Grover

Natural agents can effectively learn from multiple data sources that differ in size, quality, and types of measurements. We study this heterogeneity in the context of offline reinforcement learning (RL) by introducing a new, practically motivated semi-supervised setting. Here, an agent has access to two sets of trajectories: labelled trajectories containing state, action, reward triplets at every timestep, along with unlabelled trajectories that contain only state and reward information. For this setting, we develop a simple meta-algorithmic pipeline that learns an inverse-dynamics model on the labelled data to obtain proxy-labels for the unlabelled data, followed by the use of any offline RL algorithm on the true and proxy-labelled trajectories. Empirically, we find this simple pipeline to be highly successful --- on several D4RL benchmarks~\cite{fu2020d4rl}, certain offline RL algorithms can match the performance of variants trained on a fully labeled dataset even when we label only 10\% trajectories from the low return regime. Finally, we perform a large-scale controlled empirical study investigating the interplay of data-centric properties of the labelled and unlabelled datasets, with algorithmic design choices (e.g., inverse dynamics, offline RL algorithm) to identify general trends and best practices for training RL agents on semi-supervised offline datasets.

E-Forcing: Improving Autoregressive Models by Treating it as an Energy-Based One

Yezhen Wang,Tong Che,Bo Li,Kaitao Song,Hengzhi Pei,Yoshua Bengio,Dongsheng Li

Autoregressive generative models are commonly used to solve tasks involving sequential data. They have, however, been plagued by a slew of inherent flaws due to the intrinsic characteristics of chain-style conditional modeling (e.g., exposure bias or lack of long-range coherence), severely limiting their ability to model distributions properly. In this paper, we propose a unique method termed E-Forcing for training autoregressive generative models that takes advantage of a well-designed energy-based learning objective. By leveraging the extra degree of freedom of the softmax operation, we are allowed to make the autoregressive model itself an energy-based model for measuring the likelihood of input without introducing any extra parameters. Furthermore, we show that with the help of E-Forcing, we can alleviate the above flaws for autoregressive models. Extensive empirical results, covering numerous benchmarks demonstrate the effectiveness of the proposed approach.

****

Masked Vector Quantization

David D Nguyen,David Liebowitz,Surya Nepal,Salil S. Kanhere

Generative models with discrete latent representations have recently demonstrated an impressive ability to learn complex high-dimensional data distributions. However, their performance relies on a long sequence of tokens per instance and a large number of codebook entries, resulting in long sampling times and considerable computation to fit the categorical posterior.

To address these issues, we propose the Masked Vector Quantization (MVQ) framework which increases the representational capacity of each code vector by learning mask configurations via a stochastic winner-takes-all training regime called Multiple Hypotheses Dropout (MH-Dropout). On ImageNet 64$\times$64, reduces FID in existing vector quantization architectures by up to 68% at 2 tokens per instance and 57% at 5 tokens. These improvements widen as codebook entries is reduced and allows for $7\textup{-}45\times$ speed-up in token sampling during inference. As an additional benefit, we find that smaller latent spaces lead to MVQ identifying transferable visual representations where multiple can be smoothly combined.

****

On the Importance of the Policy Structure in Offline Reinforcement Learning

Takayuki Osa,Akinobu Hayashi,Pranav Deo,Naoki Morihira,Takahide Yoshiike

Offline reinforcement learning (RL) has attracted a great deal of attention recently as an approach to utilizing past experience to learn a policy. Recent studies have reported the challenges of offline RL, such as estimating the values of actions that are out of the data distribution. To mitigate the issues of offline

RL, we propose an algorithm that leverages a mixture of deterministic policies. With our framework, the state-action space is divided by learning discrete latent variables, and sub-policies corresponding to each region are trained. The proposed algorithm, which we call Value-Weighted Variational Auto-Encoder (V2AE), is derived by considering the variational lower bound of the offline RL objective function. The aim of this work is to shed lights on the importance on the policy structure in offline RL. We show empirically that the use of the proposed mixture policy can reduce the accumulation of the approximation error in offline RL, which was reported in previous studies. Experimental results also indicate that introducing the policy structure improves the performance on tasks with D4RL benchmarking datasets.

Bandit Learning in Many-to-one Matching Markets with Uniqueness Conditions
Liya Guo,Zilong Wang,Shuai Li
An emerging line of research is dedicated to the problem of one-to-one matching markets with bandits, where the preference of one side is unknown and thus we need to match while learning the preference through multiple rounds of interaction. However, in many real-world applications such as online recruitment platform for short-term workers, one side of the market can select more than one participant from the other side, which motivates the study of the many-to-one matching problem. Moreover, the existence of a unique stable matching is crucial to the competitive equilibrium of the market. In this paper, we first introduce a more general new \textit{$\tilde{\alpha}$}-condition to guarantee the uniqueness of stable matching in many-to-one matching problems, which generalizes some established uniqueness conditions such as \textit{SPC} and \textit{Serial Dictatorship}, and recovers the known α-condition if the problem is reduced to one-to-one matching. Under this new condition, we design an MO-UCB-D4 algorithm with $O\left(\frac{NK\log(T)}{\Delta^2}\right)$ regret bound, where T is the time horizon, N is the number of agents, K is the number of arms, and Δ is the minimum reward gap. Extensive experiments show that our algorithm achieves uniform good performances under different uniqueness conditions.

Transformer-Patcher: One Mistake Worth One Neuron
Zeyu Huang,Yikang Shen,Xiaofeng Zhang,Jie Zhou,Wenge Rong,Zhang Xiong
Large Transformer-based Pretrained Language Models (PLMs) dominate almost all Natural Language Processing (NLP) tasks. Nevertheless, they still make mistakes from time to time. For a model deployed in an industrial environment, fixing these mistakes quickly and robustly is vital to improve user experiences. Previous works formalize such problems as Model Editing (ME) and mostly focus on fixing one mistake. However, the one-mistake-fixing scenario is not an accurate abstraction of the real-world challenge. In the deployment of AI services, there are ever-emerging mistakes, and the same mistake may recur if not corrected in time. Thus a preferable solution is to rectify the mistakes as soon as they appear nonstop. Therefore, we extend the existing ME into the Sequential Model Editing (SME) to help develop more practical editing methods. Our study shows that current ME methods either fail to make a sequence of edits or to remember previous edits. We then introduce Transformer-Patcher, a novel model editor that can shift the behavior of transformer-based models by simply adding and training a few neurons in the last Feed-Forward Network layer. Experimental results on both classification and generation tasks show that Transformer-Patcher can successively correct up to thousands of errors (Reliability) and generalize to their equivalent inputs (Generality) while retaining the model’s accuracy on irrelevant inputs (Locality). Our method outperforms previous fine-tuning and HyperNetwork-based methods and achieves state-of-the-art performance for Sequential Model Editing (SME).
****

Corrupted Image Modeling for Self-Supervised Visual Pre-Training
Yuxin Fang,Li Dong,Hangbo Bao,Xinggang Wang,Furu Wei
We introduce Corrupted Image Modeling (CIM) for self-supervised visual pre-training. CIM uses an auxiliary generator with a small trainable BEiT to corrupt the input image instead of using artificial [MASK] tokens, where some patches are ra

ndomly selected and replaced with plausible alternatives sampled from the BEiT output distribution. Given this corrupted image, an enhancer network learns to either recover all the original image pixels, or predict whether each visual token is replaced by a generator sample or not. The generator and the enhancer are simultaneously trained and synergistically updated. After pre-training, the enhancer can be used as a high-capacity visual encoder for downstream tasks. CIM is a general and flexible visual pre-training framework that is suitable for various network architectures. For the first time, CIM demonstrates that both ViT and CNN can learn rich visual representations using a unified, non-Siamese framework. Experimental results show that our approach achieves compelling results in vision benchmarks, such as ImageNet classification and ADE20K semantic segmentation.

Semi-Implicit Variational Inference via Score Matching
Longlin Yu,Cheng Zhang

Semi-implicit variational inference (SIVI) greatly enriches the expressiveness of variational families by considering implicit variational distributions defined in a hierarchical manner. However, due to the intractable densities of variational distributions, current SIVI approaches often use surrogate evidence lower bounds (ELBOs) or employ expensive inner-loop MCMC runs for unbiased ELBOs for training. In this paper, we propose SIVI-SM, a new method for SIVI based on an alternative training objective via score matching. Leveraging the hierarchical structure of semi-implicit variational families, the score matching objective allows a minimax formulation where the intractable variational densities can be naturally handled with denoising score matching. We show that SIVI-SM closely matches the accuracy of MCMC and outperforms ELBO-based SIVI methods in a variety of Bayesian inference tasks.

Sharper Bounds for Uniformly Stable Algorithms with Stationary Mixing Process
Shi Fu,Yunwen Lei,Qiong Cao,Xinmei Tian,Dacheng Tao

Generalization analysis of learning algorithms often builds on a critical assumption that training examples are independently and identically distributed, which is often violated in practical problems such as time series prediction. In this paper, we use algorithmic stability to study the generalization performance of learning algorithms with ψ-mixing data, where the dependency between observations weakens over time. We show uniformly stable algorithms guarantee high-probability generalization bounds of the order $O(1/\sqrt{n})$ (within a logarithmic factor), where n is the sample size. We apply our general result to specific algorithms including regularization schemes, stochastic gradient descent and localized iterative regularization, and develop excess population risk bounds for learning with ψ-mixing data. Our analysis builds on a novel moment bound for weakly-dependent random variables on a φ-mixing sequence and a novel error decomposition of generalization error.

Few-Shot Anomaly Detection on Industrial Images through Contrastive Fine-Tuning
Jingyi Liao,Xun Xu,Manh Cuong Nguyen,Chuan-Sheng Foo

Detecting abnormal products through imagery data is essential to the quality control in manufacturing. Existing approaches towards anomaly detection~(AD) often rely on substantial amount of anomaly-free samples to train representation and density models. Nevertheless, large anomaly-free datasets may not always be available before inference stage and this requires building an anomaly detection framework with only a handful of normal samples, a.k.a. few-shot anomaly detection (FSAD). We propose two techniques to address the challenges in FSAD. First, we employ a model pretrained on large source dataset to initialize model weights. To ameliorate the covariate shift between source and target domains, we adopt contrastive training on the few-shot target domain data. Second, to encourage learning representations suitable for downstream AD, we further incorporate cross-instance pairs to increase tightness within normal sample cluster and better separation between normal and synthesized negative samples. Extensive evaluations on six few-shot anomaly detection benchmarks demonstrate the effectiveness of the proposed method.

Rate-Distortion Optimized Post-Training Quantization for Learned Image Compression

Junqi Shi,Ming Lu,fangdong chen,Shiliang Pu,Zhan Ma

Quantizing floating-point neural network to its fixed-point representation is crucial for Learned Image Compression (LIC) because it ensures the decoding consistency for interoperability and reduces space-time complexity for implementation. Existing solutions often have to retrain the network for model quantization which is time consuming and impractical. This work suggests the use of Post-Training Quantization (PTQ) to directly process pretrained, off-the-shelf LIC models. We theoretically prove that minimizing the mean squared error (MSE) in PTQ is sub-optimal for compression task and thus develop a novel Rate-Distortion (R-D) Optimized PTQ (RDO-PTQ) to best retain the compression performance. Such RDO-PTQ just needs to compress few images (e.g., 10) to optimize the transformation of weight, bias, and activation of underlying LIC model from its native 32-bit floating-point (FP32) format to 8-bit fixed-point (INT8) precision for fixed-point inference onwards. Experiments reveal outstanding efficiency of the proposed method on different LICs, showing the closest coding performance to their floating-point counterparts. And, our method is a lightweight and plug-and-play approach without any need of model retraining which is attractive to practitioners.

Benign Overfitting in Classification: Provably Counter Label Noise with Larger Models

Kaiyue Wen,Jiaye Teng,Jingzhao Zhang

Studies on benign overfitting provide insights for the success of overparameterized deep learning models. In this work, we examine whether overfitting is truly benign in real-world classification tasks. We start with the observation that a ResNet model overfits benignly on Cifar10 but not benignly on ImageNet. To understand why benign overfitting fails in the ImageNet experiment, we theoretically analyze benign overfitting under a more restrictive setup where the number of parameters is not significantly larger than the number of data points. Under this mild overparameterization setup, our analysis identifies a phase change: unlike in the previous heavy overparameterization settings, benign overfitting can now fail in the presence of label noise. Our analysis explains our empirical observations, and is validated by a set of control experiments with ResNets. Our work highlights the importance of understanding implicit bias in underfitting regimes as a future direction.

****

Predictive Inference with Feature Conformal Prediction

Jiaye Teng,Chuan Wen,Dinghuai Zhang,Yoshua Bengio,Yang Gao,Yang Yuan

Conformal prediction is a distribution-free technique for establishing valid prediction intervals. Although conventionally people conduct conformal prediction in the output space, this is not the only possibility. In this paper, we propose feature conformal prediction, which extends the scope of conformal prediction to semantic feature spaces by leveraging the inductive bias of deep representation learning. From a theoretical perspective, we demonstrate that feature conformal prediction provably outperforms regular conformal prediction under mild assumptions. Our approach could be combined with not only vanilla conformal prediction, but also other adaptive conformal prediction methods. Apart from experiments on existing predictive inference benchmarks, we also demonstrate the state-of-the-art performance of the proposed methods on \textit{large-scale} tasks such as ImageNet classification and Cityscapes image segmentation.

Recon: Reducing Conflicting Gradients From the Root For Multi-Task Learning

Guangyuan SHI,Qimai Li,Wenlong Zhang,Jiaxin Chen,Xiao-Ming Wu

A fundamental challenge for multi-task learning is that different tasks may conflict with each other when they are solved jointly, and a cause of this phenomenon is conflicting gradients during optimization. Recent works attempt to mitigate the influence of conflicting gradients by directly altering the gradients based on some criteria. However, our empirical study shows that ``gradient surgery'' cannot effectively reduce the occurrence of conflicting gradients. In this paper, we take a different approach to reduce conflicting gradients from the root. In essence, we investigate the task gradients w.r.t. each shared network layer, select the layers with high conflict scores, and turn them to task-specific layers. Our experiments show that such a simple approach can greatly reduce the occurrence of conflicting gradients in the remaining shared layers and achieve better performance, with only a slight increase in model parameters in many cases. Our approach can be easily applied to improve various state-of-the-art methods including gradient manipulation methods and branched architecture search methods. Given a network architecture (e.g., ResNet18), it only needs to search for the conflict layers once, and the network can be modified to be used with different methods on the same or even different datasets to gain performance improvement. The source code is available at https://github.com/moukamisama/Recon.

OCD: Learning to Overfit with Conditional Diffusion Models

Shahar Lutati,Lior Wolf

We present a dynamic model in which the weights are conditioned on an input sample x and are learned to match those that would be obtained by finetuning a base model on x and its label y. This mapping between an input sample and network weights is shown to be approximated by a linear transformation of the sample distribution, which suggests that a denoising diffusion model can be suitable for this task. The diffusion model we therefore employ focuses on modifying a single layer of the base model and is conditioned on the input, activations, and output of this layer. Our experiments demonstrate the wide applicability of the method for image classification, 3D reconstruction, tabular data, and speech separation. Our code is attached as supplementary.

Measure the Predictive Heterogeneity

Jiashuo Liu,Jiayun Wu,Renjie Pi,Renzhe Xu,Xingxuan Zhang,Bo Li,Peng Cui

As an intrinsic and fundamental property of big data, data heterogeneity exists in a variety of real-world applications, such as in agriculture, sociology, health care, etc. For machine learning algorithms, the ignorance of data heterogeneity will significantly hurt the generalization performance and the algorithmic fairness, since the prediction mechanisms among different sub-populations are likely to differ. In this work, we focus on the data heterogeneity that affects the prediction of machine learning models, and first formalize the Predictive Heterogeneity, which takes into account the model capacity and computational constraints. We prove that it can be reliably estimated from finite data with PAC bounds even in high dimensions. Additionally, we propose the Information Maximization (IM) algorithm, a bi-level optimization algorithm, to explore the predictive heterogeneity of data. Empirically, the explored predictive heterogeneity provides insights for sub-population divisions in agriculture, sociology, and object recognition, and leveraging such heterogeneity benefits the out-of-distribution generalization performance.

On the robustness of self-supervised models for generative spoken language modeling

Itai Gat,Felix Kreuk,Ann Lee,Jade Copet,Gabriel Synnaeve,Emmanuel Dupoux,Yossi Adi

Self-supervised representations have been extensively studied for discriminative and generative tasks. However, their robustness capabilities have not been extensively investigated. This work focuses on self-supervised representations for spoken generative language models. First, we empirically demonstrate how current state-of-the-art speech representation models lack robustness to basic signal variations that do not alter the spoken information. To overcome this, we propose an effective and efficient method to learn robust self-supervised speech representation for generative spoken language modeling. The proposed approach is based on applying a set of signal transformations to the speech signal and optimizing the model using an iterative pseudo-labeling scheme. Our method significantly improves over the evaluated baselines when considering encoding metrics. We additi onally evaluate our method on the speech-to-speech translation task. We consider Spanish-English and French-English conversions and empirically demonstrate the benefits of following the proposed approach.

Non-equispaced Fourier Neural Solvers for PDEs

Haitao Lin,Yongjie Xu,Lirong Wu,Yufei Huang,Siyuan Li,Guojiang Zhao,Stan Z. Li

Solving partial differential equations is difficult. Recently proposed neural resolution-invariant models, despite their effectiveness and efficiency, usually require equispaced spatial points of data. However, sampling in spatial domain is sometimes inevitably non-equispaced in real-world systems, limiting their applicability. In this paper, we aim to propose a Non-equispaced Fourier PDE Solver (\textsc{NFS}) with adaptive interpolation on resampled equispaced points and a variant of Fourier Neural Operators as its components. Experimental results on complex PDEs demonstrate its advantages in accuracy and efficiency. Compared with the spatially-equispaced benchmark methods, it achieves superior performance with 42.85% improvements on MAE, and is able to handle non-equispaced data with a tiny loss of accuracy. Besides, to our best knowledge, \textsc{NFS} is the first ML-based method with mesh invariant inference ability to successfully model turbulent flows in non-equispaced scenarios, with a minor deviation of the error on unseen spatial points.

Time to augment self-supervised visual representation learning

Arthur Aubret,Markus R. Ernst,Céline Teulière,Jochen Triesch

Biological vision systems are unparalleled in their ability to learn visual representations without supervision. In machine learning, self-supervised learning (SSL) has led to major advances in forming object representations in an unsupervised fashion. Such systems learn representations invariant to augmentation operations over images, like cropping or flipping. In contrast, biological vision systems exploit the temporal structure of the visual experience during natural interactions with objects. This gives access to “augmentations” not commonly used in SSL, like watching the same object from multiple viewpoints or against different backgrounds. Here, we systematically investigate and compare the potential benefits of such time-based augmentations during natural interactions for learning object categories. Our results show that incorporating time-based augmentations achieves large performance gains over state-of-the-art image augmentations. Specifically, our analyses reveal that: 1) 3-D object manipulations drastically improve the learning of object categories; 2) viewing objects against changing backgrounds is important for learning to discard background-related information from the latent representation. Overall, we conclude that time-based augmentations during natural interactions with objects can substantially improve self-supervised learning, narrowing the gap between artificial and biological vision systems.

Probable Dataset Searching Method with Uncertain Dataset Information in Adjusting Architecture Hyper Parameter

Chen Yang,Jingyuan Wang

Different types of tasks with uncertain dataset information are studied because different parts of data may have different difficulties to achieve. For example, in unsupervised learning and domain adaptation, datasets are provided without label information because of the cost of human annotation. In deep learning, adjusting architecture hyper parameters is important for the model performance and is also time consuming, so we try to adjust hyper parameters in two types of uncertain dataset information:1, dataset labels are postponed to be obtained so hyper parameters need to be adjusted without complete dataset information. 2, hyper parameters are adjusted with a subset training dataset since training models with complete training dataset is time consuming. Here, we propose several loss functions to search for probable dataset when the complete dataset information is not obtained. The experiments on 9 real world data demonstrate the performance of our method.

Towards Lightweight, Model-Agnostic and Diversity-Aware Active Anomaly Detection
Xu Zhang,Yuan Zhao,Ziang Cui,Liqun Li,Shilin He,Qingwei Lin,Yingnong Dang,Saravan Rajmohan,Dongmei Zhang
Active Anomaly Discovery (AAD) is flourishing in the anomaly detection research area, which aims to incorporate analysts’ feedback into unsupervised anomaly detectors. However, existing AAD approaches usually prioritize the samples with the highest anomaly scores for user labeling, which hinders the exploration of anomalies that were initially ranked lower. Besides, most existing AAD approaches are specially tailored for a certain unsupervised detector, making it difficult to extend to other detection models. To tackle these problems, we propose a lightweight, model-agnostic and diversity-aware AAD method, named LMADA. In LMADA, we design a diversity-aware sample selector powered by Determinantal Point Process (DPP). It considers the diversity of samples in addition to their anomaly scores for feedback querying. Furthermore, we propose a model-agnostic tuner. It approximates diverse unsupervised detectors with a unified proxy model, based on which the feedback information is incorporated by a lightweight non-linear representation adjuster. Through extensive experiments on 8 public datasets, LMADA achieved 74% F1-Score improvement on average, outperforming other comparative AAD approaches. Besides, LMADA can also achieve significant performance boosting under any unsupervised detectors.

Switching One-Versus-the-Rest Loss to Increase Logit Margins for Adversarial Robustness
Sekitoshi Kanai,Shin'ya Yamaguchi,Masanori Yamada,Hiroshi Takahashi,Kentaro Ohno,Yasutoshi Ida
Adversarial training is a promising method to improve the robustness against adversarial attacks. To enhance its performance, recent methods impose high weights on the cross-entropy loss for important data points near the decision boundary. However, these importance-aware methods are vulnerable to sophisticated attacks, e.g., Auto-Attack. In this paper, we experimentally investigate the cause of their vulnerability via margins between logits for the true label and the other labels because they should be large enough to prevent the largest logit from being flipped by the attacks. Our experiments reveal that the histogram of the logit margins of naive adversarial training has two peaks. Thus, the levels of difficulty in increasing logit margins are roughly divided into two: difficult samples (small logit margins) and easy samples (large logit margins). On the other hand, only one peak near zero appears in the histogram of importance-aware methods, i.e., they reduce the logit margins of easy samples. To increase logit margins of difficult samples without reducing those of easy samples, we propose switching one-versus-the-rest loss (SOVR), which switches from cross-entropy to one-versus-the-rest loss (OVR) for difficult samples. We derive trajectories of logit margins for a simple problem and prove that OVR increases logit margins two times larger than the weighted cross-entropy loss. Thus, SOVR increases logit margins of difficult samples, unlike existing methods. We experimentally show that SOVR achieves better robustness against Auto-Attack than importance-aware methods.

Scaled Neural Multiplicative Model for Tractable Optimization
Drishya Giri,Kenneth Kuhn,Aravind Chiruvelli
Challenging decision problems in retail and beyond are often solved using the predict-then-optimize paradigm. An initial effort to develop and parameterize a model of an uncertain environment is followed by a separate effort to identify the best possible solution of an optimization problem. Linear models are often used to ensure optimization problems are tractable. Remarkably accurate Deep Neural Network (DNN) models have recently been developed for various prediction tasks. Such models have been shown to scale to large datasets without loss of accuracy and with good computational performance. It can, however, be challenging to formulate tractable optimization problems based on DNN models. In this work we consider the problem of shelf space allocation for retail stores using DNN models. We highlight the trade-off between predictive performance and the tractability of optimization problems. We introduce a Scaled Neural Multiplicative Model (SNMM)

with shape constraints for demand learning that leads to a tractable optimization formulation. Although, this work focuses on a specific application, the formulation of the models are general enough such that they can be extended to many real world applications.

Quasi-Taylor Samplers for Diffusion Generative Models based on Ideal Derivatives
Hideyuki Tachibana,Mocho Go,Muneyoshi Inahara,Yotaro Katayama,Yotaro Watanabe
Diffusion generative models have emerged as a new challenger to popular deep neural generative models such as GANs, but have the drawback that they often require a huge number of neural function evaluations (NFEs) during synthesis unless some sophisticated sampling strategies are employed. This paper proposes new efficient samplers based on the numerical schemes derived by the familiar Taylor expansion, which directly solves the ODE/SDE of interest. In general, it is not easy to compute the derivatives that are required in higher-order Taylor schemes, but in the case of diffusion models, this difficulty is alleviated by the trick that the authors call ``ideal derivative substitution,'' in which the higher-order derivatives are replaced by tractable ones. To derive ideal derivatives, the authors argue the ``single point approximation,'' in which the true score function is approximated by a conditional one, holds in many cases, and considered the derivatives of this approximation. Applying thus obtained new quasi-Taylor samplers to image generation tasks, the authors experimentally confirmed that the proposed samplers could synthesize plausible images in small number of NFEs, and that the performance was better or at the same level as DDIM and Runge-Kutta methods. The paper also argues the relevance of the proposed samplers to the existing ones mentioned above.

Group-oriented Cooperation in Multi-Agent Reinforcement Learning
Yifan Zang,Jinmin He,Kai Li,Haobo Fu,QIANG FU,Junliang Xing,Jian Cheng
Grouping is ubiquitous in natural systems and is essential for promoting efficiency in team coordination. This paper introduces the concept of grouping into multi-agent reinforcement learning (MARL) and provides a novel formulation of Group-oriented MARL (GoMARL). In contrast to existing approaches that attempt to directly learn the complex relationship between the joint action-values and individual values, we empower groups as a bridge to model the connection between a small set of agents and encourage cooperation among them, thereby improving the efficiency of the whole team. In particular, we factorize the joint action-values as a combination of group-wise values, which guide agents to improve their policies in a fine-grained fashion. We propose a flexible grouping mechanism inspired by variable selection and sparse regularization to generate dynamic groups and group action-values. We further propose a hierarchical control for policy learning that drives the agents in the same group to specialize in similar policies and possess diversified strategies for various groups. Extensive experiments on a challenging set of StarCraft II micromanagement tasks and Google Research Football scenarios verify our method's effectiveness and learning efficiency. Detailed component studies show how grouping works and enhances performance.

Exploring Temporally Dynamic Data Augmentation for Video Recognition
Taeoh Kim,Jinhyung Kim,Minho Shim,Sangdoo Yun,Myunggu Kang,Dongyoon Wee,Sangyoun Lee
Data augmentation has recently emerged as an essential component of modern training recipes for visual recognition tasks.
However, data augmentation for video recognition has been rarely explored despite its effectiveness.
Few existing augmentation recipes for video recognition naively extend the image augmentation methods by applying the same operations to the whole video frames.
Our main idea is that the magnitude of augmentation operations for each frame needs to be changed over time to capture the real-world video's temporal variations.
These variations should be generated as diverse as possible using fewer additional hyper-parameters during training.

Through this motivation, we propose a simple yet effective video data augmentation framework, DynaAugment.

The magnitude of augmentation operations on each frame is changed by an effective mechanism, Fourier Sampling that parameterizes diverse, smooth, and realistic temporal variations.

DynaAugment also includes an extended search space suitable for video for automatic data augmentation methods.

DynaAugment experimentally demonstrates that there are additional performance rooms to be improved from static augmentations on diverse video models.

Specifically, we show the effectiveness of DynaAugment on various video datasets and tasks: large-scale video recognition (Kinetics-400 and Something-Something-v2), small-scale video recognition (UCF-101 and HMDB-51), fine-grained video recognition (Diving-48 and FineGym), video action segmentation on Breakfast, video action localization on THUMOS'14, and video object detection on MOT17Det.

Agent Prioritization with Interpretable Relation for Trajectory Prediction

Manh Huynh,Hengbo Ma,Gita Alaghband,Chiho Choi

In this paper, we present a novel multi-agent trajectory prediction model, which discovers interpretable relations among agents and prioritize agent's motion. Different from existing approaches, our interpretable design is inspired by the fundamental navigation and motion functions of agent movements, which represent 'where' and 'how' the agents move in the scenes. Specifically, it generates the relation matrix, where each element indicates the motion impact from one to another. In addition, in highly interactive scenarios, one agent may implicitly gain higher priority to move, while the motion of other agents may be impacted by the prioritized agents with higher priority (e.g., a vehicle stopping or reducing its speed due to crossing pedestrians). Based on this intuition, we design a novel motion prioritization module to learn the agent motion priorities based on the inferred relation matrix. Then, a decoder is proposed to sequentially predict and iteratively update the future trajectories of each agent based on their priority orders and the learned relation structures. We first demonstrate the effectiveness of our prediction model on simulated Charged Particles dataset. Next, extensive evaluations are performed on commonly-used datasets for robot navigation, human-robot interactions, and autonomous agents: real-world NBA basketball and INTERACTION. Finally, we show that the proposed model outperforms other state-of-the-art relation based methods, and is capable to infer interpretable, meaningful relations among agents.

z-SignFedAvg: A Unified Stochastic Sign-based Compression for Federated Learning

Zhiwei Tang,Yanmeng Wang,Tsung-Hui Chang

Federated Learning (FL) is a promising privacy-preserving distributed learning paradigm but suffers from high communication cost when training large-scale machine learning models. Sign-based methods, such as SignSGD \citep{bernstein2018signsgd}, have been proposed as a biased gradient compression technique for reducing the communication cost. However, sign-based algorithms could diverge under heterogeneous data, which thus motivated the development of advanced techniques, such as the error-feedback method and stochastic sign-based compression, to fix this issue.

Nevertheless, these methods still suffer from slower convergence rates. Besides, none of them allows multiple local SGD updates like FedAvg \citep{mcmahan2017communication}. In this paper, we propose a novel noisy perturbation scheme with a general symmetric noise distribution for sign-based compression, which not only allows one to flexibly control the tradeoff between gradient bias and convergence performance, but also provides a unified viewpoint to existing stochastic sign-based methods. More importantly, we propose the very first sign-based FedAvg algorithm (z-SignFedAvg). Theoretically, we show that z-SignFedAvg achieves a faster convergence rate than existing sign-based methods and, under the uniformly distributed noise, can enjoy the same convergence rate as its uncompressed counterpart. Last but not the least, we remark that adding random noise to the local gradients has a double benefit: it protects the clients' privacy by, e.g., the Differential Privacy. Extensive experiments are conducted to demonstrate that the z-SignFedAvg can achieve competitive empirical performance on real datasets.

Transfer Learning with Pre-trained Conditional Generative Models
Shin'ya Yamaguchi,Sekitoshi Kanai,Atsutoshi Kumagai,Daiki Chijiwa,Hisashi Kashima

Transfer learning is crucial in training deep neural networks on new target tasks. Current transfer learning methods always assume at least one of (i) source and target task label spaces overlap, (ii) source datasets are available, and (iii) target network architectures are consistent with source ones. However, holding these assumptions is difficult in practical settings because the target task rarely has the same labels as the source task, the source dataset access is restricted due to storage costs and privacy, and the target architecture is often specialized to each task. To transfer source knowledge without these assumptions, we propose a transfer learning method that uses deep generative models and is composed of the following two stages: pseudo pre-training (PP) and pseudo semi-supervised learning (P-SSL). PP trains a target architecture with an artificial dataset synthesized by using conditional source generative models. P-SSL applies SSL algorithms to labeled target data and unlabeled pseudo samples, which are generated by cascading the source classifier and generative models to condition them with target samples. Our experimental results indicate that our method can outperform the baselines of scratch training and knowledge distillation.

****

DECN: Evolution Inspired Deep Convolution Network for Black-box Optimization
Liu Penghui,Kai Wu,Jing Liu

We design a deep evolutionary convolution network (DECN) for continuous black-box optimization to force the random population to move near the optimal solution, which is the goal of population-based optimization, such as evolutionary algorithm and evolutionary strategy. DECN is composed of two modules: convolution-based reasoning module (CRM) and selection module (SM), to move from hand-designed searching strategies to learned searching strategies in population-based optimization. CRM produces a population that is closer to the optimal solution based on the convolution operators, and SM removes poor solutions. We also design a proper loss function to support the training of DECN. The experimental results on unconstrained continuous optimization problems show that DECN can learn searching strategies and surpass population-based baselines. Moreover, DECN obtains good performance when transferred to optimization problems unseen during the training stage. In addition, DECN is friendly to the acceleration with Graphics Processing Units (GPUs) and runs 102 times faster than unaccelerated EA when evolving 32 populations, each containing 6400 individuals.

Q-Pensieve: Boosting Sample Efficiency of Multi-Objective RL Through Memory Sharing of Q-Snapshots
Wei Hung,Bo Kai Huang,Ping-Chun Hsieh,Xi Liu

Many real-world continuous control problems are in the dilemma of weighing the pros and cons, multi-objective reinforcement learning (MORL) serves as a generic framework of learning control policies for different preferences over objectives. However, the existing MORL methods either rely on multiple passes of explicit search for finding the Pareto front and therefore are not sample-efficient, or utilizes a shared policy network for coarse knowledge sharing among policies. To boost the sample efficiency of MORL, we propose Q-Pensieve, a policy improvement scheme that stores a collection of Q-snapshots to jointly determine the policy update direction and thereby enables data sharing at the policy level. We show that Q-Pensieve can be naturally integrated with soft policy iteration with convergence guarantee. To substantiate this concept, we propose the technique of Q replay buffer, which stores the learned Q-networks from the past iterations, and arrive at a practical actor-critic implementation. Through extensive experiments and an ablation study, we demonstrate that with much fewer samples, th e proposed algorithm can outperform the benchmark MORL methods on a variety of MORL benchmark tasks.

****

Optformer: Beyond Transformer for Black-box Optimization

Xiaobin Li,Kai Wu,Xiaoyu Zhang,Handing Wang,Jing Liu

We design a novel Transformer for continuous unconstrained black-box optimization, called Optformer. Inspired by the similarity between Vision Transformer and evolutionary algorithms (EAs), we modify Tansformer's multi-head self-attention layer, feed-forward network, and residual connection to implement the functions of crossover, mutation, and selection operators. Moreover, we devise an iterated mode to generate and survive potential solutions like EAs. Optformer establishes a mapping from the random population to the optimal population. Compared to baselines, such as EAs, Bayesian optimization, and the learning-to-optimize method, Optformer shows the top performance in six black-box functions and one real-world application. We also find that untrained Optformer can also achieve good performance.

****

Deformable Graph Transformer

Jinyoung Park,Seongjun Yun,Hyeonjin Park,Jaewoo Kang,Jisu Jeong,Kyung-Min Kim,Jung-Woo Ha,Hyunwoo J. Kim

Transformer-based models have recently shown success in representation learning on graph-structured data beyond natural language processing and computer vision. However, the success is limited to small-scale graphs due to the drawbacks of full dot-product attention on graphs such as the quadratic complexity with respect to the number of nodes and message aggregation from enormous irrelevant nodes. To address these issues, we propose Deformable Graph Transformer (DGT) that performs sparse attention via dynamically sampled relevant nodes for efficiently handling large-scale graphs with a linear complexity in the number of nodes. Specifically, our framework first constructs multiple node sequences with various criteria to consider both structural and semantic proximity. Then, combining with our learnable Katz Positional Encodings, the sparse attention is applied to the node sequences for learning node representations with a significantly reduced computational cost. Extensive experiments demonstrate that our DGT achieves state-of-the-art performance on 7 graph benchmark datasets with 2.5 ~ 449 times less computational cost compared to transformer-based graph models with full attention.

****

Exact manifold Gaussian Variational Bayes

Martin Magris,Mostafa Shabani,Alexandros Iosifidis

We propose an optimization algorithm for Variational Inference (VI) in complex models. Our approach relies on natural gradient updates where the variational space is a Riemann manifold. We develop an efficient algorithm for Gaussian Variational Inference that implicitly satisfies the positive definite constraint on the variational covariance matrix. Our Exact manifold Gaussian Variational Bayes (EMGVB) provides exact but simple update rules and is straightforward to implement. Due to its black-box nature, EMGVB stands as a ready-to-use solution for VI in complex models. Over five datasets, we empirically validate our feasible approach on different statistical, econometric, and deep learning models, discussing its performance with respect to baseline methods.

****

Variance-Aware Sparse Linear Bandits

Yan Dai,Ruosong Wang,Simon Shaolei Du

It is well-known that for sparse linear bandits, when ignoring the dependency on sparsity which is much smaller than the ambient dimension, the worst-case minimax regret is $\widetilde{\Theta}\left(\sqrt{dT}\right)$ where d is the ambient dimension and T is the number of rounds. On the other hand, in the benign setting where there is no noise and the action set is the unit sphere, one can use divide-and-conquer to achieve $\widetilde{\mathcal O}(1)$ regret, which is (nearly) independent of d and T. In this paper, we present the first variance-aware regret guarantee for sparse linear bandits: $\widetilde{\mathcal O}\left(\sqrt{d\sum_{t=1}^T \sigma_t^2} + 1\right)$, where σ_t^2 is the variance of the noise at the t-th round. This bound naturally interpolates the regret bounds for the worst-case constant-variance regime (i.e., $\sigma_t \equiv \Omega(1)$) and the benign deterministic regimes (i.e., $\sigma_t \equiv 0$). To achieve this variance-aware regret guarantee, we develop a general framework that converts any variance-aware linear bandit algorithm to a variance-aware algorithm for sparse linear bandits in a "black-box" manner. Specifically, we take two recent algorithms as black boxes to illustrate that the claimed bounds indeed hold, where the first algorithm can handle unknown-variance cases and the second one is more efficient.

Multi-Treatment Effect Estimation with Proxy: Contrastive Learning and Rank Weighting

Minqin Zhu,Anpeng Wu,Ruoxuan Xiong,Kun Kuang

We study the treatment effect estimation problem for continuous and multi-dimensional treatments, in the setting with unobserved confounders, but high-dimension proxy variables for unobserved confounders are available. Existing methods either directly adjust the relationship between observed covariates and treatments or recover the hidden confounders by probabilistic models. However, they either rely on a correctly specified treatment assignment model or require strong prior of the unobserved confounder distribution. To relax these requirements, we propose a Contrastive Regularizer (CR) to learn the proxy representation that contains all the relevant information in unobserved confounders. Based on the CR, we propose a novel ranked weighting method (Rw) to de-bias the treatment assignment. Combining Cr and Rw, we propose a neural network framework named CRNet to estimate the effects of multiple continuous treatments under unobserved confounders, evaluated by the Average Dose-Response Function. Empirically, we demonstrate that CRNet achieves state-of-the-art performance on both synthetic and semi-synthetic datasets.

****

CircNet: Meshing 3D Point Clouds with Circumcenter Detection

Huan Lei,Ruitao Leng,Liang Zheng,Hongdong Li

Reconstructing 3D point clouds into triangle meshes is a key problem in computational geometry and surface reconstruction. Point cloud triangulation solves this problem by providing edge information to the input points. Since no vertex interpolation is involved, it is beneficial to preserve sharp details on the surface. Taking advantage of learning-based techniques in triangulation, existing methods enumerate the complete combinations of candidate triangles, which is both complex and inefficient. In this paper, we leverage the duality between a triangle and its circumcenter, and introduce a deep neural network that detects the circumcenters to achieve point cloud triangulation. Specifically, we introduce multiple anchor priors to divide the neighborhood space of each point. The neural network then learns to predict the presences and locations of circumcenters under the guidance of those anchors. We extract the triangles dual to the detected circumcenters to form a primitive mesh, from which an edge-manifold mesh is produced via simple post-processing. Unlike existing learning-based triangulation methods, the proposed method bypasses an exhaustive enumeration of triangle combinations and local surface parameterization. We validate the efficiency, generalization, and robustness of our method on prominent datasets of both watertight and open surfaces. The code and trained models are provided at \url{https://github.com/Ruitao-L/CircNet}.

****

In-sample Actor Critic for Offline Reinforcement Learning

Hongchang Zhang,Yixiu Mao,Boyuan Wang,Shuncheng He,Yi Xu,Xiangyang Ji

Offline reinforcement learning suffers from out-of-distribution issue and extrapolation error. Most methods penalize the out-of-distribution state-action pairs or regularize the trained policy towards the behavior policy but cannot guarantee to get rid of extrapolation error. We propose In-sample Actor Critic (IAC) which utilizes sampling-importance resampling to execute in-sample policy evaluation. IAC only uses the target Q-values of the actions in the dataset to evaluate the trained policy, thus avoiding extrapolation error. The proposed method per forms unbiased policy evaluation and has a lower variance than importance sampling in many cases. Empirical results show that IAC obtains competitive performance compared to the state-of-the-art methods on Gym-MuJoCo locomotion domains and much more challenging AntMaze domains.

****

Leveraging Future Relationship Reasoning for Vehicle Trajectory Prediction

Daehee Park,Hobin Ryu,Yunseo Yang,Jegyeong Cho,Jiwon Kim,Kuk-Jin Yoon

Understanding the interaction between multiple agents is crucial for realistic vehicle trajectory prediction.

Existing methods have attempted to infer the interaction from the observed past trajectories of agents using pooling, attention, or graph-based methods, which rely on a deterministic approach.

However, these methods can fail under complex road structures, as they cannot predict various interactions that may occur in the future.

In this paper, we propose a novel approach that uses lane information to predict a stochastic future relationship among agents.

To obtain a coarse future motion of agents, our method first predicts the probability of lane-level waypoint occupancy of vehicles.

We then utilize the temporal probability of passing adjacent lanes for each agent pair, assuming that agents passing adjacent lanes will highly interact.

We also model the interaction using a probabilistic distribution, which allows for multiple possible future interactions.

The distribution is learned from the posterior distribution of interaction obtained from ground truth future trajectories.

We validate our method on popular trajectory prediction datasets: nuScenes and Argoverse.

The results show that the proposed method brings remarkable performance gain in prediction accuracy, and achieves state-of-the-art performance in long-term prediction benchmark dataset.

****

DeepTime: Deep Time-index Meta-learning for Non-stationary Time-series Forecasting

Gerald Woo,Chenghao Liu,Doyen Sahoo,Akshat Kumar,Steven Hoi

Advances in I.T. infrastructure has led to the collection of longer sequences of time-series. Such sequences are typically non-stationary, exhibiting distribution shifts over time -- a challenging scenario for the forecasting task, due to the problems of covariate shift, and conditional distribution shift. In this paper, we show that deep time-index models possess strong synergies with a meta-learning formulation of forecasting, displaying significant advantages over existing neural forecasting methods in tackling the problems arising from non-stationarity. These advantages include having a stronger smoothness prior, avoiding the problem of covariate shift, and having better sample efficiency. To this end, we propose DeepTime, a deep time-index model trained via meta-learning. Extensive experiments on real-world datasets in the long sequence time-series forecasting setting demonstrate that our approach achieves competitive results with state-of-the-art methods, and is highly efficient. Code is attached as supplementary material, and will be publicly released.

****

Non-Parametric State-Space Models: Identifiability, Estimation and Forecasting

Chenghao Liu,Weiran Yao,Steven Hoi,Kun Zhang

State-space models (SSMs) provide a standard methodology for time series analysis and prediction. While recent works utilize nonlinear functions to parameterize the transition and emission processes to enhance their expressivity, the form of additive noise still limits their applicability in real-world scenarios. In this work, we propose a general formulation of SSMs with a completely non-parametric transition model and a flexible emission model which can account for sensor distortion. Besides, to deal with more general scenarios (e.g., non-stationary time series), we add a higher level model to capture time-varying characteristics of the process.

Interestingly, we find that even though the proposed model is remarkably flexibl e, the latent processes are generally identifiable. Given this, we further propose the corresponding estimation procedure and make use of it for the forecasting task. Our model can recover the latent processes and their relations from observed sequential data. Accordingly, the proposed procedure can also be viewed as a method for causal representation learning. We argue that forecasting can benefit from causal representation learning, since the estimated latent variables are generally identifiable. Empirical comparisons on various datasets validate that our model could not only reliably identify the latent processes from the observed data, but also consistently outperform baselines in the forecasting task.

****

ETSformer: Exponential Smoothing Transformers for Time-series Forecasting

Gerald Woo,Chenghao Liu,Doyen Sahoo,Akshat Kumar,Steven Hoi

Transformers have recently been actively studied for time-series forecasting. While often showing promising results in various scenarios, traditional Transformers are not designed to fully exploit the characteristics of time-series data and thus suffer some fundamental limitations, e.g., they are generally not decomposable or interpretable, and are neither effective nor efficient for long-term forecasting. In this paper, we propose ETSformer, a novel time-series Transformer architecture, which exploits the principle of exponential smoothing methods in improving Transformers for time-series forecasting. Specifically, ETSformer leverages a novel level-growth-seasonality decomposed Transformer architecture which leads to more interpretable and disentangled decomposed forecasts. We further propose two novel attention mechanisms -- the exponential smoothing attention and frequency attention, which are specially designed to overcome the limitations of the vanilla attention mechanism for time-series data. Extensive experiments on various time-series benchmarks validate the efficacy and advantages of the proposed method. Code is attached in the supplementary material, and will be made publicly available.

LMSeg: Language-guided Multi-dataset Segmentation

Qiang Zhou,Yuang Liu,Chaohui Yu,Jingliang Li,Zhibin Wang,Fan Wang

It’s a meaningful and attractive topic to build a general and inclusive segmentation model that can recognize more categories in various scenarios. A straightforward way is to combine the existing fragmented segmentation datasets and train a multi-dataset network. However, there are two major issues with multi-dataset segmentation: (i) the inconsistent taxonomy demands manual reconciliation to construct a unified taxonomy; (ii) the inflexible one-hot common taxonomy causes time-consuming model retraining and defective supervision of unlabeled categories. In this paper, we investigate the multi-dataset segmentation and propose a scalable Language-guided Multi-dataset Segmentation framework, dubbed LMSeg, which supports both semantic and panoptic segmentation. Specifically, we introduce a pretrained text encoder to map the category names to a text embedding space as a unified taxonomy, instead of using inflexible one-hot label. The model dynamically aligns the segment queries with the category embeddings. Instead of relabeling each dataset with the unified taxonomy, a category-guided decoding module is designed to dynamically guide predictions to each dataset’s taxonomy. Furthermore, we adopt a dataset-aware augmentation strategy that assigns each dataset a specific image augmentation pipeline, which can suit the properties of images from different datasets. Extensive experiments demonstrate that our method achieves significant improvements on four segmentation datasets and three panoptic datasets, while the ablation study evaluates the effectiveness of each component.

Horizon-Free Reinforcement Learning for Latent Markov Decision Processes

Runlong Zhou,Ruosong Wang,Simon Shaolei Du

We study regret minimization for reinforcement learning (RL) in Latent Markov Decision Processes (LMDPs) with context in hindsight. We design a novel model-based algorithmic framework which can be instantiated with both a model-optimistic and a value-optimistic solver. We prove an $\widetilde{O}\left(\sqrt{M \Gamma S A

K}\right)$ regret bound where M is the number of contexts, S is the number of states, A is the number of actions, K is the number of episodes, and $\Gamma \le S$ is the maximum transition degree of any state-action pair. The regret bound only scales logarithmically with the planning horizon, thus yielding the first (nearly) horizon-free regret bound for LMDP. Key in our proof is an analysis of the total variance of alpha vectors, which is carefully bounded by a recursion-based technique. We complement our positive result with a novel $\Omega\left(\sqrt{M S A K}\right)$ regret lower bound with $\Gamma = 2$, which shows our upper bound minimax optimal when Γ is a constant. Our lower bound relies on new constructions of hard instances and an argument based on the symmetrization technique from theoretical computer science, both of which are technically different from existing lower bound proof for MDPs, and thus can be of independent interest.

Learning Invariant Features for Online Continual Learning

Yiduo Guo,Bing Liu,Dongyan Zhao

It has been shown recently that learning only discriminative features that are sufficient to separate the classes in a task using a traditional learning method has a major shortcoming for continual learning (CL). This is because many features that are not learned may be necessary for distinguishing classes of some future tasks. When such a future task arrives, these features have to be learned by updating the network, which causes catastrophic forgetting (CF). A recent work on online CL showed that if the learning method can learn as many features as possible from each class, called holistic representations, CF can be significantly reduced to achieve a large performance gain. This paper argues that learning only holistic representations is still insufficient. The learned representations should also be invariant and those features that are present in the data but are irrelevant to the class (e.g., the background information) should be ignored for better generalization across tasks. This new condition further boosts the performance significantly. This paper proposes several strategies and a loss to learn holistic and invariant representations and evaluates their effectiveness in online CL.

RoPAWS: Robust Semi-supervised Representation Learning from Uncurated Data

Sangwoo Mo,Jong-Chyi Su,Chih-Yao Ma,Mido Assran,Ishan Misra,Licheng Yu,Sean Bell

Semi-supervised learning aims to train a model using limited labels. State-of-the-art semi-supervised methods for image classification such as PAWS rely on self-supervised representations learned with large-scale unlabeled but curated data. However, PAWS is often less effective when using real-world unlabeled data that is uncurated, e.g., contains out-of-class data. We propose RoPAWS, a robust extension of PAWS that can work with real-world unlabeled data. We first reinterpret PAWS as a generative classifier that models densities using kernel density estimation. From this probabilistic perspective, we calibrate its prediction based on the densities of labeled and unlabeled data, which leads to a simple closed-form solution from the Bayes' rule. We demonstrate that RoPAWS significantly improves PAWS for uncurated Semi-iNat by +5.3% and curated ImageNet by +0.4%.

Treeformer: Dense Gradient Trees for Efficient Attention Computation

Lovish Madaan,Srinadh Bhojanapalli,Himanshu Jain,Prateek Jain

Standard inference and training with transformer based architectures scale quadratically with input sequence length. This is prohibitively large for a variety of applications especially in web-page translation, query-answering etc. Consequently, several approaches have been developed recently to speedup attention computation by enforcing different attention structures such as sparsity, low-rank, approximating attention using kernels. In this work, we view attention computation as that of nearest neighbor retrieval, and use decision tree based hierarchical navigation to reduce the retrieval cost per query token from linear in sequence length to nearly logarithmic. Based on such hierarchical navigation, we design Treeformer which can use one of two efficient attention layers -- TF-Attention and TC-Attention. TF-Attention computes the attention in a fine-grained style, w hile TC-Attention is a coarse attention layer which also ensures that the gradients are "dense". To optimize such challenging discrete layers, we propose a two-level bootstrapped training method. Using extensive experiments on standard NLP benchmarks, especially for long-sequences, we demonstrate that our Treeformer architecture can be almost as accurate as baseline Transformer while using 30x lesser FLOPs in the attention layer. Compared to Linformer, the accuracy can be as much as 12% higher while using similar FLOPs in the attention layer.

****

ODAM: Gradient-based Instance-Specific Visual Explanations for Object Detection

Chenyang ZHAO,Antoni B. Chan

We propose the Gradient-weighted Object Detector Activation Mapping (Grad-ODAM), a visualized explanation technique for interpreting the predictions of object detectors. Utilizing the gradients of detector targets flowing into the intermediate feature maps, Grad-ODAM produces heat maps that show the influence of regions on the detector's decision. Compared to previous classification activation mapping works, Grad-ODAM generates instance-specific explanations rather than class-specific ones. We show that Grad-ODAM is applicable to both one-stage detectors such as FCOS and two-stage detectors such as Faster R-CNN, and produces higher-quality visual explanations than the state-of-the-art both effectively and efficiently. We next propose a training scheme, ODAM-Train, to improve the explanation ability on object discrimination of the detector through encouraging consistency between explanations for detections on the same object, and distinct explanations for detections on different objects. Based on the heat maps produced by Grad-ODAM with ODAM-Train, we propose ODAM-NMS, which considers the information of the model's explanation for each prediction to distinguish the duplicate detected objects. We present a detailed analysis of the visualized explanations of detectors and carry out extensive experiments to validate the effectiveness of the proposed ODAM.

Understanding Curriculum Learning in Policy Optimization for Online Combinatorial Optimization

Runlong Zhou,Yuandong Tian,Yi Wu,Simon Shaolei Du

Over the recent years, reinforcement learning (RL) starts to show promising results in tackling combinatorial optimization (CO) problems, in particular when coupled with curriculum learning to facilitate training. Despite emerging empirical evidence, theoretical study on why RL helps is still at its early stage. This paper presents the first systematic study on policy optimization methods for online CO problems. We show that online CO problems can be naturally formulated as latent Markov Decision Processes (LMDPs), and prove convergence bounds on natural policy gradient (NPG) for solving LMDPs. Furthermore, our theory explains the benefit of curriculum learning: it can find a strong sampling policy and reduce the distribution shift, a critical quantity that governs the convergence rate in our theorem. For a canonical online CO problem, Secretary Problem, we formally prove that distribution shift is reduced exponentially with curriculum learning even if the curriculum is randomly generated. Our theory also shows we can simplify the curriculum learning scheme used in prior work from multi-step to single-step. Lastly, we provide extensive experiments on Secretary Problem and Online Knapsack to verify our findings.

Toward Adversarial Training on Contextualized Language Representation

Hongqiu Wu,Yongxiang Liu,Hanwen Shi,hai zhao,Min Zhang

Beyond the success story of adversarial training (AT) in the recent text domain on top of pre-trained language models (PLMs), our empirical study showcases the inconsistent gains from AT on some tasks, e.g. commonsense reasoning, named entity recognition. This paper investigates AT from the perspective of the contextualized language representation outputted by PLM encoders. We find the current AT attacks lean to generate sub-optimal adversarial examples that can fool the decoder part but have a minor effect on the encoder. However, we find it necessary to effectively deviate the latter one to allow AT to gain. Based on the observati on, we propose simple yet effective \textit{Contextualized representation-Adversarial Training} (CreAT), in which the attack is explicitly optimized to deviate the contextualized representation of the encoder. It allows a global optimization of adversarial examples that can fool the entire model. We also find CreAT gives rise to a better direction to optimize the adversarial examples, to let them less sensitive to hyperparameters. Compared to AT, CreAT produces consistent performance gains on a wider range of tasks and is proven to be more effective for language pre-training where only the encoder part is kept for downstream tasks. We achieve the new state-of-the-art performances on a series of challenging benchmarks, e.g. AdvGLUE (59.1 $ \rightarrow $ 61.1), HellaSWAG (93.0 $ \rightarrow $ 94.9), ANLI (68.1 $ \rightarrow $ 69.3).

Efficient Method for Bi-level Optimization with Non-smooth Lower-Level Problem

Wanli Shi,Bin Gu

Bi-level optimization plays a key role in a lot of machine learning applications. Existing state-of-the-art bi-level optimization methods are limited to smooth or some specific non-smooth lower-level problems. Therefore, achieving an efficient algorithm for the bi-level problems with a generalized non-smooth lower-level objective is still an open problem. To address this problem, in this paper, we propose a new bi-level optimization algorithm based on smoothing and penalty techniques. Using the theory of generalized directional derivative, we derive new conditions for the bilevel optimization problem with nonsmooth, perhaps non-Lipschitz lower-level problem, and prove our method can converge to the points satisfying these conditions. We also compare our method with existing state-of-the-art bi-level optimization methods and demonstrate that our method is superior to the others in terms of accuracy and efficiency.

Estimating Riemannian Metric with Noise-Contaminated Intrinsic Distance

Jiaming Qiu,Xiongtao Dai

We extend metric learning by studying the Riemannian manifold structure of the underlying data space induced by dissimilarity measures between data points. The key quantity of interest here is the Riemannian metric, which characterizes the Riemannian geometry and defines straight lines and derivatives on the manifold. Being able to estimate the Riemannian metric allows us to gain insights into the underlying manifold and compute geometric features such as the geodesic curves. We model the observed dissimilarity measures as noisy responses generated from a function of the intrinsic geodesic distance between data points. A new local regression approach is proposed to learn the Riemannian metric tensor and its derivatives based on a Taylor expansion for the squared geodesic distances. Our framework is general and accommodates different types of responses, whether they are continuous, binary, or comparative, extending the existing works which consider a single type of response at a time. We develop theoretical foundation for our method by deriving the rates of convergence for the asymptotic bias and variance of the estimated metric tensor. The proposed method is shown to be versatile in simulation studies and a real data application involving taxi trip time in New York City.

In Search of Smooth Minima for Purifying Backdoor in Deep Neural Networks

Nazmul Karim,Abdullah Al Arafat,Umar Khalid,Zhishan Guo,Nazanin Rahnavard

The success of a deep neural network (DNN) heavily relies on the details of the training scheme; e.g., training data, architectures, hyper-parameters, etc. Recent backdoor attacks suggest that an adversary can take advantage of such training details and compromise the integrity of DNN. Our studies show that a backdoor model is usually optimized to a bad local minima, i.e., sharper minima as compared to a benign model. Intuitively, backdoor can be purified by re-optimizing the model to a smoother minima through fine-tuning with a few clean validation data. However, fine-tuning all DNN parameters often requires huge computational costs as well as sub-par clean test performance. To address this concern, we propose a novel backdoor purification technique—N atural G radient Fine-tuning (NGF)—which focuses on removing backdoor by fine-tuning only one layer. Specifically, NGF utilizes a loss surface geometry-aware optimizer that can successfully overcome the challenge of reaching a smooth minima under one-layer optimization scenario. To enhance the generalization performance of our proposed method, we introduce a clean data distribution-aware regularizer based on the knowledge of loss surface curvature matrix, i.e., Fisher Information Matrix. To validate the effectiveness of our method, we conduct extensive experimentation with four different datasets—CIFAR10, GTSRB, Tiny-ImageNet, and ImageNet; as well as 11 recent backdoor attacks, e.g., Blend, Dynamic, Clean Label, etc. NGF achieves state-of-the-art performance in most of these benchmarks.

Joint Gaussian Mixture Model for Versatile Deep Visual Model Explanation

Zhouyang Xie,Duanbing Chen

Post-hoc explanations of deep neural networks improve human understanding on the learned representations, decision-making process and uncertainty of the model with faithfulness. Explaining deep convolutional neural networks(DCNN) is especially challenging, due to the high dimensionality of deep features and the complexity of model inference. Most post-hoc explaining methods serve a single form of explanation, restricting the diversity and consistency of the explanation. This paper proposes joint Gaussian mixture model(JGMM), a probabilistic model jointly models inter-layer deep features and produces faithful and consistent post-hoc explanations. JGMM explains deep features by Gaussian mixture model and inter-layer deep feature relations by posterior distribution on the latent component variables. JGMM enables a versatile explaining framework that unifies interpretable proxy model, global or local explanatory example generation or mining. Experiments are performed on various DCNN image classifiers in comparison with other explaining methods. It shows that JGMM can efficiently produce versatile, consistent, faithful and understandable explanations.

Gromov-Wasserstein Autoencoders

Nao Nakagawa,Ren Togo,Takahiro Ogawa,Miki Haseyama

Variational Autoencoder (VAE)-based generative models offer flexible representation learning by incorporating meta-priors, general premises considered beneficial for downstream tasks. However, the incorporated meta-priors often involve ad-hoc model deviations from the original likelihood architecture, causing undesirable changes in their training. In this paper, we propose a novel representation learning method, Gromov-Wasserstein Autoencoders (GWAE), which directly matches the latent and data distributions using the variational autoencoding scheme. Instead of likelihood-based objectives, GWAE models minimize the Gromov-Wasserstein (GW) metric between the trainable prior and given data distributions. The GW metric measures the distance structure-oriented discrepancy between distributions even with different dimensionalities, which provides a direct measure between the latent and data spaces. By restricting the prior family, we can introduce meta-priors into the latent space without changing their objective. The empirical comparisons with VAE-based models show that GWAE models work in two prominent meta-priors, disentanglement and clustering, with their GW objective unchanged.

Localized Graph Contrastive Learning

Hengrui Zhang,Qitian Wu,Yu Wang,Shaofeng Zhang,Junchi Yan,Philip S. Yu

Contrastive learning methods based on InfoNCE loss are popular in node representation learning tasks on graph-structured data. However, its reliance on data augmentation and its quadratic computational complexity might lead to inconsistency and inefficiency problems. To mitigate these limitations, in this paper, we introduce a simple yet effective contrastive model named Localized Graph Contrastive Learning (Local-GCL in short). Local-GCL consists of two key designs: 1) We fa bricate the positive examples for each node directly using its first-order neighbors, which frees our method from the reliance on carefully-designed graph augmentations; 2) To improve the efficiency of contrastive learning on graphs, we devise a kernelized contrastive loss, which could be approximately computed in linear time and space complexity with respect to the graph size. We provide theoretical analysis to justify the effectiveness and rationality of the proposed methods. Experiments on various datasets with different scales and properties demonstrate that in spite of its simplicity, Local-GCL achieves quite competitive performance in self-supervised node representation learning tasks on graphs with various scales and properties.

OrthoReg: Improving Graph-regularized MLPs via Orthogonality Regularization

Hengrui Zhang,Shen Wang,Soji Adeshina,Vassilis N. Ioannidis,Jiani Zhang,Xiao Qin,Christos Faloutsos,Da Zheng,George Karypis,Philip S. Yu

Graph Neural Networks (GNNs) are currently dominating in modeling graph-structure data, while their high reliance on graph structure for inference significantly impedes them from widespread applications. By contrast, graph-Regularized MLPs (GR-MLPs) implicitly inject the graph structure information into model weights, while their performance can hardly match that of GNNs in most tasks. This motivates us to study the causes of the limited performance of GR-MLPs. In this paper, we demonstrate that node embeddings learned from conventional GR-MLPs suffer from dimensional collapse, a phenomenon in which the largest a few eigenvalues dominate the embedding space, and thus the expressive power is constrained. We further propose ORTHO-REG, a novel GR-MLP model, to mitigate the dimensional collapse issue. Through a soft regularization loss on the correlation matrix of node embeddings, ORTHO-REG explicitly encourages orthogonal node representations and thus can naturally avoid dimensionally collapsed representations. Experiments on traditional transductive semi-supervised classification tasks and inductive node classification for cold-start scenarios demonstrate its effectiveness and superiority.

Optimal Activation Functions for the Random Features Regression Model

Jianxin Wang,José Bento

The asymptotic mean squared test error and sensitivity of the Random Features Regression model (RFR) have been recently studied. We build on this work and identify in closed-form the family of Activation Functions (AFs) that minimize a combination of the test error and sensitivity of the RFR under different notions of functional parsimony. We find scenarios under which the optimal AFs are linear, saturated linear functions, or expressible in terms of Hermite polynomials. Finally, we show how using optimal AFs impacts well established properties of the RFR model, such as its double descent curve, and the dependency of its optimal regularization parameter on the observation noise level.

Learning to Learn with Generative Models of Neural Network Checkpoints

William Peebles,Ilija Radosavovic,Tim Brooks,Alexei A Efros,Jitendra Malik

We explore a data-driven approach for learning to optimize neural networks. We construct a dataset of neural network checkpoints and train a generative model on the parameters. In particular, our model is a conditional diffusion transformer that, given an initial input parameter vector and a prompted loss, error, or return, predicts the distribution over parameter updates that achieve the desired metric. At test time, it can optimize neural networks with unseen parameters for downstream tasks in just one update. We find that our approach successfully generates parameters for a wide range of loss prompts. Moreover, it can sample multimodal parameter solutions and has favorable scaling properties. We apply our method to different neural network architectures and tasks in supervised and reinforcement learning.

****

Improving Explanation Reliability through Group Attribution

Sangmin Lee,Jongseong Jang,Woohyung Lim

Although input attribution methods are mainstream in understanding predictions of DNNs for straightforward interpretations, the non-linearity of DNNs often makes the attributed scores unreliable in explaining a given prediction, deteriorating the faithfulness of the explanation.

However, the challenge could be mitigated by attributing scores to groups of explanatory components instead of the individuals, termed group attribution. While a group attribution would explain the group-wise contribution more reliably, it does not explain the component-wise contributions so that estimating component-wise scores yields less reliable explanation, indicating the trade-off of group attributions.

In this work, we introduce the generalized definition of reliability loss and group attribution, and formulate the optimization problem of the trade-off with these terms. We apply our formalization to Shapley value attribution to propose the optimization method G-SHAP. We show the effectiveness and explanatory benefits of our method through empirical results on image classification tasks.

****

Intrinsic Motivation via Surprise Memory

Hung Le,Kien Do,Dung Nguyen,Svetha Venkatesh

We present a new computing model for intrinsic rewards in reinforcement learning that addresses the limitations of existing surprise-driven explorations. The reward is the novelty of the surprise rather than the surprise norm. We estimate the surprise novelty as retrieval errors of a memory network wherein the memory stores and reconstructs surprises. Our surprise memory (SM) augments the capability of surprise-based intrinsic motivators, maintaining the agent's interest in exciting exploration while reducing unwanted attraction to unpredictable or noisy observations. Our experiments demonstrate that the SM combined with various surprise predictors exhibits efficient exploring behaviors and significantly boosts the final performance in sparse reward environments, including Noisy-TV, navigation and challenging Atari games.

Dr-Fairness: Dynamic Data Ratio Adjustment for Fair Training on Real and Generated Data

Yuji Roh,Weili Nie,De-An Huang,Steven Euijong Whang,Arash Vahdat,Anima Anandkumar

Fair visual recognition has become critical for preventing demographic disparity. A major cause of model unfairness is the imbalanced representation of different groups in training data. Recently, several works aim to alleviate this issue using generated data. However, these approaches often use generated data to obtain similar amounts of data across groups, which is not optimal for achieving high fairness due to different learning difficulties and generated data qualities across groups. To address this issue, we propose a novel adaptive sampling approach that leverages both real and generated data for fairness. We design a bilevel optimization that finds the optimal data sampling ratios among groups and between real and generated data while training a model. The ratios are dynamically adjusted considering both the model's accuracy as well as its fairness. To efficiently solve our non-convex bilevel optimization, we propose a simple approximation to the solution given by the implicit function theorem. Extensive experiments show that our framework achieves state-of-the-art fairness and accuracy on the CelebA and ImageNet People Subtree datasets. We also observe that our method adaptively relies less on the generated data when it has poor quality.

****

Improving Object-centric Learning with Query Optimization

Baoxiong Jia,Yu Liu,Siyuan Huang

The ability to decompose complex natural scenes into meaningful object-centric abstractions lies at the core of human perception and reasoning. In the recent culmination of unsupervised object-centric learning, the Slot-Attention module has played an important role with its simple yet effective design and fostered many powerful variants. These methods, however, have been exceedingly difficult to train
without supervision and are ambiguous in the notion of object, especially for co

mplex natural scenes. In this paper, we propose to address these issues by investigating the potential of learnable queries as initializations for Slot-Attention learning, uniting it with efforts from existing attempts on improving Slot-Attention learning with bi-level optimization. With simple code adjustments on Slot-Attention, our model, Bi-level Optimized Query Slot Attention, achieves state-of-the-art results on 3 challenging synthetic and 7 complex real-world datasets in unsupervised image segmentation and reconstruction, outperforming previous baselines by a large margin. We provide thorough ablative studies to validate the necessity and effectiveness of our design. Additionally, our model exhibits great potential for concept binding and zero-shot learning. Our work is made publicly available at https://bo-qsa.github.io.

Set-Level Self-Supervised Learning from Noisily-Labeled Data

Chia-Ching Lin,Shang-Fu Chen,Fu-En Yang,Yu-Chiang Frank Wang,Chin-Laung Lei

Noisy labels are inevitably presented in real-world datasets due to labeling error or visual content ambiguity. Existing methods generally approach the task of noisy label learning (NLL) by either properly regularizing the model, or reweighting clean/noisy labeled samples. While self-supervised learning (SSL) has been applied to pre-train deep neural networks without label supervision, downstream tasks like image classification still require clean labeled data. And, most SSL strategies are performed at the instance level, regardless of the correctness of its label. In this paper, we propose set-level self-supervised learning (SLSSL), which performs SSL at mini-batch levels with observed noisy labels. By corrupting the labels of each training mini-batch, our SLSSL enforces the model to exhibit sufficient robustness. Moreover, the proposed SLSSL can also be utilized for sample reweighting technique. As a result, the proposed learning scheme can be applied as an expectation-maximization (EM) algorithm during model training. Extensive experiments on synthetic and real-world noisy label data confirm the effectiveness of our framework.

Feature Reconstruction From Outputs Can Mitigate Simplicity Bias in Neural Networks

Sravanti Addepalli,Anshul Nasery,Venkatesh Babu Radhakrishnan,Praneeth Netrapalli,Prateek Jain

Deep Neural Networks are known to be brittle to even minor distribution shifts compared to the training distribution. While one line of work has demonstrated that \emph{Simplicity Bias} (SB) of DNNs -- bias towards learning only the simplest features -- is a key reason for this brittleness, another recent line of work has surprisingly found that diverse/ complex features are indeed learned by the backbone, and their brittleness is due to the linear classification head relying primarily on the simplest features. To bridge the gap between these two lines of work, we first hypothesize and verify that while SB may not altogether preclude learning complex features, it amplifies simpler features over complex ones. Namely, simple features are replicated several times in the learned representations while complex features might not be replicated. This phenomenon, we term \emph{Feature Replication Hypothesis}, coupled with the \emph{Implicit Bias} of SGD to converge to maximum margin solutions in the feature space, leads the models to rely mostly on the simple features for classification. To mitigate this bias, we propose \emph{Feature Reconstruction Regularizer (FRR)} to ensure that the learned features can be reconstructed back from the logits. The use of \emph{FRR} in linear layer training (\emph{FRR-L}) encourages the use of more diverse features for classification. We further propose to finetune the full network by freezing the weights of the linear layer trained using \emph{FRR-L}, to refine the learned features, making them more suitable for classification. Using this simple solution, we demonstrate up to 15\% gains in OOD accuracy on the recently introduced semi-synthetic datasets with extreme distribution shifts. Moreover, we demonstrate noteworthy gains over existing SOTA methods on the standard OOD benchmark DomainBed as well.

EUCLID: Towards Efficient Unsupervised Reinforcement Learning with Multi-choice

Dynamics Model

Yifu Yuan,Jianye HAO,Fei Ni,Yao Mu,YAN ZHENG,Yujing Hu,Jinyi Liu,Yingfeng Chen,Changjie Fan

Unsupervised reinforcement learning (URL) poses a promising paradigm to learn useful behaviors in a task-agnostic environment without the guidance of extrinsic rewards to facilitate the fast adaptation of various downstream tasks. Previous works focused on the pre-training in a model-free manner while lacking the study of transition dynamics modeling that leaves a large space for the improvement of sample efficiency in downstream tasks. To this end, we propose an Efficient Unsupervised Reinforcement Learning Framework with Multi-choice Dynamics model (EUCLID), which introduces a novel model-fused paradigm to jointly pre-train the dynamics model and unsupervised exploration policy in the pre-training phase, thus better leveraging the environmental samples and improving the downstream task sampling efficiency. However, constructing a generalizable model which captures the local dynamics under different behaviors remains a challenging problem. We introduce the multi-choice dynamics model that covers different local dynamics under different behaviors concurrently, which uses different heads to learn the state transition under different behaviors during unsupervised pre-training and selects the most appropriate head for prediction in the downstream task. Experimental results in the manipulation and locomotion domains demonstrate that EUCLID achieves state-of-the-art performance with high sample efficiency, basically solving the state-based URLB benchmark and reaching a mean normalized score of 104.0±1.2% in downstream tasks with 100k fine-tuning steps, which is equivalent to DDPG’s performance at 2M interactive steps with 20× more data. More visualization videos are released on our homepage.

A General Framework for Sample-Efficient Function Approximation in Reinforcement Learning

Zixiang Chen,Chris Junchi Li,Huizhuo Yuan,Quanquan Gu,Michael Jordan

With the increasing need for handling large state and action spaces, general function approximation has become a key technique in reinforcement learning (RL). In this paper, we propose a general framework that unifies model-based and model-free RL, and an Admissible Bellman Characterization (ABC) class that subsumes nearly all Markov decision process (MDP) models in the literature for tractable RL. We propose a novel estimation function with decomposable structural properties for optimization-based exploration and the functional Eluder dimension as a complexity measure of the ABC class. Under our framework, a new sample-efficient algorithm namely OPtimization-based ExploRation with Approximation (OPERA) is proposed, achieving regret bounds that match or improve over the best-known results for a variety of MDP models. In particular, for MDPs with low Witness rank, under a slightly stronger assumption, OPERA improves the state-of-the-art sample complexity results by a factor of dH. Our framework provides a generic interface to design and analyze new RL models and algorithms.

Maximizing Spatio-Temporal Entropy of Deep 3D CNNs for Efficient Video Recognition

Junyan Wang,Zhenhong Sun,Yichen Qian,Dong Gong,Xiuyu Sun,Ming Lin,Maurice Pagnucco,Yang Song

3D convolution neural networks (CNNs) have been the prevailing option for video recognition. To capture the temporal information, 3D convolutions are computed along the sequences, leading to cubically growing and expensive computations. To reduce the computational cost, previous methods resort to manually designed 3D/2D CNN structures with approximations or automatic search, which sacrifice the modeling ability or make training time-consuming. In this work, we propose to automatically design efficient 3D CNN architectures via a novel training-free neural architecture search approach tailored for 3D CNNs considering the model complexity. To measure the expressiveness of 3D CNNs efficiently, we formulate a 3D CNN as an information system and derive an analytic entropy score, based on the Maximum Entropy Principle. Specifically, we propose a spatio-temporal entropy score (STEntr-Score) with a refinement factor to handle the discrepancy of visual inf ormation in spatial and temporal dimensions, through dynamically leveraging the correlation between the feature map size and kernel size depth-wisely. Highly efficient and expressive 3D CNN architectures, i.e., entropy-based 3D CNNs (E3D family), can then be efficiently searched by maximizing the STEntr-Score under a given computational budget, via an evolutionary algorithm without training the network parameters. Extensive experiments on Something-Something V1&V2 and Kinetics400 demonstrate that the E3D family achieves state-of-the-art performance with higher computational efficiency.

Cycle to Clique (Cy2C) Graph Neural Network: A Sight to See beyond Neighborhood Aggregation

Yun Young Choi,Sun Woo Park,Youngho Woo,U Jin Choi

Graph neural networks have been successfully adapted for learning vector representations of graphs through various neighborhood aggregation schemes. Previous researches suggest, however, that they possess limitations in incorporating key non-Euclidean topological properties of graphs. This paper mathematically identifies the caliber of graph neural networks in classifying isomorphism classes of graphs with continuous node attributes up to their local topological properties. In light of these observations, we construct the Cycle to Clique graph neural network, a novel yet simple algorithm which topologically enriches the input data of conventional graph neural networks while preserving their architectural components. This method theoretically outperforms conventional graph neural networks in classifying isomorphism classes of graphs while ensuring comparable time complexity in representing random graphs. Empirical results further support that the novel algorithm produces comparable or enhanced results in classifying benchmark graph data sets compared to contemporary variants of graph neural networks.

Latent State Marginalization as a Low-cost Approach for Improving Exploration

Dinghuai Zhang,Aaron Courville,Yoshua Bengio,Qinqing Zheng,Amy Zhang,Ricky T. Q. Chen

While the maximum entropy (MaxEnt) reinforcement learning (RL) framework -- often touted for its exploration and robustness capabilities -- is usually motivated from a probabilistic perspective, the use of deep probabilistic models have not gained much traction in practice due to their inherent complexity. In this work, we propose the adoption of latent variable policies within the MaxEnt framework, which we can provably approximate any policy distribution, and additionally, naturally emerges under the use of world models with a latent belief state.

We discuss why latent variable policies are difficult to train, how naive approaches can fail, and subsequently introduce a series of improvements centered around low-cost marginalization of the latent state, allowing us to make full use of the latent state at minimal additional cost. We instantiate our method under the actor-critic framework, marginalizing both the actor and critic. The resulting algorithm, referred to as Stochastic Marginal Actor-Critic (SMAC), is simple yet effective. We experimentally validate our method on continuous control tasks, showing that effective marginalization can lead to better exploration and more robust training. Our implementation is open sourced at https://github.com/zdhNarsil/Stochastic-Marginal-Actor-Critic.

TensorVAE: A Direct Generative Model for Molecular Conformation Generation driven by Novel Feature Engineering

Hongyang Yu,Hongjiang Yu

Efficient generation of 3D conformations of a molecule from its 2D graph is a key challenge in in-silico drug discovery. Deep learning (DL) based generative modelling has recently become a potent tool to tackling this challenge. However, many existing DL-based methods are either indirect-leveraging inter-atomic distances or direct-but requiring complex feature transformation or numerous sampling steps to generate conformations. In this work, we propose a simple model abbreviated TensorVAE capable of generating conformations directly from a 2D molecular graph in a single step. The main novelty of the proposed method is focused on feature engineering. We develop a novel encoding and feature extraction mechanism r elying solely on standard convolution operation to generate token-like feature vector for each atom. These feature vectors are then transformed through standard transformer encoders under a conditional Variational Auto Encoder framework for learning to generate conformations directly. We show through experiments on two benchmark datasets that with intuitive and sensible feature engineering, a relatively simple and standard model can provide promising generative capability rivalling recent state-of-the-art models employing more sophisticated and specialized generative architecture.

Smoothed-SGDmax: A Stability-Inspired Algorithm to Improve Adversarial Generalization

Jiancong Xiao,Jiawei Zhang,Zhi-Quan Luo,Asuman E. Ozdaglar

Unlike standard training, deep neural networks can suffer from serious overfitting problems in adversarial settings, which is studied extensively by empirical papers. Recent research (e.g., Xing et al. (2021); Xiao et al. (2022)) show that SGDmax-based adversarial training algorithms with $1/s(T)$ training loss incurs a stability-based generalization bound in $\Theta(c+s(T)/n)$. Here T is the number of iterations, n is the number of samples, $s(T)\rightarrow \infty$ as $T\rightarrow \infty$, and c is a n-independent term. This reveals that adversarial training can have nonvanishing generalization errors even if the sample size n goes to infinity. A natural question arises: can we eliminate the nonvanishing term c by designing a more generalizable algorithm? We give an affirmative answer in this paper. First, by an adaptation of information-theoretical lower bound on the complexity of solving Lipschitz-convex problems using randomized algorithms, we show that a minimax lower bound for adversarial generalization gap is $\Omega(s(T)/n)$ given training loss $1/s(T)$. This implies that SGDmax does not achieve the lower bound. Next, by observing that the nonvanishing generalization error term for SGDmax comes from the non-smoothness of the adversarial loss function, we employ a smoothing technique to smooth the adversarial loss function. Based on the smoothed loss function, we design a smoothed SGDmax algorithm achieving generalization bound $\mathcal{O}(s(T)/n)$, which matches the minimax lower bound. Experimentally, we show that our algorithm improves adversarial generalization on common datasets.

Generalizing and Decoupling Neural Collapse via Hyperspherical Uniformity Gap

Weiyang Liu,Longhui Yu,Adrian Weller,Bernhard Schölkopf

The neural collapse (NC) phenomenon describes an underlying geometric symmetry for deep neural networks, where both deeply learned features and classifiers converge to a simplex equiangular tight frame. It has been shown that both cross-entropy loss and mean square error can provably lead to NC. We remove NC's key assumption on the feature dimension and the number of classes, and then present a generalized neural collapse (GNC) hypothesis that effectively subsumes the original NC. Inspired by how NC characterizes the training target of neural networks, we decouple GNC into two objectives: minimal intra-class variability and maximal inter-class separability. We then use hyperspherical uniformity (which characterizes the degree of uniformity on the unit hypersphere) as a unified framework to quantify these two objectives. Finally, we propose a general objective -- hyperspherical uniformity gap (HUG), which is defined by the difference between inter-class and intra-class hyperspherical uniformity. HUG not only provably converges to GNC, but also decouples GNC into two separate objectives. Unlike cross-entropy loss that couples intra-class compactness and inter-class separability, HUG enjoys more flexibility and serves as a good alternative loss function. Empirical results show that HUG works well in terms of generalization and robustness.

****

MaskFusion: Feature Augmentation for Click-Through Rate Prediction via Input-adaptive Mask Fusion

Chao Liao,Jianchao Tan,Jiyuan Jia,Yi Guo,Chengru Song

Click-through rate (CTR) prediction plays important role in the advertisement, recommendation, and retrieval applications. Given the feature set, how to fully utilize the information from the feature set is an active topic in deep CTR model designs. There are several existing deep CTR works focusing on feature interactions, feature attentions, and so on. They attempt to capture high-order feature interactions to enhance the generalization ability of deep CTR models. However, these works either suffer from poor high-order feature interaction modeling using DNN or ignore the balance between generalization and memorization during the recommendation. To mitigate these problems, we propose an adaptive feature fusion framework called MaskFusion, to additionally capture the explicit interactions between the input feature and the existing deep part structure of deep CTR models dynamically, besides the common feature interactions proposed in existing works. MaskFusion is an instance-aware feature augmentation method, which makes deep CTR models more personalized by assigning each feature with an instance-adaptive mask and fusing each feature with each hidden state vector in the deep part structure. MaskFusion can also be integrated into any existing deep CTR models flexibly. MaskFusion achieves state-of-the-art (SOTA) performance on all seven benchmarks deep CTR models with three public datasets.

Finite-time Analysis of Single-timescale Actor-Critic on Linear Quadratic Regulator

Xuyang Chen,Jingliang Duan,Lin Zhao

Actor-critic (AC) methods have achieved state-of-the-art performance in many challenging tasks. However, their convergence in most practical applications are still poorly understood. Existing works mostly consider the uncommon double-loop or two-timescale stepsize variants for the ease of analysis. We investigate the practical yet more challenging vanilla single-sample single-timescale AC for solving the canonical linear quadratic regulator problem. Specifically, the actor and the critic update only once with a single sample in each iteration using proportional stepsizes. We prove that the vanilla AC can attain an ϵ-optimal solution with a sample complexity of $\tilde{\mathcal{O}}(\epsilon^{-2})$, which elucidates on the practical efficiency of single-sample single-timescale AC. We develop a novel analysis framework that directly bounds the whole interconnected iteration system without the conservative decoupling commonly adopted in previous analysis of AC. Our work presents the first finite-time analysis of single-sample single-timescale AC with a global optimality guarantee.

Scalable 3D Object-centric Learning

Tianyu Wang,miaomiao Liu,Kee Siong Ng

We tackle the task of unsupervised 3D object-centric representation learning on scenes of potentially unbounded scale.

Existing approaches to object-centric representation learning exhibit significant limitations in achieving scalable inference due to their dependencies on a fixed global coordinate system.

In contrast, we propose to learn view-invariant 3D object representations in localized object coordinate systems.

To this end, we estimate the object pose and appearance representation separately and explicitly project object representations across views.

We adopt amortized variational inference to process sequential input and update object representations online.

To scale up our model to scenes with an arbitrary number of objects, we further introduce a Cognitive Map that allows the registration and querying of objects on a global map.

We employ the object-centric neural radiance field (NeRF) as our 3D scene representation, which is jointly inferred by our unsupervised object-centric learning framework.

Experimental results demonstrate that our method can infer and maintain object-centric representations of unbounded 3D scenes.

Further combined with a per-object NeRF finetuning process, our model can achieve scalable high-quality object-aware scene reconstruction.

Towards Boosting the Open-Domain Chatbot with Human Feedback

Hua Lu,Siqi Bao,Huang He,Fan Wang,Hua Wu,Haifeng Wang

Many open-domain dialogue models pre-trained with social media comments can generate coherent replies but have difficulties producing engaging responses. This phenomenon might mainly result from the deficiency of annotated human-human conversations and the misalignment with human preference. In this paper, we propose a novel and efficient framework Diamante to boost the open-domain chatbot, where two kinds of human feedback (including explicit demonstration and implicit preference) are collected and leveraged. By asking annotators to select or amend the model-generated candidate responses, Diamante efficiently collects the human demonstrated responses and constructs a Chinese chit-chat dataset. To enhance the alignment with human preference, Diamante leverages the implicit preference in the data collection process and introduces the generation-evaluation joint training. Comprehensive experiments indicate that the Diamante dataset and joint training paradigm can significantly boost the performance of pre-trained dialogue models. The overall engagingness of the previous state-of-the-art model has been improved remarkably by 50% in Chinese open-domain conversations.

Learning to Generate All Feasible Actions

Mirco Theile,Daniele Bernardini,Raphael Trumpp,Cristina Piazza,Marco Caccamo,Alberto Sangiovanni-Vincentelli

Several machine learning (ML) applications are characterized by searching for an optimal solution to a complex task. The search space for this optimal solution is often very large, so large in fact that this optimal solution is often not computable. Part of the problem is that many candidate solutions found via ML are actually infeasible and have to be discarded. Restricting the search space to only the feasible solution candidates simplifies finding an optimal solution for the tasks. Further, the set of feasible solutions could be re-used in multiple problems characterized by different tasks. In particular, we observe that complex tasks can be decomposed into subtasks and corresponding skills. We propose to learn a reusable and transferable skill by training an actor to generate all feasible actions. The trained actor can then propose feasible actions, among which an optimal one can be chosen according to a specific task. The actor is trained by interpreting the feasibility of each action as a target distribution. The training procedure minimizes a divergence of the actor's output distribution to this target. We derive the general optimization target for arbitrary f-divergences using a combination of kernel density estimates, resampling, and importance sampling. We further utilize an auxiliary critic to reduce the interactions with the environment. A preliminary comparison to related strategies shows that our approach learns to visit all the modes in the feasible action space, demonstrating the framework's potential for generating multimodal action distributions.

Rethinking Self-Supervised Visual Representation Learning in Pre-training for 3D Human Pose and Shape Estimation

Hongsuk Choi,Hyeongjin Nam,Taeryung Lee,Gyeongsik Moon,Kyoung Mu Lee

Recently, a few self-supervised representation learning (SSL) methods have outperformed the ImageNet classification pre-training for vision tasks such as object detection. However, its effects on 3D human body pose and shape estimation (3DHPSE) are open to question, whose target is fixed to a unique class, the human, and has an inherent task gap with SSL. We empirically study and analyze the effects of SSL and further compare it with other pre-training alternatives for 3DHPSE. The alternatives are 2D annotation-based pre-training and synthetic data pre-training, which share the motivation of SSL that aims to reduce the labeling cost. They have been widely utilized as a source of weak-supervision or fine-tuning, but have not been remarked as a pre-training source. SSL methods underperform the conventional ImageNet classification pre-training on multiple 3DHPSE benchmarks by 7.7% on average. In contrast, despite a much less amount of pre-training data, the 2D annotation-based pre-training improves accuracy on all benchmarks and shows faster convergence during fine-tuning. Our observations challenge the naive application of the current SSL pre-training to 3DHPSE and relight the value of other data types in the pre-training aspect.

Sparsity by Redundancy: Solving L_1 with a Simple Reparametrization
Liu Ziyin,Zihao Wang

We identify and prove a general principle: L_1 sparsity can be achieved using a redundant parametrization plus L_2 penalty. Our results lead to a simple algorithm, \textit{spred}, that seamlessly integrates L_1 regularization into any modern deep learning framework. Practically, we demonstrate (1) the efficiency of \textit{spred} in optimizing conventional tasks such as lasso and sparse coding, (2) benchmark our method for nonlinear feature selection of six gene selection tasks, and (3) illustrate the usage of the method for achieving structured and unstructured sparsity in deep learning in an end-to-end manner. Conceptually, our result bridges the gap in understanding the inductive bias of the redundant parametrization common in deep learning and conventional statistical learning.

Test-Time Adaptation for Visual Document Understanding
Sayna Ebrahimi,Sercan O Arik,Tomas Pfister

Self-supervised pretraining has been able to produce transferable representations for various visual document understanding (VDU) tasks. However, the ability of such representations to adapt to new distribution shifts at test-time has not been studied yet. We propose DocTTA, a novel test-time adaptation approach for documents that leverages cross-modality self-supervised learning via masked visual language modeling as well as pseudo labeling to adapt models learned on a \textit{source} domain to an unlabeled \textit{target} domain at test time. We also introduce new benchmarks using existing public datasets for various VDU tasks including entity recognition, key-value extraction, and document visual question answering tasks where DocTTA improves the source model performance up to 1.79\% in (F1 score), 3.43\% (F1 score), and 17.68\% (ANLS score), respectively.

Learned Index with Dynamic ϵ
Daoyuan Chen,Wuchao Li,Yaliang Li,Bolin Ding,Kai Zeng,Defu Lian,Jingren Zhou

Index structure is a fundamental component in database and facilitates broad data retrieval applications. Recent learned index methods show superior performance by learning hidden yet useful data distribution with the help of machine learning, and provide a guarantee that the prediction error is no more than a pre-defined ϵ. However, existing learned index methods adopt a fixed ϵ for all the learned segments, neglecting the diverse characteristics of different data localities. In this paper, we propose a mathematically-grounded learned index framework with dynamic ϵ, which is efficient and pluggable to existing learned index methods. We theoretically analyze prediction error bounds that link ϵ with data characteristics for an illustrative learned index method. Under the guidance of the derived bounds, we learn how to vary ϵ and improve the index performance with a better space-time trade-off. Experiments with real-world datasets and several state-of-the-art methods demonstrate the efficiency, effectiveness and usability of the proposed framework.

Boosting Multiagent Reinforcement Learning via Permutation Invariant and Permutation Equivariant Networks
Jianye HAO,Xiaotian Hao,Hangyu Mao,Weixun Wang,Yaodong Yang,Dong Li,YAN ZHENG,Zhen Wang

The state space in Multiagent Reinforcement Learning (MARL) grows exponentially with the agent number. Such a curse of dimensionality results in poor scalability and low sample efficiency, inhibiting MARL for decades. To break this curse, we propose a unified agent permutation framework that exploits the permutation invariance (PI) and permutation equivariance (PE) inductive biases to reduce the multiagent state space. Our insight is that permuting the order of entities in the factored multiagent state space does not change the information. Specifically, we propose two novel implementations: a Dynamic Permutation Network (DPN) and a Hyper Policy Network (HPN). The core idea is to build separate entity-wise PI input and PE output network modules to connect the entity-factored state space and action space in an end-to-end way. DPN achieves such connections by two separa te module selection networks, which consistently assign the same input module to the same input entity (guarantee PI) and assign the same output module to the same entity-related output (guarantee PE). To enhance the representation capability, HPN replaces the module selection networks of DPN with hypernetworks to directly generate the corresponding module weights. Extensive experiments in SMAC, Google Research Football and MPE validate that the proposed methods significantly boost the performance and the learning efficiency of existing MARL algorithms. Remarkably, in SMAC, we achieve 100% win rates in almost all hard and super-hard scenarios (never achieved before).

LAU: A novel two-parameter learnable Logmoid Activation Unit

Xue-Mei Zhou,Ling-Fang Li,Xing-Zhou Zheng,Mingxing Luo

The activation function in deep neural networks has a major impact on the performance of the training stage. In this work, we proposed a novel learnable Logmoid Activation Unit (LAU), $f(x)=x\ln(1+\alpha \textrm{sigmoid}(\beta x))$, with two free parameters α and β that can be optimized via back-propagation algorithm. We design quasi-interpolation type neural network operators with Logmoid-1 in a given feed-forward neural network for approximating any continuous function in closed spaces. This provides a theoretical basis for the excellent empirical performance of LAUs in experimental simulations. For instance, compared with ReLUs the proposed LAUs improves Top-1 classification accuracy on ImageNet-200 by 7% respectively in ShuffleNet-V2, on CIFAR-10 by 6$\%$ respectively in EfficientNet-B0, and on CIFAR-100 by 5$\%$ respectively in MobileNet-V2. Our simulations show that end-to-end learning deep neural networks with learnable Logmoids can increase the predictive performance.

N-Student Learning: An Approach to Model Uncertainty and Combat Overfitting

Ryan Y. Xu,Solomon E Garber,Antonella Di Lillo,James Storer

This work presents N-Student Learning, a pseudo-label based multi-network training setup that can be applied to nearly any supervised learning architecture in order to help combat the problem of overfitting and control the way in which a network models uncertainty in the data. The effectiveness of N-Student Learning relies on the idea that a network's predictions on unseen data are largely independent of any instance-dependent noise in the labels. In N-Student Learning, each student network is assigned a subset of the training dataset such that no data point is in every student's training subset. Unbiased pseudo-labels can thus be generated for every data point in the training set by taking the predictions of appropriate student networks. Training on these unbiased pseudo-labels minimizes the extent to which each network overfits to instance-dependent noise in the data. Furthermore, based on prior knowledge of the domain, we can control how the networks learn to model uncertainty that is present in the dataset by adjusting the way that pseudo-labels are generated. While this method is largely inspired by the general problem of overfitting, a natural application is found in the problem of classification with noisy labels — a domain where overfitting is a significant concern. After developing intuition through a toy classification task, we proceed to demonstrate that N-Student Learning performs favorably on benchmark datasets when compared to state-of-the-art methods in the problem of classification with noisy labels.

****

wav2tok: Deep Sequence Tokenizer for Audio Retrieval

Adhiraj Banerjee,Vipul Arora

Search over audio sequences is a fundamental problem. In this paper, we propose a method to extract concise discrete representations for audio that can be used for efficient retrieval. Our motivation comes from orthography which represents speech of a given language in a concise and distinct discrete form. The proposed method, wav2tok, learns such representations for any kind of audio, speech or non-speech, from pairs of similar audio. wav2tok compresses the query and target sequences into shorter sequences of tokens that are faster to match. The learning method makes use of CTC loss and expectation-maximization algorithm, which are generally used for supervised automatic speech recognition and for learning dis crete latent variables, respectively. Experiments show the consistent performance of wav2tok across two audio retrieval tasks: music search (query by humming) and speech search via audio query, outperforming state-of-the-art baselines.

Image to Sphere: Learning Equivariant Features for Efficient Pose Prediction
David Klee,Ondrej Biza,Robert Platt,Robin Walters

Predicting the pose of objects from a single image is an important but difficult computer vision problem. Methods that predict a single point estimate do not predict the pose of objects with symmetries well and cannot represent uncertainty. Alternatively, some works predict a distribution over orientations in $\mathrm{SO}(3)$. However, training such models can be computation- and sample-inefficient. Instead, we propose a novel mapping of features from the image domain to the 3D rotation manifold. Our method then leverages $\mathrm{SO}(3)$ equivariant layers, which are more sample efficient, and outputs a distribution over rotations that can be sampled at arbitrary resolution. We demonstrate the effectiveness of our method at object orientation prediction, and achieve state-of-the-art performance on the popular PASCAL3D+ dataset. Moreover, we show that our method can model complex object symmetries, without any modifications to the parameters or loss function. Code is available at \url{https://dmklee.github.io/image2sphere}.

PV3D: A 3D Generative Model for Portrait Video Generation
Eric Zhongcong Xu,Jianfeng Zhang,Jun Hao Liew,Wenqing Zhang,Song Bai,Jiashi Feng,Mike Zheng Shou

Recent advances in generative adversarial networks (GANs) have demonstrated the capabilities of generating stunning photo-realistic portrait images. While some prior works have applied such image GANs to unconditional 2D portrait video generation and static 3D portrait synthesis, there are few works successfully extending GANs for generating 3D-aware portrait videos. In this work, we propose PV3D, the first generative framework that can synthesize multi-view consistent portrait videos. Specifically, our method extends the recent static 3D-aware image GAN to the video domain by generalizing the 3D implicit neural representation to model the spatio-temporal space. To introduce motion dynamics into the generation process, we develop a motion generator by stacking multiple motion layers to generate motion features via modulated convolution. To alleviate motion ambiguities caused by camera/human motions, we propose a simple yet effective camera condition strategy for PV3D, enabling both temporal and multi-view consistent video generation. Moreover, PV3D introduces two discriminators for regularizing the spatial and temporal domains to ensure the plausibility of the generated portrait videos. These elaborated designs enable PV3D to generate 3D-aware motion-plausible portrait videos with high-quality appearance and geometry, significantly outperforming prior works. As a result, PV3D is able to support downstream applications such as static portrait animation and view-consistent motion editing. Code and models are available at https://showlab.github.io/pv3d.

k-Median Clustering via Metric Embedding: Towards Better Initialization with Differential Privacy
Chenglin Fan,Ping Li,Xiaoyun Li

In clustering algorithms, the choice of initial centers is crucial for the quality of the learned clusters. We propose a new initialization scheme for the k-median problem in the general metric space (e.g., discrete space induced by graphs), based on the construction of metric embedding tree structure of the data. From the tree, we propose a novel and efficient search algorithm, for good initial centers that can be used subsequently for the local search algorithm. The so-called HST initialization method can produce initial centers achieving lower errors than those from another popular initialization method, k-median++, with comparable efficiency. Our HST initialization can also be easily extended to the setting of differential privacy (DP) to generate private initial centers. We show that the error of applying DP local search followed by our private HST initialization improves previous results on the approximation error, and approaches the lower bound within a small factor. Experiments demonstrate the effectiveness of ou r proposed methods.

Analysis of Error Feedback in Compressed Federated Non-Convex Optimization

Xiaoyun Li,Ping Li

Communication cost between the clients and the central server could be a bottleneck in real-world Federated Learning (FL) systems. In classical distributed learning, the method of Error Feedback (EF) has been a popular technique to remedy the downsides of biased gradient compression, but literature on applying EF to FL is still very limited. In this work, we propose a compressed FL scheme equipped with error feedback, named Fed-EF, with two variants depending on the global optimizer. We provide theoretical analysis showing that Fed-EF matches the convergence rate of the full-precision FL counterparts in non-convex optimization under data heterogeneity. Moreover, we initiate the first analysis of EF under partial client participation, which is an important scenario in FL, and demonstrate that the convergence rate of Fed-EF exhibits an extra slow down factor due to the ``stale error compensation'' effect. Experiments are conducted to validate the efficacy of Fed-EF in practical FL tasks and justify our theoretical findings.

Characterizing the Influence of Graph Elements

Zizhang Chen,Peizhao Li,Hongfu Liu,Pengyu Hong

Influence function, a method from the robust statistics, measures the changes of model parameters or some functions about model parameters with respect to the removal or modification of training instances. It is an efficient and useful post-hoc method for studying the interpretability of machine learning models without the need of expensive model re-training. Recently, graph convolution networks (GCNs), which operate on graph data, have attracted a great deal of attention. However, there is no preceding research on the influence functions of GCNs to shed light on the effects of removing training nodes/edges from an input graph. Since the nodes/edges in a graph are interdependent in GCNs, it is challenging to derive influence functions for GCNs. To fill this gap, we started with the simple graph convolution (SGC) model that operates on an attributed graph, and formulated an influence function to approximate the changes of model parameters when a node or an edge is removed from an attributed graph. Moreover, we theoretically analyzed the error bound of the estimated influence of removing an edge. We experimentally validated the accuracy and effectiveness of our influence estimation function. In addition, we showed that the influence function of a SGC model could be used to estimate the impact of removing training nodes/edges on the test performance of the SGC without re-training the model. Finally, we demonstrated how to use influence functions to effectively guide the adversarial attacks on GCNs.

Adversarially Robust Neural Lyapunov Control

Li Wei,Yuankun Jiang,Chenglin Li,Wenrui Dai,Junni Zou,Hongkai Xiong

State-of-the-art learning-based stability control methods for nonlinear robotic systems suffer from the issue of reality gap, which stems from discrepancy of the system dynamics between training and target (test) environments. To mitigate this gap, we propose an adversarially robust neural Lyapunov control (ARNLC) method to improve the robustness and generalization capabilities for Lyapunov theory-based stability control. Specifically, inspired by adversarial learning, we introduce an adversary to simulate the dynamics discrepancy, which is learned through deep reinforcement learning to generate the worst-case perturbations during the controller's training. By alternatively updating the controller to minimize the perturbed Lyapunov risk and the adversary to deviate the controller from its objective, the learned control policy enjoys a theoretical guarantee of stability. Empirical evaluations on five stability control tasks with the uniform and worst-case perturbations demonstrate that ARNLC not only accelerates the convergence to asymptotic stability, but can generalize better in the entire perturbation space.

MICN: Multi-scale Local and Global Context Modeling for Long-term Series Forecasting

Huiqiang Wang,Jian Peng,Feihu Huang,Jince Wang,Junhui Chen,Yifei Xiao

Recently, Transformer-based methods have achieved surprising performance in the field of long-term series forecasting, but the attention mechanism for computing global correlations entails high complexity. And they do not allow for targeted modeling of local features as CNN structures do. To solve the above problems, we propose to combine local features and global correlations to capture the overall view of time series (e.g., fluctuations, trends). To fully exploit the underlying information in the time series, a multi-scale branch structure is adopted to model different potential patterns separately. Each pattern is extracted with down-sampled convolution and isometric convolution for local features and global correlations, respectively. In addition to being more effective, our proposed method, termed as Multi-scale Isometric Convolution Network (MICN), is more efficient with linear complexity about the sequence length with suitable convolution kernels. Our experiments on six benchmark datasets show that compared with state-of-the-art methods, MICN yields 17.2% and 21.6% relative improvements for multivariate and univariate time series, respectively.

EMP: Effective Multidimensional Persistence for Graph Representation Learning

Ignacio Segovia-Dominguez,Baris Coskunuzer,Cuneyt Gurcan Akcora,Yuzhou Chen,Zhiwei Zhen,Murat Kantarcioglu,Yulia Gel

Topological data analysis (TDA) has become increasingly popular in a broad range of machine learning tasks, ranging from anomaly detection and manifold learning to graph classification.

Persistent homology being the key approach in TDA provides a unique topological fingerprint of the data by assessing the evolution of various hidden patterns in the data as we vary a scale parameter. Current PH tools are limited to analyze the data by filtering with single parameter while in many applications, several relevant parameters are equally important to get a much finer information on the data. In this paper, we overcome this problem by introducing Effective Multidimensional Persistence (EMP) framework which enables to investigate the data by varying multiple scale parameters simultaneously. EMP framework provides a highly expressive summary of the data by integrating the multiple descriptor functions to the process successfully. EMP naturally adapts to many known single PH summaries and convert them into multidimensional summaries, for example, EMP Landscapes, EMP Silhouettes, EMP Images, and EMP Surfaces. These summaries deliver a multidimensional fingerprint of the data as matrices and arrays which are suitable for various machine learning models.

We apply EMP framework in graph classification tasks and observe that EMP boosts the performances of various single PH descriptors, and outperforms the most state-of-the-art methods on benchmark datasets. We further derive theoretical guarantees of the proposed EMP summary and prove the stability properties.

SWIFT: Rapid Decentralized Federated Learning via Wait-Free Model Communication

Marco Bornstein,Tahseen Rabbani,Evan Z Wang,Amrit Bedi,Furong Huang

The decentralized Federated Learning (FL) setting avoids the role of a potentially unreliable or untrustworthy central host by utilizing groups of clients to collaboratively train a model via localized training and model/gradient sharing. Most existing decentralized FL algorithms require synchronization of client models where the speed of synchronization depends upon the slowest client. In this work, we propose SWIFT: a novel wait-free decentralized FL algorithm that allows clients to conduct training at their own speed. Theoretically, we prove that SWIFT matches the gold-standard iteration convergence rate $\mathcal{O}(1/\sqrt{T})$ of parallel stochastic gradient descent for convex and non-convex smooth optimization (total iterations T). Furthermore, we provide theoretical results for IID and non-IID settings without any bounded-delay assumption for slow clients which is required by other asynchronous decentralized FL algorithms. Although SWIFT achieves the same iteration convergence rate with respect to T as other state-of-the-art (SOTA) parallel stochastic algorithms, it converges faster with respect to runtime due to its wait-free structure. Our experimental results demonstrate that SWIFT's runtime is reduced due to a large reduction in communication t ime per epoch, which falls by an order of magnitude compared to synchronous counterparts. Furthermore, SWIFT produces loss levels for image classification, over IID and non-IID data settings, upwards of 50\% faster than existing SOTA algorithms.

****

Hierarchical Sliced Wasserstein Distance

Khai Nguyen,Tongzheng Ren,Huy Nguyen,Litu Rout,Tan Minh Nguyen,Nhat Ho

Sliced Wasserstein (SW) distance has been widely used in different application scenarios since it can be scaled to a large number of supports without suffering from the curse of dimensionality. The value of sliced Wasserstein distance is the average of transportation cost between one-dimensional representations (projections) of original measures that are obtained by Radon Transform (RT). Despite its efficiency in the number of supports, estimating the sliced Wasserstein requires a relatively large number of projections in high-dimensional settings. Therefore, for applications where the number of supports is relatively small compared with the dimension, e.g., several deep learning applications where the mini-batch approaches are utilized, the complexities from matrix multiplication of Radon Transform become the main computational bottleneck. To address this issue, we propose to derive projections by linearly and randomly combining a smaller number of projections which are named bottleneck projections. We explain the usage of these projections by introducing Hierarchical Radon Transform (HRT) which is constructed by applying Radon Transform variants recursively. We then formulate the approach into a new metric between measures, named Hierarchical Sliced Wasserstein (HSW) distance. By proving the injectivity of HRT, we derive the metricity of HSW. Moreover, we investigate the theoretical properties of HSW including its connection to SW variants and its computational and sample complexities. Finally, we compare the computational cost and generative quality of HSW with the conventional SW on the task of deep generative modeling using various benchmark datasets including CIFAR10, CelebA, and Tiny ImageNet.

Test-time Adaptation for Better Adversarial Robustness

Zhichao Huang,Chen Liu,Mathieu Salzmann,Sabine Süsstrunk,Tong Zhang

Standard adversarial training and its variants have been widely adopted in practice to achieve robustness against adversarial attacks. However, we show in this work that such an approach does not necessarily achieve near optimal generalization performance on test samples. Specifically it is shown that under suitable assumptions, Bayesian optimal robust estimator requires test-time adaptation, and such adaptation can lead to significant performance boost over standard adversarial training. Motivated by this observation, we propose a practically easy to implement method to improve the generalization performance of adversarially-trained networks via an additional self-supervised test-time adaptation step. We further employs a meta adversarial training method to find a good starting point for test-time adaptation, which incorporates the test-time adaptation procedure into the training phase and it strengthens the correlation between the pre-text tasks in self-supervised learning and the original classification task. Extensive empirical experiments on CIFAR10, STL10 and Tiny ImageNet using several different self-supervised tasks show that our method consistently improves the robust accuracy of standard adversarial training under different white-box and black-box attack strategies.

AutoShot: A Short Video Dataset and State-of-the-Art Shot Boundary Detection

Wentao Zhu,Xiufeng Xie,Wenxian Liu,Jincan Deng,Debing Zhang,Zhangyang Wang,Ji Liu

The short-form videos have explosive popularity and have dominated the new social media trends. Prevailing short-video platforms, e.g., TikTok, Instagram Reels, and YouTube Shorts, have changed the way we consume and create content. For video content creation and understanding, the shot boundary detection (SBD) is one of the most essential components in various scenarios. In this work, we release a new public Short video sHot bOundary deTection dataset, named SHOT, consisting of 853 complete short videos and 11,606 shot annotations, with 2,716 high quali ty shot boundary annotations in 200 test videos. Leveraging this new data wealth, we propose to optimize the model design for video SBD, by conducting neural architecture search in a search space encapsulating various advanced 3D ConvNets and Transformers. Our proposed approach, named AutoShot, achieves higher F1 scores than previous state-of-the-art approaches, e.g., outperforming TransNetV2 by 4.2%, when being derived and evaluated on our newly constructed SHOT dataset. Moreover, to validate the generalizability of the AutoShot architecture, we directly evaluate it on another three public datasets: ClipShots, BBC and RAI, and the F1 scores of AutoShot outperform previous state-of-the-art approaches by 1.1%, 0.9% and 1.2%, respectively. The SHOT dataset and code will be released.

Prototypical Calibration for Few-shot Learning of Language Models

Zhixiong Han,Yaru Hao,Li Dong,Yutao Sun,Furu Wei

In-context learning of GPT-like models has been recognized as fragile across different hand-crafted templates, and demonstration permutations. In this work, we propose prototypical calibration to adaptively learn a more robust decision boundary for zero- and few-shot classification, instead of greedy decoding. Concretely, our method first adopts Gaussian mixture distribution to estimate the prototypical clusters for all categories. Then we assign each cluster to the corresponding label by solving a weighted bipartite matching problem. Given an example, its prediction is calibrated by the likelihood of prototypical clusters. Experimental results show that prototypical calibration yields a substantial improvement on a diverse set of tasks. Extensive analysis across different scales also indicates that our method calibrates the decision boundary as expected, greatly improving the robustness of GPT to templates, permutations, and class imbalance.

NERDS: A General Framework to Train Camera Denoisers from Raw-RGB Noisy Image Pairs

Heewon Kim,Kyoung Mu Lee

We aim to train accurate denoising networks for smartphone/digital cameras from single noisy images. Downscaling is commonly used as a practical denoiser for low-resolution images. Based on this processing, we found that the pixel variance of the natural images is more robust to downscaling than the pixel variance of the camera noises. Intuitively, downscaling easily removes high-frequency noises than natural textures. To utilize this property, we can adopt noisy/clean image synthesis at low-resolution to train camera denoisers. On this basis, we propose a new solution pipeline -- NERDS that estimates camera noises and synthesizes noisy-clean image pairs from only noisy images. In particular, it first models the noise in raw-sensor images as a Poisson-Gaussian distribution, then estimates the noise parameters using the difference of pixel variances by downscaling. We formulate the noise estimation as a gradient-descent-based optimization problem through a reparametrization trick. We further introduce a new Image Signal Processor (ISP) estimation method that enables denoiser training in a human-readable RGB space by transforming the synthetic raw images to the style of a given RGB noisy image. The noise and ISP estimations utilize rich augmentation to synthesize image pairs for denoiser training. Experiments show that our NERDS can accurately train CNN-based denoisers (e.g., DnCNN, ResNet-style network) outperforming previous noise-synthesis-based and self-supervision-based denoisers in real datasets.

Communication-Efficient and Drift-Robust Federated Learning via Elastic Net

Seonhyeong Kim,jiheon woo,Daewon Seo,Yongjune Kim

Federated learning (FL) is a distributed method to train a global model over a set of local clients while keeping data localized, which reduces risks of privacy and security. FL framework faces important challenges including expensive communication cost and client drift problem. Leveraging the elastic net, we propose a communication-efficient and drift-robust FL framework to improve the communication efficiency and resolve the client drift problem. We repurpose two types of the elastic net regularizers (i.e., ℓ_1 and ℓ_2 penalties on the local model updates): (1) the ℓ_1-norm regularizer sparsifies the local updates t o enhance the communication efficiency and (2) the ℓ_2-norm regularizer attempts to resolve the client drift problem by limiting the impact of drifting local updates due to data heterogeneity. Our framework is general; hence, it can be integrated with prior FL techniques, e.g., FedAvg, FedProx, SCAFFOLD, and FedDyn. We show that our framework effectively resolves the communication cost problem and the client drift problem simultaneously.

Learning Hierarchical Protein Representations via Complete 3D Graph Networks

Limei Wang,Haoran Liu,Yi Liu,Jerry Kurtin,Shuiwang Ji

We consider representation learning for proteins with 3D structures. We build 3D graphs based on protein structures and develop graph networks to learn their representations. Depending on the levels of details that we wish to capture, protein representations can be computed at different levels, \emph{e.g.}, the amino acid, backbone, or all-atom levels. Importantly, there exist hierarchical relations among different levels. In this work, we propose to develop a novel hierarchical graph network, known as ProNet, to capture the relations. Our ProNet is very flexible and can be used to compute protein representations at different levels of granularity. By treating each amino acid as a node in graph modeling as well as harnessing the inherent hierarchies, our ProNet is more effective and efficient than existing methods. We also show that, given a base 3D graph network that is complete, our ProNet representations are also complete at all levels. Experimental results show that ProNet outperforms recent methods on most datasets. In addition, results indicate that different downstream tasks may require representations at different levels. Our code is publicly available as part of the DIG library (\url{https://github.com/divelab/DIG}).

Adversarial Attacks on Adversarial Bandits

Yuzhe Ma,Zhijin Zhou

We study a security threat to adversarial multi-armed bandit, in which an attacker perturbs the loss or reward signal to control the behavior of the victim bandit player. We show that the attacker is able to mislead any no-regret adversarial bandit algorithm into selecting a suboptimal target action in every but sublinear (T−o(T)) number of rounds, while incurring only sublinear (o(T)) cumulative attack cost. This result implies critical security concern in real-world bandit-based systems, e.g., in online recommendation, an attacker might be able to hijack the recommender system and promote a desired product. Our proposed attack algorithms require knowledge of only the regret rate, thus are agnostic to the concrete bandit algorithm employed by the victim player. We also derived a theoretical lower bound on the cumulative attack cost that any victim-agnostic attack algorithm must incur. The lower bound matches the upper bound achieved by our attack, which shows that our attack is asymptotically optimal.

Grounding High Dimensional Representation Similarity by Comparing Decodability and Network Performance

Lucas Hayne,Heejung Jung,Abhijit Suresh,R. McKell Carter

To understand and interpret neural networks, representation similarity metrics have been used to compare learned representations between and across networks. Recent experiments have compared these similarity metrics to find the best performing and the most robust metrics, noting that classic baselines perform surprisingly well. These experiments are mostly constrained to studying relatively low-dimensional representations because of the computational cost of prominent representation similarity metrics. We extend previous work to test representation similarity metrics on larger convolutional networks processing larger images. In order to make this work possible, we employ reformulated representation similarity metrics for use on very high-dimensional representations. Using these reformulated similarity metrics, we test how well each metric captures changes to representations induced by ablations in two popular convolutional networks. In order to ground the effects of changes to representations in function, we use linear decoding probes and network performance measures. These measures of function allow us to test how well similarity metrics capture changes in decodable information ve rsus changes in network performance. Linear decoding methods index available information in the representation, while network performance measures index the information used by the network. We show that all the tested representation similarity metrics significantly predict changes in network function and decodability. Within these metrics, on average, Procrustes and CKA outperform regularized CCA-based methods. All metrics predict decodability changes significantly better than they do network function. Procrustes and CKA do not outperform regularized CCA-based metrics for all network and functionality measure combinations. We add to the growing literature on representational similarity metrics to facilitate the improvement of current metrics for network interpretability.

Likelihood adjusted semidefinite programs for clustering heterogeneous data

Yubo Zhuang,Xiaohui Chen,Yun Yang

Clustering is a widely deployed unsupervised learning tool. Model-based clustering is a flexible framework to tackle data heterogeneity when the clusters have different shapes. Likelihood-based inference for mixture distributions often involves non-convex and high-dimensional objective functions, imposing difficult computational and statistical challenges. The classic expectation-maximization (EM) algorithm is a computationally thrifty iterative method that maximizes a surrogate function minorizing the log-likelihood of observed data in each iteration, which however suffers from bad local maxima even in the special case of the standard Gaussian mixture model with common isotropic covariance matrices. On the other hand, recent studies reveal that the unique global solution of a semidefinite programming (SDP) relaxed K-means achieves the information-theoretically sharp threshold for perfectly recovering the cluster labels under the standard Gaussian mixture model. In this paper, we extend the SDP approach to a general setting by integrating cluster labels as model parameters and propose an iterative likelihood adjusted SDP (iLA-SDP) method that directly maximizes the \emph{exact} observed likelihood in the presence of data heterogeneity. By lifting the cluster assignment to group-specific membership matrices, iLA-SDP avoids centroids estimation -- a key feature that allows exact recovery under well-separateness of centroids without being trapped by their adversarial configurations. Thus iLA-SDP is less sensitive than EM to initialization and more stable on high-dimensional data. Our numeric experiments demonstrate that iLA-SDP can achieve lower mis-clustering errors over several widely used clustering methods including K-means, SDP and EM algorithms.

RGI: robust GAN-inversion for mask-free image inpainting and unsupervised pixel-wise anomaly detection

Shancong Mou,Xiaoyi Gu,Meng Cao,Haoping Bai,Ping Huang,Jiulong Shan,Jianjun Shi

Generative adversarial networks (GANs), trained on a large-scale image dataset, can be a good approximator of the natural image manifold. GAN-inversion, using a pre-trained generator as a deep generative prior, is a promising tool for image restoration under corruptions. However, the performance of GAN-inversion can be limited by a lack of robustness to unknown gross corruptions, i.e., the restored image might easily deviate from the ground truth. In this paper, we propose a Robust GAN-inversion (RGI) method with a provable robustness guarantee to achieve image restoration under unknown \textit{gross} corruptions, where a small fraction of pixels are completely corrupted. Under mild assumptions, we show that the restored image and the identified corrupted region mask converge asymptotically to the ground truth. Moreover, we extend RGI to Relaxed-RGI (R-RGI) for generator fine-tuning to mitigate the gap between the GAN learned manifold and the true image manifold while avoiding trivial overfitting to the corrupted input image, which further improves the image restoration and corrupted region mask identification performance. The proposed RGI/R-RGI method unifies two important applications with state-of-the-art (SOTA) performance: (i) mask-free semantic inpainting, where the corruptions are unknown missing regions, the restored background can be used to restore the missing content. (ii) unsupervised pixel-wise anomaly detection, where the corruptions are unknown anomalous regions, the retrieved mask can be used as the anomalous region’s segmentation mask.

Coverage-centric Coreset Selection for High Pruning Rates

Haizhong Zheng,Rui Liu,Fan Lai,Atul Prakash

One-shot coreset selection aims to select a representative subset of the training data, given a pruning rate, that can later be used to train future models while retaining high accuracy. State-of-the-art coreset selection methods pick the highest importance examples based on an importance metric and are found to perform well at low pruning rates. However, at high pruning rates, they suffer from a catastrophic accuracy drop, performing worse than even random sampling. This paper explores the reasons behind this accuracy drop both theoretically and empirically. We first propose a novel metric to measure the coverage of a dataset on a specific distribution by extending the classical geometric set cover problem to a distribution cover problem. This metric helps explain why coresets selected by SOTA methods at high pruning rates perform poorly compared to random sampling because of worse data coverage. We then propose a novel one-shot coreset selection method, Coverage-centric Coreset Selection (CCS), that jointly considers overall data coverage upon a distribution as well as the importance of each example. We evaluate CCS on five datasets and show that, at high pruning rates (e.g., 90%), it achieves significantly better accuracy than previous SOTA methods (e.g., at least 19.56% higher on CIFAR10) as well as random selection (e.g., 7.04% higher on CIFAR10) and comparable accuracy at low pruning rates. We make our code publicly available at https://github.com/haizhongzheng/Coverage-centric-coreset-selection.

AIA: learn to design greedy algorithm for NP-complete problems using neural networks

Zhenxin Ding,Jingyan Sui,Ruizhi Liu,Shizhe Ding,Liming Xu,Zihao Huang,Chao Wang,Haicang Zhang,Shiwei Sun,Chungong Yu,Dongbo Bu

Algorithm design is an art that heavily requires intuition and expertise of the human designers as well as insights into the problems under consideration. In particular, the design of greedy-selection rules, the core of greedy algorithms, is usually a great challenge to designer: it is relatively easy to understand a greedy algorithm while it is always difficult to find out an effective greedy-selection rule. In the study, we present an approach, called AIA, to learn algorithm design with the aid of neural networks. We consider the minimum weighted set cover (SC) problem, one of the NP-hard problems, as an representative example. Initially, we formulate a given weighted SC problem as an 0-1 integer linear program (ILP): each variable x_i has two options, i.e., $x_i=0$, which denotes abandon of the set s_i, and $x_i = 1$, which denotes selection of s_i. Each option of a variable leads to a sub-problem with respect to the original ILP problem. Next, we design a generic search framework to find the optimal solution to the ILP problem. At each search step, the value of a variable is determined with the aid of neural networks. The key of our neural network is the loss function: the original ILP problem and the sub-problems generated by assigning a variable x_i should satisfy the Bellman-Ford equation, and the dissatisfication of the Bellman-Ford equation is evaluated and used as loss function of our neural network. The trained neural network is used as greedy-selection rule. Experimental results on representative instances suggest that using the NN-based greedy selection rule, we can successfully find the optimal solutions. More importantly, the NN-based greedy-selection rule outperform the outstanding Chavatal greedy algorithm, which was designed by human expert. The basic idea of our approach can be readily extended without significant modification to design greedy algorithm for other NP-hard problems.

Self-Adaptive Perturbation Radii for Adversarial Training

Huimin Wu,Zhang Chenkang,Bin Gu

Adversarial training has been shown to be the most popular and effective technique to protect models from imperceptible adversarial samples. Despite its success, it also accompanies the significant performance degeneration to clean data. To achieve a good performance on both clean and adversarial samples, the main eff ort is searching for an adaptive perturbation radius for each training sample, which essentially suffers from a conflict between exact searching and computational overhead. To address this conflict, in this paper, firstly we show the superiority of adaptive perturbation radii intuitively and theoretically regarding the accuracy and robustness respectively. Then we propose our novel self-adaptive adjustment framework for perturbation radii without tedious searching. We also discuss this framework on both deep neural networks (DNNs) and kernel support vector machines (SVMs). Finally, extensive experimental results show that our framework can improve not only natural generalization performance but also adversarial robustness. It is also competitive with existing searching strategies in terms of running time.

GCINT: Dynamic Quantization Algorithm for Training Graph Convolution Neural Networks Using Only Integers

Qizhe Wu,Letian Zhao,Huawen Liang,Xiaotian Wang,LinFeng Tao,Teng Tian,Tingxin Wang,Zerong He,Wei Wu,Xi Jin

Quantization approaches can minimize storage costs while decreasing the computational complexity of a model, although there is minimal study in the GNN field on quantization networks. We studied the four primary reasons why existing quantization approaches cannot be employed extensively with GNNs: (1)Quantifying the distinctions between data sources; (2)Quantifying the distinctions between data streams; (3)Quantifying the distinctions between concentrations; (4)QAT’s Limitations. Based on this, we propose GCINT, which is an efficient quantization framework prepared for GNN training. The entire forward, backward, optimizer, and loss functions are calculated using integer data. We achieved a training acceleration ratio of nearly 10× compared to FP32 Cuda Core in RTX 2080TI INT8 Tensor Core. Our quantization is independent of the dataset and weight distribution, and more than 2,000 randomized trials have been undertaken on the 8 popular GNN benchmark datasets, with all achieving errors within 1% of the FP32.

ILA-DA: Improving Transferability of Intermediate Level Attack with Data Augmentation

Chiu Wai Yan,Tsz-Him Cheung,Dit-Yan Yeung

Adversarial attack aims to generate deceptive inputs to fool a machine learning model. In deep learning, an adversarial input created for a specific neural network can also trick other neural networks. This intriguing property is known as black-box transferability of adversarial examples. To improve black-box transferability, a previously proposed method called Intermediate Level Attack (ILA) fine-tunes an adversarial example by maximizing its perturbation on an intermediate layer of the source model. Meanwhile, it has been shown that simple image transformations can also enhance attack transferability. Based on these two observations, we propose ILA-DA, which employs three novel augmentation techniques to enhance ILA. Specifically, we propose (1) an automated way to apply effective image transformations, (2) an efficient reverse adversarial update technique, and (3) an attack interpolation method to create more transferable adversarial examples. Shown by extensive experiments, ILA-DA greatly outperforms ILA and other state-of-the-art attacks by a large margin. On ImageNet, we attain an average attack success rate of 84.5%, which is 19.5% better than ILA and 4.7% better than the previous state-of-the-art across nine undefended models. For defended models, ILA-DA also leads existing attacks and provides further gains when incorporated into more advanced attack methods.

Contrastive Alignment of Vision to Language Through Parameter-Efficient Transfer Learning

Zaid Khan,Yun Fu

Contrastive vision-language models (e.g. CLIP) are typically created by updating all the parameters of a vision model and language model through contrastive training. Can such models be created by a small number of parameter updates to an already-trained language model and vision model? The literature describes techniques that can create vision-language models by updating a small number of paramet

ers in a language model, but these require already aligned visual representations and are non-contrastive, hence unusable for latency-sensitive applications such as neural search. We explore the feasibility and benefits of parameter-efficient contrastive vision-language alignment through transfer learning: creating a model such as CLIP by minimally updating an already-trained vision and language model. We find that a minimal set of parameter updates ($<$7\%) can achieve the same performance as full-model training, and updating specific components ($<$1\% of parameters) can match 75\% of full-model training. We describe a series of experiments: we show that existing knowledge is conserved more strongly in parameter-efficient training and that parameter-efficient scaling scales with model and dataset size. Where paired-image text data is scarce but strong multilingual language models exist (e.g. low resource languages), parameter-efficient training is even preferable to full-model training. Given a fixed compute budget, parameter-efficient training allows training larger models on the same hardware, achieving equivalent performance in less time. Parameter-efficient training hence constitutes an energy-efficient and effective training strategy for contrastive vision-language models that may be preferable to the full-model training paradigm for common use cases.

BEEF: Bi-Compatible Class-Incremental Learning via Energy-Based Expansion and Fusion

Fu-Yun Wang,Da-Wei Zhou,Liu Liu,Han-Jia Ye,Yatao Bian,De-Chuan Zhan,Peilin Zhao

Neural networks suffer from catastrophic forgetting when sequentially learning tasks phase-by-phase, making them inapplicable in dynamically updated systems. Class-incremental learning (CIL) aims to enable neural networks to learn different categories at multi-stages. Recently, dynamic-structure-based CIL methods achieve remarkable performance. However, these methods train all modules in a coupled manner and do not consider possible conflicts among modules, resulting in spoilage of eventual predictions. In this work, we propose a unifying energy-based theory and framework called Bi-Compatible Energy-Based Expansion and Fusion (BEEF) to analyze and achieve the goal of CIL. We demonstrate the possibility of training independent modules in a decoupled manner while achieving bi-directional compatibility among modules through two additionally allocated prototypes, and then integrating them into a unifying classifier with minimal cost. Furthermore, BEEF extends the exemplar-set to a more challenging setting, where exemplars are randomly selected and imbalanced, and maintains its performance when prior methods fail dramatically.
Extensive experiments on three widely used benchmarks: CIFAR-100, ImageNet-100, and ImageNet-1000 demonstrate that BEEF achieves state-of-the-art performance in both the ordinary and challenging CIL settings. The Code is available at https://github.com/G-U-N/ICLR23-BEEF.

****

Out-of-distribution Representation Learning for Time Series Classification

Wang Lu,Jindong Wang,Xinwei Sun,Yiqiang Chen,Xing Xie

Time series classification is an important problem in the real world. Due to its non-stationary property that the distribution changes over time, it remains challenging to build models for generalization to unseen distributions. In this paper, we propose to view time series classification from the distribution perspective. We argue that the temporal complexity of a time series dataset could attribute to unknown latent distributions that need characterize. To this end, we propose DIVERSIFY for out-of-distribution (OOD) representation learning on dynamic distributions of times series. DIVERSIFY takes an iterative process: it first obtains the ‘worst-case’ latent distribution scenario via adversarial training, then reduces the gap between these latent distributions. We then show that such an algorithm is theoretically supported. Extensive experiments are conducted on seven datasets with different OOD settings across gesture recognition, speech commands recognition, wearable stress and affect detection, and sensor-based human activity recognition. Qualitative and quantitative results demonstrate that DIVERSIFY significantly outperforms other baselines and effectively characterizes the latent distributions. Code is available at https://github.com/microsoft/robustlearn.

A Closer Look at the Calibration of Differentially Private Learners
Hanlin Zhang,Xuechen Li,Prithviraj Sen,Salim Roukos,Tatsunori Hashimoto

We systematically study the calibration of classifiers trained with differentially private stochastic gradient descent (DP-SGD) and observe miscalibration across a wide range of vision and language tasks. Our analysis identifies per-example gradient clipping in DP-SGD as a major cause of miscalibration, and we show that existing approaches for improving calibration with differential privacy only provide marginal improvements in calibration error while occasionally causing large degradations in accuracy. As a solution, we show that differentially private variants of post-processing calibration methods such as temperature scaling and Platt scaling are surprisingly effective and have negligible utility cost to the overall model. Across 7 tasks, temperature scaling and Platt scaling with DP-SGD result in an average 3.1-fold reduction in the in-domain expected calibration error and only incur at most a minor percent drop in accuracy.

****

Exploring Transformer Backbones for Heterogeneous Treatment Effect Estimation
YiFan Zhang,Hanlin Zhang,Zachary Chase Lipton,Li Erran Li,Eric Xing

Previous works on Treatment Effect Estimation (TEE) are not in widespread use because they are predominantly theoretical, where strong parametric assumptions are made but untractable for practical application. Recent works use Multilayer Perceptron (MLP) for modeling casual relationships, however, MLPs lag far behind recent advances in ML methodology, which limits their applicability and generalizability. To extend beyond the single domain formulation and towards more realistic learning scenarios, we explore model design spaces beyond MLPs, i.e., transformer backbones, which provide flexibility where attention layers govern interactions among treatments and covariates to exploit structural similarities of potential outcomes for confounding control. Through careful model design, Transformers as Treatment Effect Estimators (TransTEE) is proposed. We show empirically that TransTEE can: (1) serve as a general-purpose treatment effect estimator which significantly outperforms competitive baselines on a variety of challenging TEE problems (e.g., discrete, continuous, structured, or dosage-associated treatments.) and is applicable to both when covariates are tabular and when they consist of structural data (e.g., texts, graphs); (2) yield multiple advantages: compatibility with propensity score modeling, parameter efficiency, robustness to continuous treatment value distribution shifts, explainable in covariate adjustment, and real-world utility in auditing pre-trained language models.

Few-Shot Learning with Representative Global Prototype
Yukun Liu,Daming Shi,Hexiu Lin

Few-shot learning is often challenged by low generalization performance due to the assumption that the data distribution of novel classes and base classes is similar while the model is trained only on the base classes. To mitigate the above issues, we propose a few-shot learning with representative global prototype method. Specifically, to enhance the generalization to novel classes, we propose a method to jointly train the base classes and the novel classes, using selected representative and non-representative samples to optimize representative global prototypes, respectively. Additionally, a method that organically combines the sample of base classes conditional on semantic embedding to generate new samples of novel classes with the original data is proposed to enhance the data of novel classes. Results show that this training method improves the model's ability to describe novel classes, improving the classification performance for a few shots. Intensive experiments have been conducted on two popular benchmark datasets, and the experimental results show that this method significantly improves the classification ability of few-shot learning tasks and achieves state-of-the-art performance.

Feature-Driven Talking Face Generation with StyleGAN2

Tao Zhang,Kai Tang,Weiwu Zhang,Kazushige Ouchi

In this work, we wish to use a face image that generate a more natural and real face talking animation video. This is not an easy task because face appearance variation and semantics of speech are coupled together when tacking face have a micro movement. Audio features sometimes contain information about expressions, but they are not accurate enough. So a single audio feature cannot fully represent the movement of the face. For the above reason, we want to use different features to generate talking faces. The StyleGan series show good performance in the direction of image processing, and can perform the style migration task of portraits very well at the same time. We find that StyleGan can be used as a talking face generator. At the same time, we also encode and extract non-identity features and non-lip features, and try to find the subtle relationship between the features and the talking face. We also use the evaluation and ablation study to measure the quality of the generated videos and examine whether our approach is effective and feasible.

Schema Inference for Interpretable Image Classification

Haofei Zhang,Mengqi Xue,Xiaokang Liu,Kaixuan Chen,Jie Song,Mingli Song

In this paper, we study a novel inference paradigm, termed as schema inference, that learns to deductively infer the explainable predictions by rebuilding the prior deep neural network (DNN) forwarding scheme, guided by the prevalent philosophical cognitive concept of schema. We strive to reformulate the conventional model inference pipeline into a graph matching policy that associates the extracted visual concepts of an image with the pre-computed scene impression, by analogy with human reasoning mechanism via impression matching. To this end, we devise an elaborated architecture, termed as SchemaNet, as a dedicated instantiation of the proposed schema inference concept, that models both the visual semantics of input instances and the learned abstract imaginations of target categories as topological relational graphs. Meanwhile, to capture and leverage the compositional contributions of visual semantics in a global view, we also introduce a universal Feat2Graph scheme in SchemaNet to establish the relational graphs that contain abundant interaction information. Both the theoretical analysis and the experimental results on several benchmarks demonstrate that the proposed schema inference achieves encouraging performance and meanwhile yields a clear picture of the deductive process leading to the predictions. Our code is available at https://github.com/zhfeing/SchemaNet-PyTorch.

Supernet Training for Federated Image Classification Under System Heterogeneity

Taehyeon Kim,Se-Young Yun

Efficient deployment of deep neural networks across many devices and resource constraints, particularly on edge devices, is one of the most challenging problems in the presence of data-privacy preservation issues. Conventional approaches have evolved to either improve a single global model while keeping each local heterogeneous training data decentralized (i.e. data heterogeneity; Federated Learning (FL)) or to train an overarching network that supports diverse architectural settings to address heterogeneous systems equipped with different computational capabilities (i.e. system heterogeneity; Neural Architecture Search). However, few studies have considered both directions simultaneously. This paper proposes the federation of supernet training (FedSup) framework to consider both scenarios simultaneously, i.e., where clients send and receive a supernet that contains all possible architectures sampled from itself. The approach is inspired by observing that averaging parameters during model aggregation for FL is similar to weight-sharing in supernet training. Thus, the proposed FedSup framework combines a weight-sharing approach widely used for training single shot models with FL averaging (FedAvg). Furthermore, we develop an efficient algorithm (E-FedSup) by sending the sub-model to clients on the broadcast stage to reduce communication costs and training overhead, including several strategies to enhance supernet training in the FL environment. We verify the proposed approach with extensive empirical evaluations. The resulting framework also ensures data and model heterogeneity robustness on several standard benchmarks.

CircuitNet: A Generic Neural Network to Realize Universal Circuit Motif Modeling
Yansen Wang,XINYANG JIANG,Kan Ren,Caihua Shan,Xufang Luo,Kaitao Song,Dongsheng Li

The successes of artificial neural networks (ANNs) are largely attributed to mimicking the human brain structures. Recent advances in neuroscience revealed that neurons interact with each other through various kinds of connectivity patterns to process information, in which the common connectivity patterns are also called circuit motifs. However, many existing ANNs can only model one or two circuit motifs in their architectures, so that their performance may drastically vary among different types of machine learning tasks.

In this paper, we propose a new type of neural network inspired by the architectures of neuronal circuits, namely Circuit Neural Network (CircuitNet). In CircuitNet, a group of densely connected neurons, namely circuit motif unit (CMU), form the basic unit of the network, which is capable of modeling universal circuit motifs by adjusting the weights within the CMUs. Compared with traditional feed-forward networks, CircuitNet has the ability to model more types of neuron connections such as feed-back and lateral motifs.

Inspired by the locally dense and globally sparse structure of the human brain, several iterations of signal transmission among different CMUs are achieved by sparse connections through the input ports and output ports of different CMUs.

Experiments have demonstrated that CircuitNet can outperform popular neural network architectures in function approximation, reinforcement learning, image classification, and time series forecasting tasks.

Your Contrastive Learning Is Secretly Doing Stochastic Neighbor Embedding
Tianyang Hu,Zhili LIU,Fengwei Zhou,Wenjia Wang,Weiran Huang

Contrastive learning, especially self-supervised contrastive learning (SSCL), has achieved great success in extracting powerful features from unlabeled data. In this work, we contribute to the theoretical understanding of SSCL and uncover its connection to the classic data visualization method, stochastic neighbor embedding (SNE), whose goal is to preserve pairwise distances. From the perspective of preserving neighboring information, SSCL can be viewed as a special case of SNE with the input space pairwise similarities specified by data augmentation. The established correspondence facilitates deeper theoretical understanding of learned features of SSCL, as well as methodological guidelines for practical improvement. Specifically, through the lens of SNE, we provide novel analysis on domain-agnostic augmentations, implicit bias and robustness of learned features. To illustrate the practical advantage, we demonstrate that the modifications from SNE to t-SNE can also be adopted in the SSCL setting, achieving significant improvement in both in-distribution and out-of-distribution generalization.

Covariance-Robust Minimax Probability Machines for Algorithmic Recourse
Ngoc Bui,Duy Nguyen,Kim-Cuc Nguyen,Man-Chung Yue,Viet Anh Nguyen

Algorithmic recourse is rising as a prominent technique to promote the explainability and transparency of the predictive model in ethical machine learning. Existing approaches to algorithmic recourse often assume an invariant predictive model; however, this model, in reality, is usually updated temporally upon the input of new data. Thus, a recourse that is valid respective to the present model may become invalid for the future model. To resolve this issue, we propose a pipeline to generate a model-agnostic recourse that is robust to model shifts. Our pipeline first estimates a linear surrogate of the nonlinear (black-box) model using covariance-robust minimax probability machines (MPM); then, the recourse is generated with respect to this robust linear surrogate. We show that the covariance-robust MPM recovers popular regularization schemes, including l_2-regularization and class-reweighting. We also show that our covariance-robust MPM pushes the decision boundary in an intuitive manner, which facilitates an interpretable generation of a robust recourse. The numerical results demonstrate the usefulness and robustness of our pipeline.

Harnessing Mixed Offline Reinforcement Learning Datasets via Trajectory Weighting

Zhang-Wei Hong,Pulkit Agrawal,Remi Tachet des Combes,Romain Laroche

Most offline reinforcement learning (RL) algorithms return a target policy maximizing a trade-off between (1) the expected performance gain over the behavior policy that collected the dataset, and (2) the risk stemming from the out-of-distribution-ness of the induced state-action occupancy. It follows that the performance of the target policy is strongly related to the performance of the behavior policy and, thus, the trajectory return distribution of the dataset. We show that in mixed datasets consisting of mostly low-return trajectories and minor high-return trajectories, state-of-the-art offline RL algorithms are overly restrained by low-return trajectories and fail to exploit high-performing trajectories to the fullest. To overcome this issue, we show that, in deterministic MDPs with stochastic initial states, the dataset sampling can be re-weighted to induce an artificial dataset whose behavior policy has a higher return. This re-weighted sampling strategy may be combined with any offline RL algorithm. We further analyze that the opportunity for performance improvement over the behavior policy correlates with the positive-sided variance of the returns of the trajectories in the dataset. We empirically show that while CQL, IQL, and TD3+BC achieve only a part of this potential policy improvement, these same algorithms combined with our reweighted sampling strategy fully exploit the dataset. Furthermore, we empirically demonstrate that, despite its theoretical limitation, the approach may still be efficient in stochastic environments.

Self-Consistency Improves Chain of Thought Reasoning in Language Models

Xuezhi Wang,Jason Wei,Dale Schuurmans,Quoc V Le,Ed H. Chi,Sharan Narang,Aakanksha Chowdhery,Denny Zhou

Chain-of-thought prompting combined with pretrained large language models has achieved encouraging results on complex reasoning tasks. In this paper, we propose a new decoding strategy, self-consistency, to replace the naive greedy decoding used in chain-of-thought prompting. It first samples a diverse set of reasoning paths instead of only taking the greedy one, and then selects the most consistent answer by marginalizing out all possible reasoning paths. Self-consistency leverages the intuition that a complex reasoning problem typically admits multiple different ways of thinking leading to its unique correct answer. Our extensive empirical evaluation shows that self-consistency boosts the performance of chain-of-thought prompting with a striking margin on a range of popular arithmetic and commonsense reasoning benchmarks, including GSM8K (+17.9%), SVAMP (+11.0%), AQuA (+12.2%), StrategyQA (+6.4%) and ARC-challenge (+3.9%).

****

Ensuring DNN Solution Feasibility for Optimization Problems with Linear Constraints

Tianyu Zhao,Xiang Pan,Minghua Chen,Steven Low

We propose preventive learning as the first framework to guarantee Deep Neural Network (DNN) solution feasibility for optimization problems with linear constraints without post-processing, upon satisfying a mild condition on constraint calibration. Without loss of generality, we focus on problems with only inequality constraints. We systematically calibrate the inequality constraints used in training, thereby anticipating DNN prediction errors and ensuring the obtained solutions remain feasible. We characterize the calibration rate and a critical DNN size, based on which we can directly construct a DNN with provable solution feasibility guarantee. We further propose an Adversarial-Sample Aware training algorithm to improve its optimality performance. We apply the framework to develop DeepOPF+ for solving essential DC optimal power flow problems in grid operation. Simulation results over IEEE test cases show that it outperforms existing strong DNN baselines in ensuring 100\% feasibility and attaining consistent optimality loss (<0.19%) and speedup (up to x228) in both light-load and heavy-load regimes, as compared to a state-of-the-art solver. We also apply our framework to a non-convex problem and show its performance advantage over existing schemes.

EM-Network: Learning Better Latent Variable for Sequence-to-Sequence Models

Ji Won Yoon,SungHwan Ahn,Hyeonseung Lee,Minchan Kim,SeokMin Kim,Nam Soo Kim

In a sequence-to-sequence (seq2seq) framework, the use of an unobserved latent variable, such as latent alignment and representation, is important to address the mismatch problem between the source input and target output sequences. Existing seq2seq literature typically learns the latent space by only consuming the source input, which might produce a sub-optimal latent variable for predicting the target. Extending an expectation-maximization (EM)-like algorithm, we introduce EM-Network that can yield the promising latent variable by leveraging the target sequence as the model's additional training input. The target input is used as guidance to provide the target-side context and reduce the candidates of the latent variable. The proposed framework is trained in a new self-distillation setup, allowing the original sequence model to benefit from the latent variable of the EM-Network. Specifically, the EM-Network's prediction serves as a soft label for training the inner sequence model, which only takes the source as input. We theoretically show that our training objective can be a lower bound for the log-likelihood of the sequence model and is justified from the EM perspective. We conduct comprehensive experiments on two sequence learning tasks: speech recognition and machine translation. Experimental results demonstrate that the EM-Network significantly advances the current state-of-the-art self-supervised learning approaches. It improves over the best prior work on speech recognition and establishes state-of-the-art performance on WMT'14 and IWSLT'14 datasets. Moreover, the proposed method even achieves considerable performance improvement for fully supervised learning.

****

AutoFHE: Automated Adaption of CNNs for Efficient Evaluation over FHE

Wei Ao,Vishnu Boddeti

Secure inference of deep convolutional neural networks (CNNs) was recently demonstrated under the RNS-CKKS fully homomorphic encryption (FHE) scheme. The state-of-the-art solution uses a high-order composite polynomial to approximate non-arithmetic ReLUs and refreshes zero-level ciphertext through bootstrapping. However, this solution suffers from prohibitively high latency, both due to the number of levels consumed by the polynomials (47%) and the inference time consumed by bootstrapping operations (70%). Furthermore, it requires a hand-crafted architecture for homomorphically evaluating CNNs by placing a bootstrapping operation after every Conv-BN layer. To accelerate CNNs on FHE and automatically design a homomorphic evaluation architecture, we propose AutoFHE: Automated adaption of CNNs for evaluation over FHE. AutoFHE exploits the varying sensitivity of approximate activations across different layers in a network and jointly evolves polynomial activations (EvoReLUs) and searches for placement of bootstrapping operations for evaluation under RNS-CKKS. The salient features of AutoFHE include: i) a multi-objective co-evolutionary (MOCoEv) search algorithm to maximize validation accuracy and minimize the number of bootstrapping operations, ii) a gradient-free search algorithm, R-CCDE, to optimize EvoReLU coefficients, and iii) polynomial-aware training (PAT) to fine-tune polynomial-only CNNs for one epoch to adapt trainable weights to EvoReLUs. We demonstrate the efficacy of AutoFHE through the evaluation of ResNets on CIFAR-10 and CIFAR-100 under RNS-CKKS. Experimental results on CIFAR-10 indicate that in comparison to the state-of-the-art solution, AutoFHE reduces inference time (50 images on 50 threads) by 1,000 seconds and amortized inference time (per image) by 28% and 17% for ResNet-20 and ResNet-32, respectively.

REPRESENTATIVE PROTOTYPE WITH CONSTRASTIVE LEARNING FOR SEMI-SUPENVISED FEW-SHOT CLASSIFICATION

Hexiu Lin,Daming Shi,Yukun Liu

Few-shot learning aims to learn novel classes in the dataset with few samples per class, which is a very challenging task. To mitigate this issue, the prior work obtain representative prototypes with semantic embeddin based on prototypical networks. While the above methods do not meet the requirement of few-shot learning, which requires abundant labeled samples. Therefore, We propose a new model f ramework to get representative prototypes with semi-supervised learning. Specifically, we introduces the dataset containing unlabeled samples to assist training the model. More importantly, to fully utilize these unlabeled samples, we adopt conditional variational autoencoder to construct more representative prototypes. Simultaneously, we develop novel contrastive loss to improve the model generalization ability. We evaluate our method on miniImageNet and tieredImageNet benchmarks for both 1-shot and 5-shot settings and achieve better performance over the state-of-the-art semi■supervised few-shot method.

Data-efficient Supervised Learning is Powerful for Neural Combinatorial Optimization

Shunyu Yao,Xi Lin,Zhenkun Wang,Qingfu Zhang

Neural combinatorial optimization (NCO) is a promising learning-based approach to solve difficult combinatorial optimization problems. However, how to efficiently train a powerful NCO solver remains challenging. The widely-used reinforcement learning method suffers from sparse rewards and low data efficiency, while the supervised learning approach requires a large number of high-quality solutions. In this work, we develop efficient methods to extract sufficient supervised information from limited labeled data, which can significantly overcome the main shortcoming of supervised learning. To be specific, we propose a set of efficient data augmentation methods and a novel bidirectional loss to better leverage the equivalent properties of problem instances, which finally lead to a promising supervised learning approach. The thorough experimental studies demonstrate our proposed method can achieve state-of-the-art performance on the traveling salesman problem (TSP) only with a small set of 50,000 labeled instances, while it also enjoys better generalization performance. We believe this somewhat surprising finding could lead to valuable rethinking on the value of efficient supervised learning for NCO.

****

Temporally-Weighted Spike Encoding for Event-based Object Detection and Classification

Nikolaus Salvatore,Justin Fletcher

Event-based cameras exhibit high dynamic range and temporal precision that could make them ideal for detecting objects with high speeds and low relative luminance. These properties have made event-based cameras especially interesting for use in space domain awareness tasks, such as detecting dim, artificial satellites with high brightness backgrounds using ground-based optical sensors; however, the asynchronous nature of event-based data presents new challenges to performing objection detection. While spiking neural networks (SNNs) have been shown to naturally complement the asynchronous and binary properties of event-based data, they also present a number of challenges in their training, such as the spike vanishing problem and the large number of timesteps required for maximizing classification and detection accuracy. Furthermore, the extremely high sampling rate of event-based sensors and the density of noisy space-based data collections can results in excessively large event streams within a short window of recording. We present a temporally-weighted spike encoding that greatly reduces the number of spikes derived from an event-based data stream, enabling the training of larger SNNs with fewer timesteps for maximal accuracy. We propose using this spike encoding with a variant of convolutional SNN trained utilizing surrogate spiking neuron gradients with backpropagation-through-time (BPTT) for both classification and object detection tasks with an emphasis on space-domain awareness. To demonstrate the efficacy of our encoding and SNN approach, we present competitive classification accuracies on benchmark datasets N-MNIST (99.7%), DVS-CIFAR10 (74.0%), and N-Caltech101 (72.8%), as well as state-of-the-art object detection performance on event-based, satellite collections.

Spiking Convolutional Neural Networks for Text Classification

Changze Lv,Jianhan Xu,Xiaoqing Zheng

Spiking neural networks (SNNs) offer a promising pathway to implement deep neural networks (DNNs) in a more energy-efficient manner since their neurons are spar sely activated and inferences are event-driven. However, there have been very few works that have demonstrated the efficacy of SNNs in language tasks partially because it is non-trivial to represent words in the forms of spikes and to deal with variable-length texts by SNNs. This work presents a "conversion + fine-tuning'' two-step method for training SNN for text classification and proposes a simple but effective way to encode pre-trained word embeddings as spike trains. We show empirically that after further fine-tuning with surrogate gradients, the converted SNNs achieve comparable results to their DNN counterparts across multiple datasets for Both English and Chinese. We also demonstrate that such SNNs are more robust against adversarial attacks than DNNs.

****

Personalized Federated Learning with Feature Alignment and Classifier Collaboration

Jian Xu,Xinyi Tong,Shao-Lun Huang

Data heterogeneity is one of the most challenging issues in federated learning, which motivates a variety of approaches to learn personalized models for participating clients. One such approach in deep neural networks based tasks is employing a shared feature representation and learning a customized classifier head for each client. However, previous works do not utilize the global knowledge during local representation learning and also neglect the fine-grained collaboration between local classifier heads, which limits the model generalization ability. In this work, we conduct explicit local-global feature alignment by leveraging global semantic knowledge for learning a better representation. Moreover, we quantify the benefit of classifier combination for each client as a function of the combining weights and derive an optimization problem for estimating optimal weights. Finally, extensive evaluation results on benchmark datasets with various heterogeneous data scenarios demonstrate the effectiveness of our proposed method.

****

Distributionally Robust Recourse Action

Duy Nguyen,Ngoc Bui,Viet Anh Nguyen

A recourse action aims to explain a particular algorithmic decision by showing one specific way in which the instance could be modified to receive an alternate outcome. Existing recourse generation methods often assume that the machine learning model does not change over time. However, this assumption does not always hold in practice because of data distribution shifts, and in this case, the recourse action may become invalid. To redress this shortcoming, we propose the Distributionally Robust Recourse Action (DiRRAc) framework, which generates a recourse action that has high probability of being valid under a mixture of model shifts. We first formulate the robustified recourse setup as a min-max optimization problem, where the max problem is specified by Gelbrich distance over an ambiguity set around the distribution of model parameters. Then we suggest a projected gradient descent algorithm to find a robust recourse according to the min-max objective. We also show that our DiRRAc framework can be extended to hedge against the misspecification of the mixture weights. Numerical experiments with both synthetic and three real-world datasets demonstrate the benefits of our proposed framework over the state-of-the-art recourse methods, which generate robust recourses.

****

Rethinking the Structure of Stochastic Gradients: Empirical and Statistical Evidence

Zeke Xie,Qian-Yuan Tang,Zheng He,Mingming Sun,Ping Li

It is well known that stochastic gradients significantly improve both optimization and generalization of deep neural networks (DNNs). Some works attempted to explain the success of stochastic optimization for deep learning by the arguably heavy-tail properties of gradient noise, while other works presented theoretical and empirical evidence against the heavy-tail hypothesis on gradient noise. Unfortunately, formal statistical tests for analyzing the structure and heavy tails of stochastic gradients in deep learning are still under-explored. In this paper, we mainly make two contributions. First, we conduct formal statistical tests o n the distribution of stochastic gradients and gradient noise across both parameters and iterations. Our statistical tests reveal that dimension-wise gradients usually exhibit power-law heavy tails, while iteration-wise gradients and stochastic gradient noise caused by minibatch training usually do not exhibit power-law heavy tails. Second, we further discover that the covariance spectra of stochastic gradients have the power-law structures in deep learning. While previous papers believed that the anisotropic structure of stochastic gradients matters to deep learning, they did not expect the gradient covariance can have such an elegant mathematical structure. Our work challenges the existing belief and provides novel insights on the structure of stochastic gradients. The novel structure of stochastic gradients may help understand the success of stochastic optimization for deep learning.

Representing Multi-view Time-series Graph Structures for Multivariate Long-term Time-series Forecasting

Wzh Rslh,Jin Fan,Huifeng Wu,Danfeng Sun

Multivariate long-term time-series forecasting task is a very challenging task in real-world application areas, such as electricity consumption and influenza-like illness forecasting. At present, researchers are focusing on designing robust and effective models, and have achieved good results. However, there are several issues with existing models that need to be overcome to ensure they provide optimal performance. First, the lack of a relationship structure between multivariate variables needs to be addressed. Second, most models only have a weak ability to capture local dynamic changes across the entire long-term time-series. And, third, the current models suffer from high computational complexity and unsatisfactory accuracy. To address these issues, we propose a novel method called Multi-view Time-series Graph Structure Representation (MTGSR) for multivariate long-term time-series forecasting tasks. MTGSR uses graph convolutional networks (GCNs) to construct topological relationships in the multivariate long-term time-series from three different perspectives: time, dimension, and crossing segments. Variation trends in the different dimensions of the multivariate long-term time-series are extracted through a difference operation so as to construct a topological map that reflects the correlations between the different dimensions. Then, to capture the dynamically changing characteristics of the fluctuation correlations between adjacent local sequences, MTGSR constructs a cross graph by calculating the correlation coefficients between adjacent local sequences. Extensive experiments on five different datasets show that MTGSR reduces errors by 20.41% over the state-of-the-art while maintaining linear complexity. Additionally, memory use is decreased by 66.52% and running time is reduced by 78.09%.

Improving Language Model Pretraining with Text Structure Information

Yi-Siang Wang,Ryohei Sasano,Koichi Takeda

Inter-sentence pretraining tasks learn from sentence relationships and facilitate high-level language understanding that cannot be directly learned in word-level pretraining tasks. However, we have found experimentally that existing inter-sentence methods for general-purpose language pretraining improve performance only at a relatively small scale but not at larger scales. For an alternative, we propose Text Structure Prediction (TSP), a more sophisticated inter-sentence task that uses text structure to provide more abundant self-supervised learning signals to pretraining models at larger scales. TSP classifies sentence pairs over six designed text structure relationships and it can be seen as an implicit form of learning high-level language understanding by identifying key concepts and relationships in texts. Experiments show that TSP provides improved performance on language understanding tasks for models at various scales. Our approach thus serves as an initial attempt to demonstrate that the exploitation of text structure can facilitate language understanding.

Chasing Better Deep Image Priors Between Over- and Under-parameterization

Qiming Wu,Xiaohan Chen,Yifan Jiang,Zhangyang Wang

Deep Neural Networks (DNNs) are well-known to act as over-parameterized deep ima ge priors (DIP) that regularize various image inverse problems. Meanwhile, researchers also proposed extremely compact, under-parameterized image priors (e.g., deep decoder) that are strikingly competent for image restoration too, despite a loss of accuracy. These two extremes push us to think whether there exists a better solution in the middle: between over- and under-parameterized image priors, can one identify "intermediate" parameterized image priors that achieve better trade-offs between performance, efficiency, and even preserving strong transferability? Drawing inspirations from the lottery ticket hypothesis (LTH), we conjecture and study a novel "lottery image prior" (LIP) by exploiting DNN inherent sparsity, stated as: given an over-parameterized DNN-based image prior, it will contain a sparse subnetwork that can be trained in isolation, to match the original DNN's performance when being applied as a prior to various image inverse problems}. Our results validate the superiority of LIPs: we can successfully locate the LIP subnetworks from over-parameterized DIPs at substantial sparsity ranges. Those LIP subnetworks significantly outperform deep decoders under comparably compact model sizes (by often fully preserving the effectiveness of their over-parameterized counterparts), and they also possess high transferability across different images as well as restoration task types. Besides, we also extend LIP to compressive sensing image reconstruction, where a pre-trained GAN generator is used as the prior (in contrast to untrained DIP or deep decoder), and confirm its validity in this setting too. To our best knowledge, this is the first time that LTH is demonstrated to be relevant in the context of inverse problems or image priors. Codes will be publicly available upon acceptance.

Generalizable Person Re-identification Without Demographics

YiFan Zhang,Feng Li,Zhang Zhang,Baosheng Yu,Liang Wang,Dacheng Tao,Tieniu Tan

Domain generalizable person re-identification (DG-ReID) aims to learn a ready-to-use domain-agnostic model directly for cross-dataset/domain evaluation, while current methods mainly explore the demographic information such as domain and/or camera labels for domain-invariant representation learning. However, the above-mentioned demographic information is not always accessible in practice due to privacy and security issues. In this paper, we consider the problem of person re-identification in a more general setting, \ie domain generalizable person re-identification without demographics (\textbf{DGWD-ReID}). To address the underlying uncertainty of domain distribution, we introduce distributionally robust optimization (DRO) to learn robust person re-identification models that perform well on all possible data distributions within the uncertainty set without demographics. However, directly applying the popular Kullback-Leibler divergence constrained DRO (or KL-DRO) fails to generalize well under the distribution shifts in real-world scenarios, since the convex condition may not hold for overparameterized neural networks. Inspired by this, we analyze and reformulate the popular KL-DRO by applying the change-of-measure technique, and then propose a simple yet efficient approach, \textbf{Unit-DRO}, which minimizes the loss over a new dataset with hard samples upweighted and other samples downweighted. We perform extensive experiments on both domain generalizable and cross-domain person re-identification tasks, and the empirical results on several large-scale benchmarks show that \iw~achieves superior performance compared to all baselines without using demographics.

LightGCL: Simple Yet Effective Graph Contrastive Learning for Recommendation

Xuheng Cai,Chao Huang,Lianghao Xia,Xubin Ren

Graph neural network (GNN) is a powerful learning approach for graph-based recommender systems. Recently, GNNs integrated with contrastive learning have shown superior performance in recommendation with their data augmentation schemes, aiming at dealing with highly sparse data. Despite their success, most existing graph contrastive learning methods either perform stochastic augmentation (e.g., node/edge perturbation) on the user-item interaction graph, or rely on the heuristic-based augmentation techniques (e.g., user clustering) for generating contrastive views. We argue that these methods cannot well preserve the intrinsic semanti c structures and are easily biased by the noise perturbation. In this paper, we propose a simple yet effective graph contrastive learning paradigm LightGCL that mitigates these issues impairing the generality and robustness of CL-based recommenders. Our model exclusively utilizes singular value decomposition for contrastive augmentation, which enables the unconstrained structural refinement with global collaborative relation modeling. Experiments conducted on several benchmark datasets demonstrate the significant improvement in performance of our model over the state-of-the-arts. Further analyses demonstrate the superiority of LightGCL's robustness against data sparsity and popularity bias. The source code of our model is available at https://github.com/HKUDS/LightGCL.

MemoNav: Working Memory Model for Visual Navigation

Hongxin Li,Xu Yang,Zeyu Wang,yuran Yang,Shuqi Mei,Zhaoxiang Zhang

We present MemoNav, a novel memory model for image-goal navigation, which utilizes a working memory-inspired pipeline to improve navigation performance. Specifically, the node features on the topological map are stored in the short-term memory (STM), as these features are dynamically updated. The MemoNav retains the informative fraction of the STM via a forgetting module to improve navigation efficiency. To learn a global representation of 3D scenes, we introduce long-term memory (LTM) that continuously aggregates the STM. Afterward, a graph attention module encodes the retained STM and the LTM to generate working memory (WM). After encoding, the WM contains the informative features in the retained STM and the scene-level feature in the LTM and is finally used to generate actions. Consequently, the synergy of these three types of memory increases navigation performance by selectively retaining goal-relevant information and learning a high-level scene feature. When evaluated on multi-goal tasks, the MemoNav outperforms the SoTA methods at all difficulty levels in both Gibson and Matterport3D scenes. The MemoNav also achieves consistent improvements on traditional 1-goal tasks. Moreover, the qualitative results show that our model is less likely to be trapped in a deadlock.

Write and Paint: Generative Vision-Language Models are Unified Modal Learners

Shizhe Diao,Wangchunshu Zhou,Xinsong Zhang,Jiawei Wang

Recent advances in vision-language pre-training have pushed the state-of-the-art on various vision-language tasks, making machines more capable of multi-modal writing (image-to-text generation) and painting (text-to-image generation). However, few studies investigate if these two essential capabilities can be learned together and boost each other, making a versatile and powerful multi-modal foundation model. In this work, we disclose the potential of symmetric generative vision-language pre-training in learning to write and paint concurrently, and propose a new unified modal model, named DaVinci, trained with prefix language modeling and prefix image modeling, a simple generative self-supervised objective on image-text pairs. Thanks to the proposed prefix multi-modal modeling framework, DaVinci is simple to train, scalable to huge data, adaptable to both writing and painting tasks, and also strong on other vision, text, and multi-modal understanding tasks. DaVinci achieves competitive performance on a wide range of 27 generation/understanding tasks and demonstrates the superiority of combining vision/language generative pre-training. Furthermore, we carefully benchmark the performance of different vision-language pre-training objectives on different scales of pre-training datasets on a heterogeneous and broad distribution coverage. Our results demonstrate the potential of exploiting self-supervision in both language and vision inputs, and establish new, stronger baselines for future comparisons at different data scales. The code and pre-trained models are available at https://github.com/shizhediao/DaVinci.

Progressive Voronoi Diagram Subdivision Enables Accurate Data-free Class-Incremental Learning

Chunwei Ma,Zhanghexuan Ji,Ziyun Huang,Yan Shen,Mingchen Gao,Jinhui Xu

Data-free Class-incremental Learning (CIL) is a challenging problem because rehearsing data from previous phases is strictly prohibited, causing catastrophic fo rgetting of Deep Neural Networks (DNNs). In this paper, we present \emph{iVoro}, a novel framework derived from computational geometry. We found Voronoi Diagram (VD), a classical model for space subdivision, is especially powerful for solving the CIL problem, because VD itself can be constructed favorably in an incremental manner -- the newly added sites (classes) will only affect the proximate classes, making the non-contiguous classes hardly forgettable. Furthermore, we bridge DNN and VD using Power Diagram Reduction, and show that the VD structure can be progressively refined along the phases using a divide-and-conquer algorithm. Moreover, our VD construction is not restricted to the deep feature space, but is also applicable to multiple intermediate feature spaces, promoting VD to be multilayer VD that efficiently captures multi-grained features from DNN. Importantly, \emph{iVoro} is also capable of handling uncertainty-aware test-time Voronoi cell assignment and has exhibited high correlations between geometric uncertainty and predictive accuracy (up to ${\sim}0.9$). Putting everything together, \emph{iVoro} achieves up to 25.26%, 37.09%, and 33.21% improvements on CIFAR-100, TinyImageNet, and ImageNet-Subset, respectively, compared to the state-of-the-art non-exemplar CIL approaches. In conclusion, \emph{iVoro} enables highly accurate, privacy-preserving, and geometrically interpretable CIL that is particularly useful when cross-phase data sharing is forbidden, e.g. in medical applications.

Data Valuation Without Training of a Model

Ki Nohyun,Hoyong Choi,Hye Won Chung

Many recent works on understanding deep learning try to quantify how much individual data instances influence the optimization and generalization of a model. Such attempts reveal characteristics and importance of individual instances, which may provide useful information in diagnosing and improving deep learning. However, most of the existing works on data valuation require actual training of a model, which often demands high-computational cost. In this paper, we provide a training-free data valuation score, called complexity-gap score, which is a data-centric score to quantify the influence of individual instances in generalization of two-layer overparameterized neural networks. The proposed score can quantify irregularity of the instances and measure how much each data instance contributes in the total movement of the network parameters during training. We theoretically analyze and empirically demonstrate the effectiveness of the complexity-gap score in finding `irregular or mislabeled' data instances, and also provide applications of the score in analyzing datasets and diagnosing training dynamics. Our code is publicly available at https://github.com/JJchy/CG_score.

HotProtein: A Novel Framework for Protein Thermostability Prediction and Editing

Tianlong Chen,Chengyue Gong,Daniel Jesus Diaz,Xuxi Chen,Jordan Tyler Wells,qiang liu,Zhangyang Wang,Andrew Ellington,Alex Dimakis,Adam Klivans

The molecular basis of protein thermal stability is only partially understood and has major significance for drug and vaccine discovery. The lack of datasets and standardized benchmarks considerably limits learning-based discovery methods. We present \texttt{HotProtein}, a large-scale protein dataset with \textit{growth temperature} annotations of thermostability, containing 182K amino acid sequences and 3K folded structures from 230 different species with a wide temperature range $-20^{\circ}\texttt{C}\sim 120^{\circ}\texttt{C}$. Due to functional domain differences and data scarcity within each species, existing methods fail to generalize well on our dataset. We address this problem through a novel learning framework, consisting of (1) Protein structure-aware pre-training (SAP) which leverages 3D information to enhance sequence-based pre-training; (2) Factorized sparse tuning (FST) that utilizes low-rank and sparse priors as an implicit regularization, together with feature augmentations. Extensive empirical studies demonstrate that our framework improves thermostability prediction compared to other deep learning models. Finally, we introduce a novel editing algorithm to efficiently generate positive amino acid mutations that improve thermostability. Codes are available in https://github.com/VITA-Group/HotProtein.

Agent-Controller Representations: Principled Offline RL with Rich Exogenous Information

Riashat Islam,Manan Tomar,Alex Lamb,Hongyu Zang,Yonathan Efroni,Dipendra Misra,Xin Li,Harm van Seijen,Remi Tachet des Combes,John Langford

Learning to control an agent from data collected offline in a rich pixel-based visual observation space is vital for real-world applications of reinforcement learning (RL). A major challenge in this setting is the presence of input information that is hard to model and irrelevant to controlling the agent. This problem has been approached by the theoretical RL community through the lens of exogenous information, i.e, any control-irrelevant information contained in observations. For example, a robot navigating in busy streets needs to ignore irrelevant information, such as other people walking in the background, textures of objects, or birds in the sky. In this paper, we focus on the setting with visually detailed exogenous information, and introduce new offline RL benchmarks offering the ability to study this problem. We find that contemporary representation learning techniques can fail on datasets where the noise is a complex and time dependent process, which is prevalent in practical applications. To address these, we propose to use multi-step inverse models, which have seen a great deal of interest in the RL theory community, to learn Agent-Controller Representations for Offline-RL (ACRO). Despite being simple and requiring no reward, we show theoretically and empirically that the representation created by this objective greatly outperforms baselines.

RPM: Generalizable Multi-Agent Policies for Multi-Agent Reinforcement Learning

Wei Qiu,Xiao Ma,Bo An,Svetlana Obraztsova,Shuicheng YAN,Zhongwen Xu

Despite the recent advancement in multi-agent reinforcement learning (MARL), the MARL agents easily overfit the training environment and perform poorly in evaluation scenarios where other agents behave differently. Obtaining generalizable policies for MARL agents is thus necessary but challenging mainly due to complex multi-agent interactions. In this work, we model the MARL problem with Markov Games and propose a simple yet effective method, called ranked policy memory (RPM), i.e., to maintain a look-up memory of policies to achieve good generalizability. The main idea of RPM is to train MARL policies via gathering massive multi-agent interaction data. In particular, we first rank each agent’s policies by its training episode return, i.e., the episode return of each agent in the training environment; we then save the ranked policies in the memory; when an episode starts, each agent can randomly select a policy from the RPM as the behavior policy. Each agent uses the behavior policy to gather multi-agent interaction data for MARL training. This innovative self-play framework guarantees the diversity of multi-agent interaction in the training data. Experimental results on Melting Pot demonstrate that RPM enables MARL agents to interact with unseen agents in multi-agent generalization evaluation scenarios and complete given tasks. It significantly boosts the performance up to 818% on average.

Behavior Prior Representation learning for Offline Reinforcement Learning

Hongyu Zang,Xin Li,Jie Yu,Chen Liu,Riashat Islam,Remi Tachet des Combes,Romain Laroche

Offline reinforcement learning (RL) struggles in environments with rich and noisy inputs, where the agent only has access to a fixed dataset without environment interactions. Past works have proposed common workarounds based on the pre-training of state representations, followed by policy training. In this work, we introduce a simple, yet effective approach for learning state representations. Our method, Behavior Prior Representation (BPR), learns state representations with an easy-to-integrate objective based on behavior cloning of the dataset: we first learn a state representation by mimicking actions from the dataset, and then train a policy on top of the fixed representation, using any off-the-shelf Offline RL algorithm. Theoretically, we prove that BPR carries out performance guarantees when integrated into algorithms that have either policy improvement guarantees (conservative algorithms) or produce lower bounds of the policy values (pessimistic algorithms). Empirically, we show that BPR combined with existing state-of

-the-art Offline RL algorithms leads to significant improvements across several offline control benchmarks. The code is available at \url{https://github.com/bit1029public/offline_bpr}

How Does Adaptive Optimization Impact Local Neural Network Geometry?

Kaiqi Jiang,Dhruv Malik,Yuanzhi Li

Adaptive optimization methods are well known to achieve superior convergence relative to vanilla gradient methods. The traditional viewpoint in optimization, particularly in convex optimization, explains this improved performance by arguing that, unlike vanilla gradient schemes, adaptive algorithms mimic the behavior of a second-order method by adapting to the global geometry of the loss function. We argue that in the context of neural network optimization, this traditional viewpoint is insufficient. Instead, we advocate for a local trajectory analysis. For iterate trajectories produced by running a generic optimization algorithm OPT, we introduce $R^{\text{OPT}}_{\text{med}}$, a statistic that is analogous to the condition number of the loss Hessian evaluated at the iterates. Through extensive experiments, we show that adaptive methods such as Adam bias the trajectories towards regions where $R^{\text{Adam}}_{\text{med}}$ is small, where one might expect faster convergence. By contrast, vanilla gradient methods like SGD bias the trajectories towards regions where $R^{\text{SGD}}_{\text{med}}$ is comparatively large. We complement these empirical observations with a theoretical result that provably demonstrates this phenomenon in the simplified setting of a two-layer linear network. We view our findings as evidence for the need of a new explanation of the success of adaptive methods, one that is different than the conventional wisdom.

Substructured Graph Convolution for Non-overlapping Graph Decomposition

Youngkyu Lee,Chang-Ock Lee

Graph convolutional networks have been widely used to solve the graph problems such as node classification, link prediction, and recommender systems. It is well known that large graphs require large amount of memory and time to train graph convolutional networks. To deal with large graphs, many methods are being done, such as graph sampling or decomposition. In particular, graph decomposition has the advantage of parallel computation, but information loss occurs in the interface part. In this paper, we propose a novel substructured graph convolution that reinforces the interface part lost by graph decomposition. Numerical results indicate that the proposed method is robust in the number of subgraphs compared to other methods.

****

On the Neural Tangent Kernel of Equilibrium Models

Zhili Feng,J Zico Kolter

This work studies the neural tangent kernel (NTK) of deep equilibrium (DEQ) model, a practical ``infinite-depth'' architecture which directly computes the infinite-depth limit of a weight-tied network via root-finding. Even though the NTK of a fully-connected neural network is stochastic if its width and depth both tend to infinity simultaneously, we show that contrarily a DEQ model still enjoys a deterministic NTK despite its width and depth going to infinity at the same time. Moreover, such deterministic NTK can be found efficiently via root-finding.

From Play to Policy: Conditional Behavior Generation from Uncurated Robot Data

Zichen Jeff Cui,Yibin Wang,Nur Muhammad Mahi Shafiullah,Lerrel Pinto

While large-scale sequence modelling from offline data has led to impressive performance gains in natural language generation and image generation, directly translating such ideas to robotics has been challenging. One critical reason for this is that uncurated robot demonstration data, i.e. play data, collected from non-expert human demonstrators are often noisy, diverse, and distributionally multi-modal. This makes extracting useful, task-centric behaviors from such data a difficult generative modelling problem. In this work, we present Conditional Behavior Transformers (C-BeT), a method that combines the multi-modal generation ability of Behavior Transformer with future-conditioned goal specification. On a su ite of simulated benchmark tasks, we find that C-BeT improves upon prior state-of-the-art work in learning from play data by an average of 45.7%. Further, we demonstrate for the first time that useful task-centric behaviors can be learned on a real-world robot purely from play data without any task labels or reward information. Robot videos are best viewed on our project website: play-to-policy.github.io

Beyond Counting Linear Regions of Neural Networks, Simple Linear Regions Dominate!

FENGLEI FAN,Wei Huang,Lecheng Ruan,Tieyong Zeng,Huan Xiong,Fei Wang

Functions represented by a neural network with the widely-used ReLU activation are piecewise linear functions over linear regions (polytopes). Figuring out the properties of such polytopes is of fundamental importance for the development of neural networks.

So far, either theoretical or empirical studies on polytopes stay at the level of counting their number. Despite successes in explaining the power of depth and so on, counting the number of polytopes puts all polytopes on an equal booting, which is essentially an incomplete characterization of polytopes. Beyond counting, here we study the shapes of polytopes via the number of simplices obtained by triangulations of polytopes. First, we demonstrate the properties of the number of simplices in triangulations of polytopes, and compute the upper and lower bounds of the maximal number of simplices that a network can generate. Next, by computing and analyzing the histogram of simplices across polytopes, we find that a ReLU network has surprisingly uniform and simple polytopes, although these polytopes theoretically can be rather diverse and complicated. This finding is a novel implicit bias that concretely reveals what kind of simple functions a network learns and sheds light on why deep learning does not overfit. Lastly, we establish a theorem to illustrate why polytopes produced by a deep network are simple and uniform. The core idea of the proof is counter-intuitive: adding depth probably does not create a more complicated polytope. We hope our work can inspire more research into investigating polytopes of a ReLU neural network, thereby upgrading the knowledge of neural networks to a new level.

Recovering Top-Two Answers and Confusion Probability in Multi-Choice Crowdsourcing

Hyeonsu Jeong,Hye Won Chung

We consider multi-choice crowdsourced labeling with the goal of recovering not only the ground truth but also the most confusing answer and the confusion probability. The most confusing answer provides useful information about the task by revealing the most plausible answer other than the ground truth and how plausible it is. To theoretically analyze such scenarios, we propose a model where there are top-two plausible answers for each task, distinguished from the rest of choices. Task difficulty is quantified by the confusion probability between the top two, and worker reliability is quantified by the probability of giving an answer among the top two. Under this model, we propose a two-stage inference algorithm to infer the top-two answers, where the first stage uses the spectral method to obtain an initial estimate for the top two, and the second stage uses the result of the first stage to refine the estimates based on the maximum likelihood estimator (MLE). We show that our algorithm achieves the minimax optimal convergence rate. We conduct both synthetic and real-data experiments and demonstrate that our algorithm achieves the performance near the optimal MLE for synthetic datasets and the best performance for real datasets compared to other recent algorithms. This shows that our model explains well the real datasets with heterogeneous task difficulties due to confusion between plausible answers.

SCALE-UP: An Efficient Black-box Input-level Backdoor Detection via Analyzing Scaled Prediction Consistency

Junfeng Guo,Yiming Li,Xun Chen,Hanqing Guo,Lichao Sun,Cong Liu

Deep neural networks (DNNs) are vulnerable to backdoor attacks, where adversarie

s embed a hidden backdoor trigger during the training process for malicious prediction manipulation. These attacks pose great threats to the applications of DNNs under the real-world machine learning as a service (MLaaS) setting, where the deployed model is fully black-box while the users can only query and obtain its predictions. Currently, there are many existing defenses to reduce backdoor threats. However, almost all of them cannot be adopted in MLaaS scenarios since they require getting access to or even modifying the suspicious models. In this paper, we propose a simple yet effective black-box input-level backdoor detection, called SCALE-UP, which requires only the predicted labels to alleviate this problem. Specifically, we identify and filter malicious testing samples by analyzing their prediction consistency during the pixel-wise amplification process. Our defense is motivated by an intriguing observation (dubbed \emph{scaled prediction consistency}) that the predictions of poisoned samples are significantly more consistent compared to those of benign ones when amplifying all pixel values. Besides, we also provide theoretical foundations to explain this phenomenon. Extensive experiments are conducted on benchmark datasets, verifying the effectiveness and efficiency of our defense and its resistance to potential adaptive attacks. Our codes are available at \url{https://github.com/JunfengGo/SCALE-UP}.

On the Perils of Cascading Robust Classifiers
Ravi Mangal,Zifan Wang,Chi Zhang,Klas Leino,Corina Pasareanu,Matt Fredrikson
Ensembling certifiably robust neural networks is a promising approach for improving the \emph{certified robust accuracy} of neural models.
Black-box ensembles that assume only query-access to the constituent models (and their robustness certifiers) during prediction are particularly attractive due to their modular structure. Cascading ensembles are a popular instance of black-box ensembles that appear to improve certified robust accuracies in practice. However, we show that the robustness certifier used by a cascading ensemble is unsound. That is, when a cascading ensemble is certified as locally robust at an input x (with respect to ϵ), there can be inputs x' in the ϵ-ball centered at x, such that the cascade's prediction at x' is different from x and thus the ensemble is not locally robust. Our theoretical findings are accompanied by empirical results that further demonstrate this unsoundness. We present a new attack against cascading ensembles and show that: (1) there exists an adversarial input for up to 88\% of the samples where the ensemble claims to be certifiably robust and accurate; and (2) the accuracy of a cascading ensemble under our attack is as low as 11\% when it claims to be certifiably robust and accurate on 97\% of the test set. Our work reveals a critical pitfall of cascading certifiably robust models by showing that the seemingly beneficial strategy of cascading can actually hurt the robustness of the resulting ensemble. Our code is available at https://github.com/TristaChi/ensembleKW.

Visual Classification via Description from Large Language Models
Sachit Menon,Carl Vondrick
Vision-language models such as CLIP have shown promising performance on a variety of recognition tasks using the standard zero-shot classification procedure -- computing similarity between the query image and the embedded words for each category. By only using the category name, they neglect to make use of the rich context of additional information that language affords. The procedure gives no intermediate understanding of why a category is chosen, and furthermore provides no mechanism for adjusting the criteria used towards this decision. We present an alternative framework for classification with VLMs, which we call classification by description. We ask VLMs to check for descriptive features rather than broad categories: to find a tiger, look for its stripes; its claws; and more. By basing decisions on these descriptors, we can provide additional cues that encourage using the features we want to be used. In the process, we can get a clear idea of what the model ``thinks" it is seeing to make its decision; it gains some level of inherent explainability. We query large language models (e.g., GPT-3) for these descriptors to obtain them in a scalable way. Extensive experiments show our framework has numerous advantages past interpretability. We show improvements

in accuracy on ImageNet across distribution shifts; demonstrate the ability to adapt VLMs to recognize concepts unseen during training; and illustrate how descriptors can be edited to effectively mitigate bias compared to the baseline.

Contrastive Novelty Learning: Anticipating Outliers with Large Language Models

Albert Xu,Xiang Ren,Robin Jia

In many task settings, text classification models are likely to encounter examples from novel classes on which they cannot predict correctly. Selective prediction, in which models abstain on low-confidence examples, provides a possible solution, but existing models are often overly confident on OOD examples. To remedy this overconfidence, we introduce Contrastive Novelty Learning (CNL), a two-step method that generates OOD examples representative of novel classes, then trains to decrease confidence on them. First, we generate OOD examples by prompting a large language model twice: we prompt it to enumerate novel classes relevant to the label set, then generate examples from each novel class matching the task format. Second, we train our classifier with a novel contrastive objective that encourages lower confidence on generated OOD examples than training examples. When trained with CNL, classifiers improve in their ability to detect and abstain on OOD examples over prior methods by an average of 2.3% AUAC and 5.5% AUROC across 4 NLP datasets, with no cost to in-distribution accuracy.

MIMT: Masked Image Modeling Transformer for Video Compression

Jinxi Xiang,Kuan Tian,Jun Zhang

Deep learning video compression outperforms its hand-craft counterparts with enhanced flexibility and capacity. One key component of the learned video codec is the autoregressive entropy model conditioned on spatial and temporal priors. Operating autoregressive on raster scanning order naively treats the context as unidirectional. This is neither efficient nor optimal, considering that conditional information probably locates at the end of the sequence. We thus introduce an entropy model based on a masked image modeling transformer (MIMT) to learn the spatial-temporal dependencies. Video frames are first encoded into sequences of tokens and then processed with the transformer encoder as priors. The transformer decoder learns the probability mass functions (PMFs) \emph{conditioned} on the priors and masked inputs. Then it is capable of selecting optimal decoding orders without a fixed direction. During training, MIMT aims to predict the PMFs of randomly masked tokens by attending to tokens in all directions. This allows MIMT to capture the temporal dependencies from encoded priors and the spatial dependencies from the unmasked tokens, i.e., decoded tokens. At inference time, the model begins with generating PMFs of all masked tokens in parallel and then decodes the frame iteratively from the previously-selected decoded tokens (i.e., with high confidence). In addition, we improve the overall performance with more techniques, e.g., manifold conditional priors accumulating a long range of information, shifted window attention to reduce complexity. Extensive experiments demonstrate the proposed MIMT framework equipped with the new transformer entropy model achieves state-of-the-art performance on HEVC, UVG, and MCL-JCV datasets, generally outperforming the VVC in terms of PSNR and SSIM.

Speculative Decoding: Lossless Speedup of Autoregressive Translation

Heming Xia,Tao Ge,Si-Qing Chen,Furu Wei,Zhifang Sui

Different from some previous work accelerating autoregressive translation (AT) at the sacrifice of quality, we propose Speculative Decoding (SpecDec) -- a novel decoding paradigm inspired by speculative execution in computer architecture, which combines respective advantages of AT and non-autoregressive translation (NAT) for lossless speedup of translation. At each decoding step, SpecDec first speculatively drafts (i.e. decodes) next k tokens with an NAT model and then verifies them with an AT model, where only the drafted tokens passing the verification are accepted as decoded tokens for guaranteeing its translation result is exactly the same as AT. The collaboration of NAT drafting and AT verification leads to a much higher decoding speed without quality loss due to parallel computing enabled by speculative decoding.

We conduct experiments in 4 standard WMT translation benchmarks and confirm the vanilla SpecDec yields exactly the same results as AT greedy decoding with an around $3\times$ speedup, and that its variant (SpecDec++) with an advanced verification strategy not only outperforms AT greedy decoding, but also further improves the decoding speed, resulting in an around $5\times$ speedup over AT. Moreover, SpecDec can be easily generalized for speeding up other seq2seq tasks like Abstractive Summarization, and benefit more from stronger computing devices, demonstrating its potential to become a de facto decoding standard in the future for efficient and lossless seq2seq generation.

$$CONVOLUTION AND POOLING OPERATION MODULE WITH ADAPTIVE STRIDE PROCESSING EFFEC$$

■■ ■,■■ ■

$$Convolutional neural network is one of the representative models of deep learning, which has a wide range of applications. Convolution and pooling are two key operations in convolutional neural networks. They play an important role in extracting input features and mapping low-level semantic features to high-level semantic features. Stride is an important parameter involved in convolution and pooling operations, which refers to the distance of each slide of the convolution kernel (pooling kernel) during the convolution (pooling) operation. The stride has an impact on the granularity of feature extraction and the selection (filtering) of features, thus affecting the performance of convolutional neural networks. At present, in the training of convolutional neural networks, the content of convolution kernel and pooling kernel can be determined by the optimization algorithm based on gradient descent. However, the stride usually cannot be treated similarly, and can only be selected manually as a hyperparameter. Most of the existing related works choose a fixed stride, for example, the value is 1. In fact, different tasks or inputs may require different stride for better model processing. Therefore, this paper views the role of stride in convolution and pooling operation from the perspective of sampling, and proposes a convolution and pooling operation module with adaptive stride processing effect. The feature of the proposed module is that the feature map finally obtained by convolution or pooling operation is no longer limited to equal interval downsampling (feature extraction) according to a fixed stride, but adaptively extracted according to the changes of input features. We apply the proposed module on many convolutional neural network models, including VGG, Alexnet and MobileNet for image classification, YOLOX-S for object detection, Unet for image segmentation, and so on. Simulation results show that the proposed module can effectively improve the perform$$

Transformer Module Networks for Systematic Generalization in Visual Question Answering

Moyuru Yamada,Vanessa D'Amario,Kentaro Takemoto,Xavier Boix,Tomotake Sasaki

Transformers achieve great performance on Visual Question Answering (VQA). However, their systematic generalization capabilities, i.e., handling novel combinations of known concepts, is unclear. We reveal that Neural Module Networks (NMNs),

i.e., question-specific compositions of modules that tackle a sub-task, achieve better or similar systematic generalization performance than the conventional Transformers, even though NMNs' modules are CNN-based. In order to address this shortcoming of Transformers with respect to NMNs, in this paper we investigate whether and how modularity can bring benefits to Transformers. Namely, we introduce Transformer Module Network (TMN), a novel NMN based on compositions of Transformer modules. TMNs achieve state-of-the-art systematic generalization performance in three VQA datasets, improving more than 30% over standard Transformers for novel compositions of sub-tasks. We show that not only the module composition but also the module specialization for each sub-task are the key of such performance gain.

Diving into Unified Data-Model Sparsity for Class-Imbalanced Graph Representation Learning

Chunhui Zhang,Chao Huang,Yijun Tian,Qianlong Wen,Zhongyu Ouyang,Youhuan Li,Yanfang Ye,Chuxu Zhang

Even pruned by the state-of-the-art network compression methods, recent research shows that deep learning model training still suffers from the demand of massive data usage. In particular, Graph Neural Networks (GNNs) trained upon non-Euclidean graph data often encounter relatively higher time costs, due to its irregular and nasty density properties, compared with data in the regular Euclidean space (e.g., image or text). Another natural property accompanied with graphs is class-imbalance which cannot be alleviated even with massive data, therefore hinders GNNs’ ability in generalization. To fully tackle these unpleasant properties, (i) theoretically, we introduce a hypothesis about to what extent a subset of the training data can approximate the full dataset’s learning effectiveness. The effectiveness is further guaranteed and proved by the gradients’ distance between the subset and the full set; (ii) empirically, we discover that during the learning process of a GNN, some samples in the training dataset are informative in providing gradients to update model parameters. Moreover, the informative subset evolves dynamically during the training process, for samples that are informative in the current training epoch may not be so in the next one. We refer this observation as dynamic data sparsity. We also notice that sparse subnets pruned from a well-trained GNN sometimes forget the information provided by the informative subset, reflected in their poor performance upon the subset. Based on these findings, we develop a unified data-model dynamic sparsity framework named Graph Decantation (GraphDec) to address challenges brought by training upon a massive class-imbalanced graph dataset. The key idea of GraphDec is to identify the informative subset dynamically during the training process by adopting sparse graph contrastive learning. Extensive experiments on multiple benchmark datasets demonstrate that GraphDec outperforms state-of-the-art baselines for the class-imbalanced graph classification and class-imbalanced node classification tasks, with respect to classification accuracy and data usage efficiency.

Learning Math Reasoning from Self-Sampled Correct and Partially-Correct Solutions

Ansong Ni,Jeevana Priya Inala,Chenglong Wang,Alex Polozov,Christopher Meek,Dragomir Radev,Jianfeng Gao

Pretrained language models have shown superior performance on many natural language processing tasks, yet they still struggle at multi-step formal reasoning tasks like grade school math problems. One key challenge of finetuning them to solve such math reasoning problems is that many existing datasets only contain one reference solution for each problem, despite the fact that there are often alternative solutions resembling different reasoning paths to the final answer. This way, the finetuned models are biased towards the limited reference solutions, which limits their generalization to unseen examples. To mitigate this issue, we propose to let the model perform sampling during training and learn from both self-sampled fully-correct solutions, which yield the correct answer upon execution, and partially-correct solutions, whose intermediate state matches an intermediate state of a known correct solution. We show that our use of self-sampled corre ct and partially-correct solutions can benefit learning and help guide the sampling process, leading to more efficient exploration of the solution space. Additionally, we explore various training objectives to support learning from multiple solutions per example and find they greatly affect the performance. Experiments on two math reasoning datasets show the effectiveness of our method compared to learning from a single reference solution with MLE, where we improve PASS@100 from 35.5% to 44.5% for GSM8K, and 27.6% to 36.2% PASS@80 for MathQA. Such improvements are also consistent across different model sizes.

Adaptive Robust Evidential Optimization For Open Set Detection from Imbalanced Data

Hitesh Sapkota,Qi Yu

Open set detection (OSD) aims at identifying data samples of an unknown class ($i.e.$, open set) from those of known classes ($i.e.$, closed set) based on a model trained from closed set samples. However, a closed set may involve a highly imbalanced class distribution. Accurately differentiating open set samples and those from a minority class in the closed set poses a fundamental challenge as the model may be equally uncertain when recognizing samples from the minority class. In this paper, we propose Adaptive Robust Evidential Optimization (AREO) that offers a principled way to quantify sample uncertainty through evidential learning while optimally balancing the model training over all classes in the closed set through adaptive distributively robust optimization (DRO). To avoid the model to primarily focus on the most difficult samples by following the standard DRO, adaptive DRO training is performed, which is governed by a novel multi-scheduler learning mechanism to ensure an optimal model training behavior that gives sufficient attention to the difficult samples and the minority class while capable of learning common patterns from the majority classes. Our experimental results on multiple real-world datasets demonstrate that the proposed model outputs uncertainty scores that can clearly separate samples from closed and open sets, respectively, and the detection results outperform the competitive baselines.

The Modality Focusing Hypothesis: Towards Understanding Crossmodal Knowledge Distillation

Zihui Xue,Zhengqi Gao,Sucheng Ren,Hang Zhao

Crossmodal knowledge distillation (KD) extends traditional knowledge distillation to the area of multimodal learning and demonstrates great success in various applications. To achieve knowledge transfer across modalities, a pretrained network from one modality is adopted as the teacher to provide supervision signals to a student network learning from the other modality. In contrast to the empirical success reported in prior works, the working mechanism of crossmodal KD remains a mystery. In this paper, we present a thorough understanding of crossmodal KD. We begin by providing two failure cases and demonstrate that KD is not a universal cure in crossmodal knowledge transfer. We then present the modality Venn diagram to understand modality relationships and the modality focusing hypothesis revealing the decisive factor in the efficacy of crossmodal KD. Experimental results on 6 multimodal datasets help justify our hypothesis, diagnose failure cases, and point directions to improve crossmodal knowledge transfer in the future.

Hungry Hungry Hippos: Towards Language Modeling with State Space Models

Daniel Y Fu,Tri Dao,Khaled Kamal Saab,Armin W Thomas,Atri Rudra,Christopher Re

State space models (SSMs) have demonstrated state-of-the-art sequence modeling performance in some modalities, but underperform attention in language modeling. Moreover, despite scaling nearly linearly in sequence length instead of quadratically, SSMs are still slower than Transformers due to poor hardware utilization. In this paper, we make progress on understanding the expressivity gap between SSMs and attention in language modeling, and on reducing the hardware barrier between SSMs and attention. First, we use synthetic language modeling tasks to understand the gap between SSMs and attention. We find that existing SSMs struggle with two capabilities: recalling earlier tokens in the sequence and comparing tokens across the sequence. To understand the impact on language modeling, we propo se a new SSM layer, H3, that is explicitly designed for these abilities. H3 matches attention on the synthetic languages and comes within 0.4 PPL of Transformers on OpenWebText. Furthermore, a hybrid 125M-parameter H3-attention model that retains two attention layers surprisingly outperforms Transformers on OpenWebText by 1.0 PPL. Next, to improve the efficiency of training SSMs on modern hardware, we propose FlashConv. FlashConv uses a fused block FFT algorithm to improve efficiency on sequences up to 8K, and introduces a novel state passing algorithm that exploits the recurrent properties of SSMs to scale to longer sequences. FlashConv yields 2$\times$ speedup on the long-range arena benchmark and allows hybrid language models to generate text 2.4$\times$ faster than Transformers. Using FlashConv, we scale hybrid H3-attention language models up to 2.7B parameters on the Pile and find promising initial results, achieving lower perplexity than Transformers and outperforming Transformers in zero- and few-shot learning on a majority of tasks in the SuperGLUE benchmark.

FINE: Future-Aware Inference for Streaming Speech Translation

Biao Fu,Kai Fan,Minpeng Liao,Zhongqiang Huang,Boxing Chen,Xiaodong Shi,Yidong Chen

A popular approach to streaming speech translation is to employ a single offline model together with a \textit{wait-k} policy to support different latency requirements. It is a simpler alternative compared to training multiple online models with different latency constraints. However, there is an apparent mismatch in using a model trained with complete utterances on partial streaming speech during online inference. We demonstrate that there is a significant difference between the speech representations extracted at the end of a streaming input and their counterparts at the same positions when the complete utterance is available. Built upon our observation that this problem can be alleviated by introducing a few frames of future speech signals, we propose \textbf{F}uture-aware \textbf{in}ferenc\textbf{e} (FINE) for streaming speech translation with two different methods to make the model aware of the future. The first method FINE-Mask incorporates future context through a trainable masked speech model. The second method FINE-Wait simply waits for more actual future audio frames at the cost of extra latency. Experiments on the MuST-C EnDe, EnEs and EnFr benchmarks show that both methods are effective and can achieve better trade-offs between translation quality and latency than strong baselines, and a hybrid approach combining the two can achieve further improvement. Extensive analyses suggest that our methods can effectively alleviate the aforementioned mismatch problem between offline training and online inference.

Dual Diffusion Implicit Bridges for Image-to-Image Translation

Xuan Su,Jiaming Song,Chenlin Meng,Stefano Ermon

Common image-to-image translation methods rely on joint training over data from both source and target domains. The training process requires concurrent access to both datasets, which hinders data separation and privacy protection; and existing models cannot be easily adapted for translation of new domain pairs. We present Dual Diffusion Implicit Bridges (DDIBs), an image translation method based on diffusion models, that circumvents training on domain pairs. Image translation with DDIBs relies on two diffusion models trained independently on each domain, and is a two-step process: DDIBs first obtain latent encodings for source images with the source diffusion model, and then decode such encodings using the target model to construct target images. Both steps are defined via ordinary differential equations (ODEs), thus the process is cycle consistent only up to discretization errors of the ODE solvers. Theoretically, we interpret DDIBs as concatenation of source to latent, and latent to target Schrodinger Bridges, a form of entropy-regularized optimal transport, to explain the efficacy of the method. Experimentally, we apply DDIBs on synthetic and high-resolution image datasets, to demonstrate their utility in a wide variety of translation tasks and their inherent optimal transport properties.

HYPERPRUNING: EFFICIENT PRUNING THROUGH LYAPUNOV METRIC HYPERSEARCH

Yang Zheng,Eli Shlizerman

A variety of pruning methods have been introduced for over-parameterized recurrent neural networks to improve efficiency in terms of power and storage. With the advance in pruning methods and their variety, a new problem of ‘hyperpruning’ is becoming apparent: finding a suitable pruning method with optimal hyperparameter configuration for a particular task and network. Such search is different from the standard hyperparameter search, where the accuracy of the optimal configuration is unknown. In the context of network pruning, the accuracy of the non-pruned (dense) model sets the target for the accuracy of the pruned model. Thereby, the goal of hyperpruning is to reach or even surpass this target. It is critical to develop efficient strategies for hyperpruning since direct search through pruned variants would require time-consuming training without guarantees for improved performance. To address this problem, we introduce a novel distance based on Lyapunov Spectrum (LS) which provides means to compare pruned variants with the dense model and early in training to estimate the accuracy that pruned variants will achieve after extensive training. The ability to predict performance allows us to incorporate the LS-based distance with Bayesian hyperparameter optimization methods and to propose an efficient and first-of-its-kind hyperpruning approach called LS-based Hyperpruning (LSH) which can optimize the search time by an order of magnitude compared to standard full training search with the loss (or perplexity) being the accuracy metric. Our experiments on stacked LSTM and RHN language models trained with the Penn Treebank dataset show that with a given budget of training epochs and desired pruning ratio, LSH obtains more optimal variants than standard loss-based hyperparameter optimization methods. Furthermore, as a result of the search, LSH identifies pruned variants that outperform state-of-the-art pruning methods and surpass the accuracy of the dense model.

Relational Curriculum Learning for Graph Neural Networks

Zheng Zhang,Junxiang Wang,Liang Zhao

Graph neural networks have achieved great success in representing structured data and its downstream tasks such as node classification. The key idea is to recursively propagate and aggregate information along the edges of a given graph topology. However, edges in real-world graphs often have varying degrees of difficulty, and some edges may even be noisy to the downstream tasks. Therefore, existing graph neural network models may lead to suboptimal learned representations because they usually consider every edge in a given graph topology equally. On the other hand, curriculum learning, which mimics the human learning principle of learning data samples in a meaningful order, has been shown to be effective in improving the generalization ability of representation learners by gradually proceeding from easy to more difficult samples during training. Unfortunately, most existing curriculum learning strategies are designed for i.i.d data samples and cannot be trivially generalized to handle structured data with dependencies. In order to address these issues, in this paper we propose a novel curriculum learning method for structured data to leverage the various underlying difficulties of data dependencies to improve the quality of learned representations on structured data. Specifically, we design a learning strategy that gradually incorporates edges in a given graph topology into training according to their difficulty from easy to hard, where the degree of difficulty is measured by a self-supervised learning paradigm. We demonstrate the strength of our proposed method in improving the generalization ability of learned representations through extensive experiments on nine synthetic datasets and seven real-world datasets with different commonly used graph neural network models as backbone models.

The World is Changing: Improving Fair Training under Correlation Shifts

Yuji Roh,Kangwook Lee,Steven Euijong Whang,Changho Suh

Model fairness is an essential element for Trustworthy AI. While many techniques for model fairness have been proposed, most of them assume that the training and deployment data distributions are identical, which is often not true in practice. In particular, when the bias between labels and sensitive groups changes, the fairness of the trained model is directly influenced and can worsen. We make t wo contributions for solving this problem. First, we analytically show that existing in-processing fair algorithms have fundamental limits in accuracy and fairness. We introduce the notion of correlation shifts, which can explicitly capture the change of the above bias. Second, we propose a novel pre-processing step that samples the input data to reduce correlation shifts and thus enables the in-processing approaches to overcome their limitations. We formulate an optimization problem for adjusting the data ratio among labels and sensitive groups to reflect the shifted correlation. A key advantage of our approach lies in decoupling the roles of pre-processing and in-processing approaches: correlation adjustment via pre-processing and unfairness mitigation on the processed data via in-processing. Experiments show that our framework effectively improves existing in-processing fair algorithms w.r.t. accuracy and fairness, both on synthetic and real datasets.

ACMP: Allen-Cahn Message Passing with Attractive and Repulsive Forces for Graph Neural Networks

Yuelin Wang,Kai Yi,Xinliang Liu,Yu Guang Wang,Shi Jin

Neural message passing is a basic feature extraction unit for graph-structured data considering neighboring node features in network propagation from one layer to the next. We model such process by an interacting particle system with attractive and repulsive forces and the Allen-Cahn force arising in the modeling of phase transition. The dynamics of the system is a reaction-diffusion process which can separate particles without blowing up. This induces an Allen-Cahn message passing (ACMP) for graph neural networks where the numerical iteration for the particle system solution constitutes the message passing propagation. ACMP which has a simple implementation with a neural ODE solver can propel the network depth up to one hundred of layers with theoretically proven strictly positive lower bound of the Dirichlet energy. It thus provides a deep model of GNNs circumventing the common GNN problem of oversmoothing. GNNs with ACMP achieve state of the art performance for real-world node classification tasks on both homophilic and heterophilic datasets. Codes are available at https://github.com/ykiiiiii/ACMP

Average Sensitivity of Decision Tree Learning

Satoshi Hara,Yuichi Yoshida

A decision tree is a fundamental model used in data mining and machine learning. In practice, the training data used to construct a decision tree may change over time or contain noise, and a drastic change in the learned tree structure owing to such data perturbation is unfavorable. For example, in data mining, a change in the tree implies a change in the extracted knowledge, which raises the question of whether the extracted knowledge is truly reliable or is only a noisy artifact. To alleviate this issue, we design decision tree learning algorithms that are stable against insignificant perturbations in the training data. Specifically, we adopt the notion of average sensitivity as a stability measure, and design an algorithm with low average sensitivity that outputs a decision tree whose accuracy is close to the optimal decision tree. The experimental results on real-world datasets demonstrate that the proposed algorithm enables users to select suitable decision trees considering the trade-off between average sensitivity and accuracy.

Minimum Curvature Manifold Learning

Yonghyeon Lee,Frank C. Park

It is widely observed that vanilla autoencoders can have low manifold learning accuracy given a noisy or small training dataset.
Recent work has discovered that it is important to regularize the decoder that explicitly parameterizes the manifold,
where a neighborhood graph is employed for decoder regularization. However, one caveat of this method is that it is not always straightforward to construct a correct graph. Alternatively, one may consider naive graph-free regularization methods such as minimizing the norm of the decoder's Jacobian or Hessian, but these norms are not coordinate-invariant (i.e. reparametrization-invariant) and hence

do not capture any meaningful geometric quantity of the manifold nor result in geometrically meaningful manifold regularization effects.

Another recent work called the isometric regularization implicitly forces the manifold to have zero intrinsic curvature, resulting in some geometrically meaningful regularization effects. But, since the intrinsic curvature does not capture how the manifold is embedded in the data space from an extrinsic perspective, the regularization effects are often limited. In this paper, we propose a {\it minimum extrinsic curvature principle} for manifold regularization and {\bf Minimum Curvature Autoencoder (MCAE)}, a graph-free coordinate-invariant extrinsic curvature minimization framework for autoencoder regularization. Experiments with various standard datasets demonstrate that MCAE improves manifold learning accuracy compared to existing methods, especially showing strong robustness to noise.

Causal Proxy Models For Concept-Based Model Explanations

Zhengxuan Wu,Karel D'Oosterlinck,Atticus Geiger,Amir Zur,Christopher Potts

Explainability methods for NLP systems encounter a version of the fundamental problem of causal inference: for a given ground-truth input text, we never truly observe the counterfactual texts necessary for isolating the causal effects of model representations on outputs. In response, many explainability methods make no use of counterfactual texts, assuming they will be unavailable. In this paper, we show that robust causal explainability methods can be created using approximate counterfactuals, which can be written by humans to approximate a specific counterfactual or simply sampled using metadata-guided heuristics. The core of our proposal is the Causal Proxy Model (CPM). A CPM explains a black-box model $\mathcal{N}$ because it is trained to have the same \emph{actual} input/output behavior as $\mathcal{N}$ while creating neural representations that can be intervened upon to simulate the \emph{counterfactual} input/output behavior of $\mathcal{N}$. Furthermore, we show that the best CPM for $\mathcal{N}$ performs comparably to $\mathcal{N}$ in making factual predictions, which means that the CPM can simply replace $\mathcal{N}$, leading to more explainable deployed models.

Offline Reinforcement Learning with Differential Privacy

Dan Qiao,Yu-Xiang Wang

The offline reinforcement learning (RL) problem is often motivated by the need to learn data-driven decision policies in financial, legal and healthcare applications. However, the learned policy could retain sensitive information of individuals in the training data (e.g., treatment and outcome of patients), thus susceptible to various privacy risks. We design offline RL algorithms with differential privacy guarantees which provably prevent such risks. These algorithms also enjoy strong instance-dependent learning bounds under both tabular and linear Markov Decision Process (MDP) settings. Our theory and simulation suggest that the privacy guarantee comes at (almost) no drop in utility comparing to the non-private counterpart for a medium-size dataset.

Relational Attention: Generalizing Transformers for Graph-Structured Tasks

Cameron Diao,Ricky Loynd

Transformers flexibly operate over sets of real-valued vectors representing task-specific entities and their attributes, where each vector might encode one word-piece token and its position in a sequence, or some piece of information that carries no position at all. As set processors, transformers are at a disadvantage in reasoning over more general graph-structured data where nodes represent entities and edges represent relations between entities. To address this shortcoming, we generalize transformer attention to consider and update edge vectors in each transformer layer. We evaluate this relational transformer on a diverse array of graph-structured tasks, including the large and challenging CLRS Algorithmic Reasoning Benchmark. There, it dramatically outperforms state-of-the-art graph neural networks expressly designed to reason over graph-structured data. Our analysis demonstrates that these gains are attributable to relational attention's inherent ability to leverage the greater expressivity of graphs over sets.

Distilling Model Failures as Directions in Latent Space
Saachi Jain,Hannah Lawrence,Ankur Moitra,Aleksander Madry

Existing methods for isolating hard subpopulations and spurious correlations in datasets often require human intervention. This can make these methods labor-intensive and dataset-specific. To address these shortcomings, we present a scalable method for automatically distilling a model's failure modes. Specifically, we harness linear classifiers to identify consistent error patterns, and, in turn, induce a natural representation of these failure modes as directions within the feature space. We demonstrate that this framework allows us to discover and automatically caption challenging subpopulations within the training dataset. Moreover, by combining our framework with off-the-shelf diffusion models, we can generate images that are especially challenging for the analyzed model, and thus can be used to perform synthetic data augmentation that helps remedy the model's failure modes.

Stable Target Field for Reduced Variance Score Estimation in Diffusion Models
Yilun Xu,Shangyuan Tong,Tommi S. Jaakkola

Diffusion models generate samples by reversing a fixed forward diffusion process. Despite already providing impressive empirical results, these diffusion models algorithms can be further improved by reducing the variance of the training targets in their denoising score-matching objective. We argue that the source of such variance lies in the handling of intermediate noise-variance scales, where multiple modes in the data affect the direction of reverse paths. We propose to remedy the problem by incorporating a reference batch which we use to calculate weighted conditional scores as more stable training targets. We show that the procedure indeed helps in the challenging intermediate regime by reducing (the trace of) the covariance of training targets. The new stable targets can be seen as trading bias for reduced variance, where the bias vanishes with increasing reference batch size. Empirically, we show that the new objective improves the image quality, stability, and training speed of various popular diffusion models across datasets with both general ODE and SDE solvers. When used in combination with EDM, our method yields a current SOTA FID of 1.90 with 35 network evaluations on the unconditional CIFAR-10 generation task. The code is available at https://github.com/Newbeeer/stf

Graph Contrastive Learning Under Heterophily: Utilizing Graph Filters to Generate Graph Views
Wenhan Yang,Baharan Mirzasoleiman

Graph Neural Networks have achieved tremendous success in (semi-)supervised tasks for which task-specific node labels are available. However, obtaining labels is expensive in many domains, specially as the graphs grow larger in size. Hence, there has been a growing interest in the application of self-supervised techniques, in particular contrastive learning (CL), to graph data. In general, CL methods work by maximizing the agreement between encoded augmentations of the same example, and minimizing agreement between encoded augmentations of different examples. However, we show that existing graph CL methods perform very poorly on graphs with heterophily, in which connected nodes tend to belong to different classes. First, we show that this is attributed to the ineffectiveness of existing graph augmentation methods. Then, we leverage graph filters to directly generate augmented graph views for graph CL under heterophily. In particular, instead of explicitly augmenting the graph topology and encoding the augmentations, we use a high-pass filter in the encoder to generate node representations only based on high-frequency graph signals. Then, we contrast the high-pass filtered representations with their low-pass counterparts produced by the same encoder, to generate representations. Our experimental results confirm that our proposed method, HLCL, outperforms state-of-the-art CL methods on benchmark graphs with heterophily, by up to 10%.

Countinuous pseudo-labeling from the start
Dan Berrebbi,Ronan Collobert,Samy Bengio,Navdeep Jaitly,Tatiana Likhomanenko

Self-training (ST), or pseudo-labeling has sparked significant interest in the automatic speech recognition (ASR) community recently because of its success in harnessing unlabeled data. Unlike prior semi-supervised learning approaches that relied on iteratively regenerating pseudo-labels (PLs) from a trained model and using them to train a new model, recent state-of-the-art methods perform `continuous training' where PLs are generated using a very recent version of the model being trained. Nevertheless, these approaches still rely on bootstrapping the ST using an initial supervised learning phase where the model is trained on labeled data alone. We believe this has the potential for over-fitting to the labeled dataset in low resource settings and that ST from the start of training should reduce over-fitting. In this paper we show how we can do this by dynamically controlling the evolution of PLs during the training process in ASR. To the best of our knowledge, this is the first study that shows the feasibility of generating PLs from the very start of the training. We are able to achieve this using two techniques that avoid instabilities which lead to degenerate models that do not generalize. Firstly, we control the evolution of PLs through a curriculum that uses the online changes in PLs to control the membership of the cache of PLs and improve generalization. Secondly, we find that by sampling transcriptions from the predictive distribution, rather than only using the best transcription, we can stabilize training further. With these techniques, our ST models match prior works without an external language model.

Hybrid Federated Learning for Feature & Sample Heterogeneity: Algorithms and Implementation

Xinwei Zhang,Wotao Yin,Mingyi Hong,Tianyi Chen

Federated learning (FL) is a popular distributed machine learning paradigm dealing with distributed and private data sets. Based on the data partition pattern, FL is often categorized into horizontal, vertical, and hybrid settings. All three settings have many applications, but the hybrid FL remains relatively less explored, because it deals with the challenging situation where both the feature space and the data samples are heterogeneous.

This work designs a novel mathematical model that effectively allows the clients to aggregate distributed data with heterogeneous, and possibly overlapping features and samples. Our main idea is to partition each client's model into a feature extractor part and a classifier part, where the former can be used to process the input data, while the latter is used to perform the learning from the extracted features. The heterogeneous feature aggregation is done through building a server model, which assimilates local classifiers and feature extractors through a carefully designed matching mechanism. A communication-efficient algorithm is then designed to train both the client and server models. Finally, we conducted numerical experiments on multiple image classification data sets to validate the performance of the proposed algorithm. To our knowledge, this is the first formulation and algorithm developed for hybrid FL.

Policy Architectures for Compositional Generalization in Control

Allan Zhou,Vikash Kumar,Chelsea Finn,Aravind Rajeswaran

Several tasks in control, robotics, and planning can be specified through desired goal configurations for entities in the environment. Learning goal-conditioned policies is a natural paradigm to solve such tasks. However, learning and generalizing on complex tasks can be challenging due to variations in number of entities or compositions of goals. To address this challenge, we introduce the Entity-Factored Markov Decision Process (EFMDP), a formal framework for modeling the entity-based compositional structure in control tasks. Geometrical properties of the EFMDP framework provide theoretical motivation for policy architecture design, particularly Deep Sets and popular relational mechanisms such as graphs and self attention. These structured policy architectures are flexible and can be trained end-to-end with standard reinforcement and imitation learning algorithms. We study and compare the learning and generalization properties of these architectures on a suite of simulated robot manipulation tasks, finding that they achieve significantly higher success rates with less data compared to standard multila

yer perceptrons. Structured policies also enable broader and more compositional generalization, producing policies that extrapolate to different numbers of entities than seen in training, and stitch together (i.e. compose) learned skills in novel ways. Video results can be found at https://sites.google.com/view/comp-gen-anon.

GNNDelete: A General Strategy for Unlearning in Graph Neural Networks
Jiali Cheng,George Dasoulas,Huan He,Chirag Agarwal,Marinka Zitnik
Graph unlearning, which involves deleting graph elements such as nodes, node labels, and relationships from a trained graph neural network (GNN) model, is crucial for real-world applications where data elements may become irrelevant, inaccurate, or privacy-sensitive. However, existing methods for graph unlearning either deteriorate model weights shared across all nodes or fail to effectively delete edges due to their strong dependence on local graph neighborhoods. To address these limitations, we introduce GNNDelete, a novel model-agnostic layer-wise operator that optimizes two critical properties, namely, Deleted Edge Consistency and Neighborhood Influence, for graph unlearning. Deleted Edge Consistency ensures that the influence of deleted elements is removed from both model weights and neighboring representations, while Neighborhood Influence guarantees that the remaining model knowledge is preserved after deletion. GNNDelete updates representations to delete nodes and edges from the model while retaining the rest of the learned knowledge. We conduct experiments on seven real-world graphs, showing that GNNDelete outperforms existing approaches by up to 38.8% (AUC) on edge, node, and node feature deletion tasks, and 32.2% on distinguishing deleted edges from non-deleted ones. Additionally, GNNDelete is efficient, taking 12.3x less time and 9.3x less space than retraining GNN from scratch on WordNet18.

Lower Bounds for Differentially Private ERM: Unconstrained and Non-Euclidean
Zhou Lu,Daogao Liu
We consider the lower bounds of differentially private empirical risk minimization (DP-ERM) for convex functions in both constrained and unconstrained cases concerning the general ℓ_p norm beyond the ℓ_2 norm considered by most of the previous works.

We provide a simple black-box reduction approach that can generalize lower bounds in constrained to unconstrained cases.
Moreover, for (ϵ,δ)-DP, we achieve the optimal $\Omega(\frac{\sqrt{d \log(1/\delta)}}{\epsilon n})$ lower bounds for both constrained and unconstrained cases and any ℓ_p geometry where $p\geq 1$ by considering ℓ_1 loss over the ℓ_{∞} ball.
****
The Convergence Rate of SGD's Final Iterate: Analysis on Dimension Dependence
Daogao Liu,Zhou Lu
Stochastic Gradient Descent (SGD) is among the simplest and most popular optimization and machine learning methods. Running SGD with a fixed step size and outputting the final iteration is an ideal strategy one can hope for, but it is still not well-understood even though SGD has been studied extensively for over 70 years. Given the $\Theta(\log T)$ gap between current upper and lower bounds for running SGD for T steps, it was then asked by [Koren and Segal COLT 20'] how to characterize the final-iterate convergence of SGD with a fixed step size in the constant dimension setting, i.e., $d=O(1)$.

In this paper, we consider the more general setting for any $d\leq T$, proving $\Omega(\log d/\sqrt{T})$ lower bounds for the sub-optimality of the final iterate of SGD in minimizing non-smooth Lipschitz convex functions with standard step sizes. Our results provide the first general dimension-dependent lower bound on the convergence of SGD's final iterate, partially resolving the COLT open question raised by [Koren and Segal COLT 20'].
Moreover, we present a new method in one dimension based on martingale and Freedman’s inequality, which gets the tight $O(1/\sqrt{T})$ upper bound with mild ass

umptions and recovers the same bounds $O(\log T/\sqrt{T})$ as previous best results under the standard assumptions.

Multi-Rate VAE: Train Once, Get the Full Rate-Distortion Curve

Juhan Bae,Michael R. Zhang,Michael Ruan,Eric Wang,So Hasegawa,Jimmy Ba,Roger Baker Grosse

Variational autoencoders (VAEs) are powerful tools for learning latent representations of data used in a wide range of applications. In practice, VAEs usually require multiple training rounds to choose the amount of information the latent variable should retain. This trade-off between the reconstruction error (distortion) and the KL divergence (rate) is typically parameterized by a hyperparameter β. In this paper, we introduce Multi-Rate VAE (MR-VAE), a computationally efficient framework for learning optimal parameters corresponding to various β in a single training run. The key idea is to explicitly formulate a response function using hypernetworks that maps β to the optimal parameters. MR-VAEs construct a compact response hypernetwork where the pre-activations are conditionally gated based on β. We justify the proposed architecture by analyzing linear VAEs and showing that it can represent response functions exactly for linear VAEs. With the learned hypernetwork, MR-VAEs can construct the rate-distortion curve without additional training and can be deployed with significantly less hyperparameter tuning. Empirically, our approach is competitive and often exceeds the performance of multiple β-VAEs training with minimal computation and memory overheads.

Adaptive Gradient Methods with Local Guarantees

Zhou Lu,Wenhan Xia,Sanjeev Arora,Elad Hazan

Adaptive gradient methods are the method of choice for optimization in machine learning and used to train the largest deep models. In this paper we study the problem of learning a local preconditioner, that can change as the data is changing along the optimization trajectory. We propose an adaptive gradient method that has provable adaptive regret guarantees vs. the best local preconditioner. To derive this guarantee, we prove a new adaptive regret bound in online learning that improves upon previous adaptive online learning methods.

We demonstrate the robustness of our method in automatically choosing the optimal learning rate schedule for popular benchmarking tasks in vision and language domains. Without the need to manually tune a learning rate schedule, our method can, in a single run, achieve comparable and stable task accuracy as a fine-tuned optimizer.

Combinatorial-Probabilistic Trade-Off: P-Values of Community Properties Test in the Stochastic Block Models

Shuting Shen,Junwei Lu

We propose an inferential framework testing the general community combinatorial properties of the stochastic block model. We aim to test the hypothesis on whether a certain community property is satisfied, e.g., whether a given set of nodes belong to the same community, and provide p-values for uncertainty quantification. Our framework is applicable to all symmetric community properties. To ease the challenges caused by the combinatorial nature of community properties, we develop a novel shadowing bootstrap method. Utilizing the symmetry, our method can find a shadowing representative of the true assignment and the number of tested assignments in the alternative is largely reduced. In theory, we introduce a combinatorial distance between two community classes and show a combinatorial-probabilistic trade-off phenomenon. Our test is honest as long as the product of the combinatorial distance between two communities and the probabilistic distance between two connection probabilities is sufficiently large. Besides, we show that such trade-off also exists in the information-theoretic lower bound. We also implement numerical experiments to show the validity of our method.

****

Min-Max Zero-Shot Multi-Label Classification

Sima Behpour

In many classification problems, acquiring labeled examples for many classes is difficult, resulting in high interest in zero-shot learning frameworks. Zero-shot learning (ZSL) is a problem setup, where at test time, a learner observes samples from classes that were not observed/trained in the training phase and is required to predict the category they belong to. Zero-shot learning transfers knowledge from seen classes (observed classes in the training phase) to unseen classes (unobserved classes in the training phase but present in the testing phase), reducing human labor of data annotation to build new classifiers. However, most zero-shot learning researches target single-label classification (multi-class setting). There are few studies on multi-label zero-shot learning due to the difficulty in modeling complex semantics conveyed by a set of labels.

We propose a novel probabilistic model that incorporates more general feature representation (e.g., Word-Net hierarchy, word2vec features, convolutional neural network features (layer-wise), and co-occurrence statistics) and learns the knowledge transfer in terms of data structure and relations. We also investigate the effect of leveraging different CNN layers' features. Our experimental results prove the efficacy of our model in handling unseen labels. We run additional experiments to analyze the flat-sharp minima convergence of methods as a generalization factor. Our study suggests that our proposed method converges to flat minima resulting in strong generalization.

Meta-Learning in Games

Keegan Harris,Ioannis Anagnostides,Gabriele Farina,Mikhail Khodak,Steven Wu,Tuomas Sandholm

In the literature on game-theoretic equilibrium finding, focus has mainly been on solving a single game in isolation. In practice, however, strategic interactions—ranging from routing problems to online advertising auctions—evolve dynamically, thereby leading to many similar games to be solved. To address this gap, we introduce meta-learning for equilibrium finding and learning to play games. We establish the first meta-learning guarantees for a variety of fundamental and well-studied games, including two-player zero-sum games, general-sum games, Stackelberg games, and multiple extensions thereof. In particular, we obtain rates of convergence to different game-theoretic equilibria that depend on natural notions of similarity between the sequence of games encountered, while at the same time recovering the known single-game guarantees when the sequence of games is arbitrary. Along the way, we prove a number of new results in the single-game regime through a simple and unified framework, which may be of independent interest. Finally, we evaluate our meta-learning algorithms on endgames faced by the poker agent Libratus against top human professionals. The experiments show that games with varying stack sizes can be solved significantly faster using our meta-learning techniques than by solving them separately, often by an order of magnitude.

GLASU: A Communication-Efficient Algorithm for Federated Learning with Vertically Distributed Graph Data

Xinwei Zhang,Mingyi Hong,Jie Chen

Vertical federated learning (VFL) is a distributed learning paradigm, where computing clients collectively train a model based on the partial features of the same set of samples they possess. Current research on VFL focuses on the case when samples are independent, but it rarely addresses an emerging scenario when samples are interrelated through a graph. For graph-structured data, graph neural networks (GNNs) are rather competitive machine learning models, but a naive implementation in the VFL setting causes a significant communication overhead; moreover, the analysis is faced with a challenge caused by the biased stochastic gradients. In this paper, we propose a model splitting method that splits a backbone GNN across the clients and the server and a communication-efficient algorithm, GLASU, to train such a model. GLASU adopts lazy aggregation and stale updates to skip aggregation when evaluating the model and skip feature exchanges during training, greatly reducing communication. We offer a theoretical analysis and conduc t extensive numerical experiments on real-world datasets, showing that the proposed algorithm effectively trains a GNN model, whose performance matches that of the backbone GNN when trained in a centralized manner.

Dynamic Embeddings of Temporal High-Order Interactions via Neural Diffusion-Reaction Processes

Zheng Wang,shikai fang,Shibo Li,Shandian Zhe

High-order interactions of multiple entities are ubiquitous in practical applications. The associated data often includes the participants, interaction results, and the timestamps when each interaction occurred. While tensor factorization is a popular tool to analyze such data, it often ignores or underuses valuable timestamp information. More important, standard tensor factorization only estimates a static representation for each entity and ignores the temporal variation of the representations. However, such variations might reflect important evolution patterns of the underlying properties of the entities. To address these limitations, we propose Dynamical eMbedIngs of TempoRal hIgh-order interactions (DMITRI). We develop a neural diffusion-reaction process model to estimate the dynamic embeddings for the participant entities. Specifically, based on the observed interactions, we build a multi-partite graph to encode the correlation between the entities. We construct a graph diffusion process to co-evolve the embedding trajectories of the correlated entities and use a neural network to construct a reaction process for each individual entity. In this way, our model is able to capture both the commonalities and personalities during the evolution of the embeddings for different entities. We then use a neural network to model the interaction result as a nonlinear function of the embedding trajectories. For model estimation, we combine ODE solvers to develop a stochastic mini-batch learning algorithm. We propose a simple stratified sampling method to balance the cost of processing each mini-batch so as to improve the overall efficiency. We show the advantage of our approach in both the ablation study and real-world applications.

****

Fair Federated Learning via Bounded Group Loss

Shengyuan Hu,Steven Wu,Virginia Smith

In federated learning, fair prediction across protected groups is an important constraint for many applications. Unfortunately, prior work studying group fair federated learning lacks formal convergence or fairness guarantees. In this work we propose a general framework for provably fair federated learning. In particular, we explore and extend the notion of Bounded Group Loss as a theoretically-grounded approach for group fairness. Using this setup, we propose a scalable federated optimization method that optimizes the empirical risk under a number of group fairness constraints. We provide convergence guarantees for the method as well as fairness guarantees for the resulting solution. Empirically, we evaluate our method across common benchmarks from fair ML and federated learning, showing that it can provide both fairer and more accurate predictions than baseline approaches.

****

DiffDock: Diffusion Steps, Twists, and Turns for Molecular Docking

Gabriele Corso,Hannes Stärk,Bowen Jing,Regina Barzilay,Tommi S. Jaakkola

Predicting the binding structure of a small molecule ligand to a protein---a task known as molecular docking---is critical to drug design. Recent deep learning methods that treat docking as a regression problem have decreased runtime compared to traditional search-based methods but have yet to offer substantial improvements in accuracy. We instead frame molecular docking as a generative modeling problem and develop DiffDock, a diffusion generative model over the non-Euclidean manifold of ligand poses. To do so, we map this manifold to the product space of the degrees of freedom (translational, rotational, and torsional) involved in docking and develop an efficient diffusion process on this space. Empirically, DiffDock obtains a 38% top-1 success rate (RMSD<2A) on PDBBind, significantly outperforming the previous state-of-the-art of traditional docking (23%) and deep learning (20%) methods. Moreover, while previous methods are not able to dock on computationally folded structures (maximum accuracy 10.4%), DiffDock maintains s ignificantly higher precision (21.7%). Finally, DiffDock has fast inference times and provides confidence estimates with high selective accuracy.

An Upper Bound for the Distribution Overlap Index and Its Applications
Hao Fu,Prashanth Krishnamurthy,Siddharth Garg,Farshad Khorrami

The overlap index between two probability distributions has various applications in statistics, machine learning, and other scientific research. However, approximating the overlap index is challenging when the probability distributions are unknown (i.e., distribution-free settings). This paper proposes an easy-to-compute upper bound for the overlap index without requiring any knowledge of the distribution models. We first utilize the bound to find the upper limit for the accuracy of a trained machine learning model when a domain shift exists. We additionally employ this bound to study the distribution membership classification of given samples. Specifically, we build a novel, distribution-free, computation-efficient, memory-efficient one-class classifier by converting the bound into a confidence score function. The proposed classifier does not need to train any parameters and requires only a small number of in-class samples to be accurate. The classifier shows its efficacy on various datasets and outperforms many state-of-the-art methods in different one-class classification scenarios, including novelty detection, out-of-distribution detection, and backdoor detection. The obtained results show significant promise toward broadening the applications of overlap-based metrics.

****

Learning by Distilling Context
Charlie Victor Snell,Dan Klein,Ruiqi Zhong

Language models significantly benefit from context tokens, such as prompts or scratchpads. They perform better when prompted with concrete training examples and abstract statements about the target task (instructions), and they acquire new capabilities to perform complex tasks by generating step-by-step reasoning (scratch-pad) before predicting the final answers. However, they do not internalize these performance gains, which disappear when the context tokens are gone. Consequently, we always need to pay extra computation for this gain, and it is unclear how to transfer the capabilities acquired by context tokens to other tasks, or how to leverage the context tokens when their length exceeds the context window size. Our work proposes to apply context distillation so that a language model can internalize these gains. Concretely, given an input for the target task, we let the model use all relevant context tokens to generate the output, using ``[instructions] + [task-input]'' to predict ``[scratch-pad] + [final answer]''; then we fine-tune the same model to predict the above ``[final answer]'' conditioned on the ``[task-input]'', without seeing the ``[instructions]'' or using the ``[scratch-pad]''. This incentivizes the model to behave as if the context were present, hence updating the parameters to internalize the context information. We show that context distillation can be used as a general method for learning. In particular, we demonstrate that context distillation can effectively internalize 3 types of contexts: 1) abstract task instructions and natural language explanations of why an output is correct or incorrect on Natural-Instructions-V2; 2) step-by-step reasoning on 8-digit addition questions, where we show the model can apply this newly acquired capability to downstream question answering tasks; and 3) concrete training examples on the SPIDER Text-to-SQL dataset, where context distillation outperforms directly learning with gradient descent by 7%.

Target-Free Ligand Scoring via One-Shot Learning
Peter Eckmann,Jake Anderson,Michael K Gilson,Rose Yu

Scoring ligands in a library based on their structural similarity to a known hit compound is widely used in drug discovery following high-throughput screening. However, such "similarity search" relies on the assumption that structurally similar compounds have similar activities, and will therefore only retrieve ligands with hit-like affinity, requiring resource-intensive tweaking by medicinal chemists to reach a more active lead compound. We propose a novel approach, One-Shot Ligand Scoring (OSLS), that is much more capable of directly retrieving lead-li ke compounds from a library using a novel one-shot learning technique. For this new task, we design a Siamese-inspired neural architecture using two Transformer encoders without tied weights, a novel positional encoding-like mechanism, and a final prediction head. OSLS is able to score ligands by activity against a target without any target-specific knowledge beyond a single known activity value, a cost-effective approach to ligand-based or phenotypic drug discovery. We show that OSLS surpasses traditional similarity search as well as modern deep learning baselines on a simulated ligand retrieval task. Furthermore, we demonstrate the applicability of our approach on various drug discovery tasks that also involve ligand scoring, including drug repositioning, precision patient-level drug efficacy prediction, and even molecular generative modeling.

Structured Pruning of CNNs at Initialization

Yaohui Cai,Weizhe Hua,Hongzheng Chen,Fengyu Li,G. Edward Suh,Christopher De Sa,Zhiru Zhang

Pruning-at-initialization (PAI) proposes to prune the individual weights of the CNN before training, thus avoiding expensive fine-tuning or retraining of the pruned model. While PAI shows promising results in reducing model size, the pruned model still requires unstructured sparse matrix computation, making it difficult to achieve wall-clock speedups. In this work, we show theoretically and empirically that the accuracy of CNN models pruned by PAI methods only depends on the fraction of remaining parameters in each layer (i.e., layer-wise density), regardless of the granularity of pruning. We formulate the PAI problem as a convex optimization of our newly proposed expectation-based proxy for model accuracy, which leads to finding the optimal layer-wise density of that specific model. Based on our formulation, we further propose a structured and hardware-friendly PAI method, named PreCrop, to prune or reconfigure CNNs in the channel dimension. Our empirical results show that PreCrop achieves a higher accuracy than existing PAI methods on several modern CNN architectures, including ResNet, MobileNetV2, and EfficientNet for both CIFAR-10 and ImageNet. PreCrop achieves an accuracy improvement of up to 2.7% over the state-of-the-art PAI algorithm when pruning MobileNetV2 on ImageNet. PreCrop also improves the accuracy of EfficientNetB0 by 0.3% on ImageNet with only 80% of the parameters and the same FLOPs.

****

Constructive TT-representation of the tensors given as index interaction functions with applications

Gleb Ryzhakov,Ivan Oseledets

This paper presents a method to build explicit tensor-train (TT) representations. We show that a wide class of tensors can be explicitly represented with sparse TT-cores, obtaining, in many cases, optimal TT-ranks. Numerical experiments show that our method outperforms the existing ones in several practical applications, including game theory problems. Theoretical estimations of the number of operations show that in some problems, such as permanent calculation, our methods are close to the known optimal asymptotics, which are obtained by a completely different type of methods.

****

Thinking Two Moves Ahead: Anticipating Other Users Improves Backdoor Attacks in Federated Learning

Yuxin Wen,Jonas Geiping,Liam H Fowl,Hossein Souri,Rama Chellappa,Micah Goldblum,Tom Goldstein

Federated learning is particularly susceptible to model poisoning and backdoor attacks because individual users have direct control over the training data and model updates. At the same time, the attack power of an individual user is limited because their updates are quickly drowned out by those of many other users. Existing attacks do not account for future behaviors of other users, and thus require many sequential updates and their effects are quickly erased. We propose an attack that anticipates and accounts for the entire federated learning pipeline, including behaviors of other clients, and ensures that backdoors are effective quickly and persist even after multiple rounds of community updates. We show th at this new attack is effective in realistic scenarios where the attacker only contributes to a small fraction of randomly sampled rounds and demonstrate this attack on image classification, next-word prediction, and sentiment analysis.

****

Continuized Acceleration for Quasar Convex Functions in Non-Convex Optimization

Jun-Kun Wang,Andre Wibisono

Quasar convexity is a condition that allows some first-order methods to efficiently minimize a function even when the optimization landscape is non-convex. Previous works develop near-optimal accelerated algorithms for minimizing this class of functions, however, they require a subroutine of binary search which results in multiple calls to gradient evaluations in each iteration, and consequently the total number of gradient evaluations does not match a known lower bound. In this work, we show that a recently proposed continuized Nesterov acceleration can be applied to minimizing quasar convex functions and achieves the optimal bound with a high probability. Furthermore, we find that the objective functions of training generalized linear models (GLMs) satisfy quasar convexity, which broadens the applicability of the relevant algorithms, while known practical examples of quasar convexity in non-convex learning are sparse in the literature. We also show that if a smooth and one-point strongly convex, Polyak-Lojasiewicz, or quadratic-growth function satisfies quasar convexity, then attaining an accelerated linear rate for minimizing the function is possible under certain conditions, while acceleration is not known in general for these classes of functions.

Towards Global Optimality in Cooperative MARL with Sequential Transformation

Jianing Ye,Chenghao Li,Jianhao Wang,Qianchuan Zhao,Chongjie Zhang

Policy learning in multi-agent reinforcement learning (MARL) is challenging due to the exponential growth of joint state-action space with respect to the number of agents. To achieve higher scalability, the paradigm of centralized training with decentralized execution (CTDE) is broadly adopted with factorized structure in MARL. However, we observe that existing CTDE algorithms in cooperative MARL cannot achieve optimality even in simple matrix games. To understand this phenomenon, we analyze two mainstream classes of CTDE algorithms -- actor-critic algorithms and value-decomposition algorithms. Our theoretical and experimental results characterize the weakness of these two classes of algorithms when the optimization method is taken into consideration, which indicates that the currently used centralized training manner is deficient in compatibility with decentralized policy. To address this issue, we present a transformation framework that reformulates a multi-agent MDP as a special "single-agent" MDP with a sequential structure and can allow employing off-the-shelf single-agent reinforcement learning (SARL) algorithms to efficiently learn corresponding multi-agent tasks. After that, a decentralized policy can still be learned by distilling the "single-agent" policy. This framework retains the optimality guarantee of SARL algorithms into cooperative MARL. To instantiate this transformation framework, we propose a Transformed PPO, called T-PPO, which can theoretically perform optimal policy learning in the finite multi-agent MDPs and shows significant outperformance on a large set of cooperative multi-agent tasks.

Sparse tree-based Initialization for Neural Networks

Patrick Lutz,Ludovic Arnould,Claire Boyer,Erwan Scornet

Dedicated neural network (NN) architectures have been designed to handle specific data types (such as CNN for images or RNN for text), which ranks them among state-of-the-art methods for dealing with these data. Unfortunately, no architecture has been found for dealing with tabular data yet, for which tree ensemble methods (tree boosting, random forests) usually show the best predictive performances. In this work, we propose a new sparse initialization technique for (potentially deep) multilayer perceptrons (MLP): we first train a tree-based procedure to detect feature interactions and use the resulting information to initialize the network, which is subsequently trained via standard gradient descent (GD) strategies. Numerical experiments on several tabular data sets showthe benefits of t his new, simple and easy-to-use method, both in terms of generalization capacity and computation time, compared to default MLP initialization and even to existing complex deep learning solutions. In fact, this wise MLP initialization raises the performances of the resulting NN methods to that of gradient boosting on tabular data. Besides, such initializations are able to preserve the sparsity of weights introduced in the first layers of the network throughout the training, which emphasizes that the first layers act as a sparse feature extractor (like convolutional layers in CNN).

Learning Soft Constraints From Constrained Expert Demonstrations

Ashish Gaurav,Kasra Rezaee,Guiliang Liu,Pascal Poupart

Inverse reinforcement learning (IRL) methods assume that the expert data is generated by an agent optimizing some reward function. However, in many settings, the agent may optimize a reward function subject to some constraints, where the constraints induce behaviors that may be otherwise difficult to express with just a reward function. We consider the setting where the reward function is given, and the constraints are unknown, and propose a method that is able to recover these constraints satisfactorily from the expert data. While previous work has focused on recovering hard constraints, our method can recover cumulative soft constraints that the agent satisfies on average per episode. In IRL fashion, our method solves this problem by adjusting the constraint function iteratively through a constrained optimization procedure, until the agent behavior matches the expert behavior. We demonstrate our approach on synthetic environments, robotics environments and real world highway driving scenarios.

VoGE: A Differentiable Volume Renderer using Gaussian Ellipsoids for Analysis-by-Synthesis

Angtian Wang,Peng Wang,Jian Sun,Adam Kortylewski,Alan Yuille

Differentiable rendering allows the application of computer graphics on vision tasks, e.g. object pose and shape fitting, via analysis-by-synthesis, where gradients at occluded regions are important when inverting the rendering process.To obtain those gradients, state-of-the-art (SoTA) differentiable renderers use rasterization to collect a set of nearest components for each pixel and aggregate them based on the viewing distance. In this paper, we propose VoGE, which uses ray tracing to capture nearest components with their volume density distributions on the rays and aggregates via integral of the volume densities based on Gaussian ellipsoids, which brings more efficient and stable gradients. To efficiently render via VoGE, we propose an approximate close-form solution for the volume density aggregation and a coarse-to-fine rendering strategy. Finally, we provide a CUDA implementation of VoGE, which gives a competitive rendering speed in comparison to PyTorch3D. Quantitative and qualitative experiment results show VoGE outperforms SoTA counterparts when applied to various vision tasks, e.g., object pose estimation, shape/texture fitting, and occlusion reasoning. The VoGE code is available at: https://github.com/Angtian/VoGE.

Unravel Structured Heterogeneity of Tasks in Meta-Reinforcement Learning via Exploratory Clustering

Zhendong Chu,Hongning Wang

Meta-reinforcement learning (meta-RL) is developed to quickly solve new tasks by leveraging knowledge from prior tasks. The assumption that tasks are drawn IID is typically made in previous studies, which ignore possible structured heterogeneity of tasks. The non-transferable knowledge caused by structured heterogeneity hinders fast adaptation in new tasks. In this paper, we formulate the structured heterogeneity of tasks via clustering such that transferable knowledge can be inferred within different clusters and non-transferable knowledge would be excluded across clusters thereby. To facilitate so, we develop a dedicated exploratory policy to discover task clusters by reducing uncertainty in posterior inference. Within the identified clusters, the exploitation policy is able to solve related tasks by utilizing knowledge shared within the clusters. Experiments on various MuJoCo tasks showed the proposed method can unravel cluster structures effe ctively in both rewards and state dynamics, proving strong advantages against a set of state-of-the-art baselines.

An Investigation of Domain Generalization with Rademacher Complexity

Da Li,Henry Gouk,Timothy Hospedales

The domain generalization (DG) setting challenges a model trained on multiple known data distributions to generalise well on unseen data distributions. Due to its practical importance, many methods have been proposed to address this challenge.

However much work in general purpose DG is heuristically motivated,
as the DG problem is hard to model formally; and recent evaluations have cast doubt on existing methods’ practical efficacy -- in particular compared to a well tuned empirical risk minimisation baseline.

We present a novel learning-theoretic generalisation bound for DG that bounds unseen domain generalisation performance in terms of the model’s empirical risk and Rademacher complexity -- providing a sufficient condition for DG. Based on this insight, we empirically analyze the performance of several methods and show that their performance is indeed influenced by model complexity in practice.

Algorithmically, our analysis suggests that tuning for domain generalisation should be achieved by simply performing regularised ERM with a leave-one-domain-out cross-validation objective. Empirical results on the DomainBed benchmark corroborate this.

FedDA: Faster Framework of Local Adaptive Gradient Methods via Restarted Dual Averaging

Junyi Li,Feihu Huang,Heng Huang

Federated learning (FL) is an emerging learning paradigm to tackle massively distributed data. In Federated Learning, a set of clients jointly perform a machine learning task under the coordination of a server. The FedAvg algorithm is one of the most widely used methods to solve Federated Learning problems. In FedAvg, the learning rate is a constant rather than changing adaptively. The adaptive gradient methods show superior performance over the constant learning rate schedule; however, there is still no general framework to incorporate adaptive gradient methods into the federated setting. In this paper, we propose \textbf{FedDA}, a novel framework for local adaptive gradient methods. The framework adopts a restarted dual averaging technique and is flexible with various gradient estimation methods and adaptive learning rate formulations. In particular, we analyze \textbf{FedDA-MVR}, an instantiation of our framework, and show that it achieves gradient complexity $\tilde{O}(\epsilon^{-1.5})$ and communication complexity $\tilde{O}(\epsilon^{-1})$ for finding a stationary point ϵ. This matches the best known rate for first-order FL algorithms and \textbf{FedDA-MVR} is the first adaptive FL algorithm that achieves this rate. We also perform extensive numerical experiments to verify the efficacy of our method.

The Lazy Neuron Phenomenon: On Emergence of Activation Sparsity in Transformers

Zonglin Li,Chong You,Srinadh Bhojanapalli,Daliang Li,Ankit Singh Rawat,Sashank J. Reddi,Ke Ye,Felix Chern,Felix Yu,Ruiqi Guo,Sanjiv Kumar

This paper studies a curious phenomenon that machine learning model with Transformer architectures have sparse activation maps. By activation map we refer to the intermediate output of the multi-layer perceptrons (MLPs) after a ReLU activation function, and by "sparse" we mean that on average very few entries (e.g., 3.0% for T5-Base and 6.3% for ViT-B16) are nonzero for each input to MLP. Moreover, larger Transformers with more layers and wider MLP hidden dimensions are sparser as measured by the percentage of nonzero entries. Through extensive experiments we demonstrate that the emergence of sparsity is a prevalent phenomenon that occurs for both natural language processing and vision tasks, on both training and evaluation data, for Transformers of various configurations, at layers of all depth levels. We discuss how sparsity immediately implies a way to significantly reduce the FLOP count and improve efficiency for Transformers. Moreover, we demonstrate perhaps surprisingly that enforcing an even sparser activation via Top

-k thresholding with a small k brings a collection of desired properties, namely less sensitivity to noisy training data, more robustness to input corruptions, and better calibration for their prediction confidence.

Explainable Recommender with Geometric Information Bottleneck

Hanqi Yan,Lin Gui,Yulan He

Explainable recommender systems have attracted much interest in recent years as they can explain their recommendation decisions, enhancing user trust in the systems. Most explainable recommender systems rely on human-generated rationales or annotated aspect features from user reviews to train models for rational generation or extraction. The rationales produced are often confined to a single review. To avoid the expensive human annotation process and to generate explanations beyond individual reviews, we propose an explainable recommender system trained on user reviews by developing a transferable Geometric Information Bottleneck (GIANT), which leverages the prior knowledge acquired through clustering on a user-item graph built on user-item rating interactions, since graph nodes in the same cluster tend to share common characteristics or preferences. We then feed user reviews and item reviews into a variational network to learn latent topic distributions which are regularised by the distributions of user/item estimated based on their distances to various cluster centroids of the user-item graph. By iteratively refining the instance-level review latent topics with GIANT, our method learns a robust latent space from the text for rating prediction and explanation generation. Experimental results on three e-commerce datasets show that our model significantly improves the interpretability of a variational recommender using a standard Gaussian prior, in terms of coherence, diversity and faithfulness, while achieving performance comparable to existing content-based recommender systems in terms of rating prediction accuracy.

Near-optimal Policy Identification in Active Reinforcement Learning

Xiang Li,Viraj Mehta,Johannes Kirschner,Ian Char,Willie Neiswanger,Jeff Schneider,Andreas Krause,Ilija Bogunovic

Many real-world reinforcement learning tasks require control of complex dynamical systems that involve both costly data acquisition processes and large state spaces. In cases where the expensive transition dynamics can be readily evaluated at specified states (e.g., via a simulator), agents can operate in what is often referred to as planning with a \emph{generative model}. We propose the AE-LSVI algorithm for best policy identification, a novel variant of the kernelized least-squares value iteration (LSVI) algorithm that combines optimism with pessimism for active exploration (AE). AE-LSVI provably identifies a near-optimal policy \emph{uniformly} over an entire state space and achieves polynomial sample complexity guarantees that are independent of the number of states. When specialized to the recently introduced offline contextual Bayesian optimization setting, our algorithm achieves improved sample complexity bounds. Experimentally, we demonstrate that AE-LSVI outperforms other RL algorithms in a variety of environments when robustness to the initial state is required.

Algorithmic Determination of the Combinatorial Structure of the Linear Regions of ReLU Neural Networks

Marissa Masden

We algorithmically determine the regions and facets of all dimensions of the canonical polyhedral complex, the universal object into which a ReLU network decomposes its input space. We show that the locations of the vertices of the canonical polyhedral complex along with their signs with respect to layer maps determine the full facet structure across all dimensions. We present an algorithm which calculates this full combinatorial structure, making use of our theorems that the dual complex to the canonical polyhedral complex is cubical and it possesses a multiplication compatible with its facet structure. The resulting algorithm is numerically stable, polynomial time in the number of intermediate neurons, and obtains accurate information across all dimensions. This permits us to obtain, for example, the true topology of the decision boundaries of networks with low-dime nsional inputs. We run empirics on such networks at initialization, finding that width alone does not increase observed topology, but width in the presence of depth does.

****

Are Neurons Actually Collapsed? On the Fine-Grained Structure in Neural Representations

Yongyi Yang,Jacob Steinhardt,Wei Hu

Recent work has observed an intriguing "Neural Collapse" phenomenon in well-trained neural networks, where the last-layer representations of training samples with the same label collapse into each other. This suggests that the last-layer representations are completely determined by the labels, and do not depend on the intrinsic structure of input distribution. We provide evidence that this is not a complete description, and that the apparent collapse hides important fine-grained structure in the representations. Specifically, even when representations apparently collapse, the small amount of remaining variation can still faithfully and accurately captures the intrinsic structure of input distribution. As an example, if we train on CIFAR-10 using only 5 coarse-grained labels (by combining two classes into one super-class) until convergence, we can reconstruct the original 10-class labels from the learned representations via unsupervised clustering. The reconstructed labels achieve 93% accuracy on the CIFAR-10 test set, nearly matching the normal CIFAR-10 accuracy for the same architecture. Our findings show concretely how the structure of input data can play a significant role in determining the fine-grained structure of neural representations, going beyond what Neural Collapse predicts.

****

FoSR: First-order spectral rewiring for addressing oversquashing in GNNs

Kedar Karhadkar,Pradeep Kr. Banerjee,Guido Montufar

Graph neural networks (GNNs) are able to leverage the structure of graph data by passing messages along the edges of the graph. While this allows GNNs to learn features depending on the graph structure, for certain graph topologies it leads to inefficient information propagation and a problem known as oversquashing. This has recently been linked with the curvature and spectral gap of the graph. On the other hand, adding edges to the message-passing graph can lead to increasingly similar node representations and a problem known as oversmoothing. We propose a computationally efficient algorithm that prevents oversquashing by systematically adding edges to the graph based on spectral expansion. We combine this with a relational architecture, which lets the GNN preserve the original graph structure and provably prevents oversmoothing. We find experimentally that our algorithm outperforms existing graph rewiring methods in several graph classification tasks.

Early Stopping for Deep Image Prior

Hengkang Wang,Taihui Li,Zhong Zhuang,Tiancong Chen,Hengyue Liang,Ju Sun

Deep image prior (DIP) and its variants have shown remarkable potential for solving inverse problems in computational imaging (CI), needing no separate training data. Practical DIP models are often substantially overparameterized. During the learning process, these models learn the desired visual content first and then pick up the potential modeling and observational noise, i.e., overfitting. Thus, the practicality of DIP hinges on early stopping (ES) that captures the transition period. In this regard, the majority of prior DIP works for CI tasks only demonstrate the potential of the models---reporting the peak performance against the groundtruth but providing no clue about how to operationally obtain near-peak performance without access to the groundtruth. In this paper, we set to break this practicality barrier of DIP, and propose an efficient ES strategy that consistently detects near-peak performance across several CI tasks and DIP variants. Simply based on the running variance of DIP intermediate reconstructions, our ES method not only outpaces the existing ones---which only work in very narrow regimes, but also remains effective when combined with methods that try to mitigate overfitting.

****

In-Context Policy Iteration

Ethan Brooks,Logan A Walls,Richard Lewis,Satinder Singh

This work presents In-Context Policy Iteration, an algorithm for performing Reinforcement Learning (RL), in-context, using foundation models. While the application of foundation models to RL has received considerable attention, most approaches rely on either (1) the curation of expert demonstrations (either through manual design or task-specific pretraining) or (2) adaptation to the task of interest using gradient methods (either fine-tuning or training of adapter layers). Both of these techniques have drawbacks. Collecting demonstrations is labor-intensive, and algorithms that rely on them do not outperform the experts from which the demonstrations were derived. All gradient techniques are inherently slow, sacrificing the “few-shot” quality that made in-context learning attractive to begin with. In this work, we present an algorithm, ICPI, that learns to perform RL tasks without expert demonstrations or gradients. Instead we present a policy-iteration method in which the prompt content is the entire locus of learning. ICPI iteratively updates the contents of the prompt from which it derives its policy through trial-and-error interaction with an RL environment. In order to eliminate the role of in-weights learning (on which approaches like Decision Transformer rely heavily), we demonstrate our algorithm using Codex Chen et al. (2021b), a language model with no prior knowledge of the domains on which we evaluate it.

Learning to Grow Pretrained Models for Efficient Transformer Training

Peihao Wang,Rameswar Panda,Lucas Torroba Hennigen,Philip Greengard,Leonid Karlinsky,Rogerio Feris,David Daniel Cox,Zhangyang Wang,Yoon Kim

Scaling transformers has led to significant breakthroughs in many domains, leading to a paradigm in which larger versions of existing models are trained and released on a periodic basis. New instances of such models are typically trained completely from scratch, despite the fact that they are often just scaled-up versions of their smaller counterparts. How can we use the implicit knowledge in the parameters of smaller, extant models to enable faster training of newer, larger models? This paper describes an approach for accelerating transformer training by learning to grow pretrained transformers, where we learn to linearly map the parameters of the smaller model to initialize the larger model. For tractable learning, we factorize the linear transformation as a composition of (linear) width- and depth-growth operators, and further employ a Kronecker factorization of these growth operators to encode architectural knowledge. Extensive experiments across both language and vision transformers demonstrate that our learned Linear Growth Operator (LiGO) can save up to 50% computational cost of training from scratch, while also consistently outperforming strong baselines that also reuse smaller pretrained models to initialize larger models.

****

Generative Modeling Helps Weak Supervision (and Vice Versa)

Benedikt Boecking,Nicholas Roberts,Willie Neiswanger,Stefano Ermon,Frederic Sala,Artur Dubrawski

Many promising applications of supervised machine learning face hurdles in the acquisition of labeled data in sufficient quantity and quality, creating an expensive bottleneck. To overcome such limitations, techniques that do not depend on ground truth labels have been studied, including weak supervision and generative modeling. While these techniques would seem to be usable in concert, improving one another, how to build an interface between them is not well-understood. In this work, we propose a model fusing programmatic weak supervision and generative adversarial networks and provide theoretical justification motivating this fusion. The proposed approach captures discrete latent variables in the data alongside the weak supervision derived label estimate. Alignment of the two allows for better modeling of sample-dependent accuracies of the weak supervision sources, improving the estimate of unobserved labels. It is the first approach to enable data augmentation through weakly supervised synthetic images and pseudolabels. Additionally, its learned latent variables can be inspected qualitatively. The model outperforms baseline weak supervision label models on a number of multiclass image classification datasets, improves the quality of generated images, and further improves end-model performance through data augmentation with synthetic samples.

What does a platypus look like? Generating customized prompts for zero-shot image classification

Sarah M Pratt,Rosanne Liu,Ali Farhadi

Open vocabulary models are a promising new paradigm for image classification. Unlike traditional classification models, open vocabulary models classify among any arbitrary set of categories specified with natural language during inference. This natural language, called "prompts", typically consists of a set of hand-written templates (e.g., "a photo of a {}”) which are completed with each of the category names. This work introduces a simple method to generate higher accuracy prompts, without relying on any explicit knowledge of the task domain and with far fewer hand-constructed sentences. To achieve this, we combine open vocabulary models with large language models (LLMs) to create Customized Prompts via Language models (CuPL, pronounced "couple"). In particular, we leverage the knowledge contained in LLMs in order to generate many descriptive sentences that are customized for each object category. We find that this straightforward and general approach improves accuracy on a range of zero-shot image classification benchmarks, including over one percentage point gain on ImageNet. Finally, this simple baseline requires no additional training and remains completely zero-shot.

Provable Memorization Capacity of Transformers

Junghwan Kim,Michelle Kim,Barzan Mozafari

Quantifying memorization capacity is essential for understanding the expressiveness and generalizability of deep learning model architectures. However, the memorization capacity of the Transformer architecture has yet to be explored. In this work, we present the first study of the memorization capacity of the Transformer architecture. We prove that Transformers are capable of memorizing N sequence-to-sequence mappings of length n with d-dimensional input tokens using $\tilde{O}(d + n + \sqrt{nN})$ parameters. Our theory supports memorization both with and without permutation equivariance, utilizing positional encodings in the latter case. Building on our theory, we also analyze the memorization capacity of Transformers in the sequence classification and language modeling tasks. To verify these theoretical findings, we conduct experiments analyzing the memorization capacity of Transformers in the natural language domain.

Knowledge-Driven New Drug Recommendation

Zhenbang Wu,Huaxiu Yao,Zhe Su,David M Liebovitz,Lucas M Glass,James Zou,Chelsea Finn,Jimeng Sun

Drug recommendation assists doctors in prescribing personalized medications to patients based on their health conditions. Existing drug recommendation solutions adopt the supervised multi-label classification setup and only work with existing drugs with sufficient prescription data from many patients. However, newly approved drugs do not have much historical prescription data and cannot leverage existing drug recommendation methods. To address this, we formulate the new drug recommendation as a few-shot learning problem. Yet, directly applying existing few-shot learning algorithms faces two challenges: (1) complex relations among diseases and drugs and (2) numerous false-negative patients who were eligible but did not yet use the new drugs. To tackle these challenges, we propose EDGE, which can quickly adapt to the recommendation for a new drug with limited prescription data from a few support patients. EDGE maintains a drug-dependent multi-phenotype few-shot learner to bridge the gap between existing and new drugs. Specifically, EDGE leverages the drug ontology to link new drugs to existing drugs with similar treatment effects and learns ontology-based drug representations. Such drug representations are used to customize the metric space of the phenotype-driven patient representations, which are composed of a set of phenotypes capturing complex patient health status. Lastly, EDGE eliminates the false-negative supervision signal using an external drug-disease knowledge base. We evaluate EDGE on two real-world datasets: the public EHR data (MIMIC-IV) and private industrial claims data. Results show that EDGE achieves 7.3% improvement on the ROC-AUC score over the best baseline.

Beyond Traditional Transfer Learning: Co-finetuning for Action Localisation

Anurag Arnab,Xuehan Xiong,Alexey A. Gritsenko,Rob Romijnders,Josip Djolonga,Mostafa Dehghani,Chen Sun,Mario Lucic,Cordelia Schmid

Transfer learning is the predominant paradigm for training deep networks on small target datasets. Models are typically pretrained on large “upstream” datasets for classification, as such labels are easy to collect, and then finetuned on downstream” tasks such as action localisation, which are smaller due to their finer-grained annotations.

In this paper, we question this approach, and propose co-finetuning -- simultaneously training a single model on multiple “upstream” and “downstream” tasks. We demonstrate that co-finetuning outperforms traditional transfer learning when using the same total amount of data, and also show how we can easily extend our approach to multiple “upstream” datasets to further improve performance. In particular, co-finetuning significantly improves the performance on rare classes in our downstream task, as it has a regularising effect, and enables the network to learn feature representations that transfer between different datasets. Finally, we observe how co-finetuning with public, video classification datasets, we are able to achieve state-of-the-art results for spatio-temporal action localisation on the challenging AVA and AVA-Kinetics datasets, outperforming recent works which develop intricate models.

Output Distribution over the Entire Input Space: A Novel Perspective to Understand Neural Networks

Weitang Liu,Yi-Zhuang You,Jingbo Shang

Understanding the input-output mapping relationship in the \emph{entire input space} contributes a novel perspective to a comprehensive understanding of deep neural networks. In this paper, we focus on binary neural classifiers and propose to first uncover the histogram about the number of inputs that are mapped to certain output values and then scrutinize the representative inputs from a certain output range of interest, such as the positive-logit region that corresponds to one of the classes. A straightforward solution is uniform sampling (or exhaustive enumeration) in the entire input space but when the inputs are high dimensional, it can take almost forever to converge. We connect the output histogram to the \emph{density of states} in physics by making an analogy between the energy of a system and the neural network output. Inspired by the Wang-Landau algorithm designed for sampling the density of states, we propose an efficient sampler that is driven to explore the under-explored output values through a gradient-based proposal. Compared with the random proposal in Wang-Landau algorithm, our gradient-based proposal converges faster as it can propose the inputs corresponding to the under-explored output values. Extensive experiments have verified the accuracy of the histogram generated by our sampler and also demonstrated interesting findings. For example, the models map many human unrecognizable images to very negative logit values. These properties of a neural model are revealed for the first time through our sampled statistics. We believe that our approach opens a new gate for neural model evaluation and shall be further explored in future works.

Learning Control Policies for Region Stabilization in Stochastic Systems

Matin Ansaripour,Mathias Lechner,■or■e Žikeli■,Krishnendu Chatterjee,Thomas A Henzinger

We consider the problem of learning control policies in stochastic systems which guarantee that the system stabilizes within some specified stabilization region with probability 1. Our approach is based on the novel notion of stabilizing ranking supermartingales (sRSMs) that we introduce in this work. Our sRSMs overcom

e the limitation of methods proposed in previous works whose applicability is restricted to systems in which the stabilizing region cannot be left once entered under any control policy. We present a learning procedure that learns a control policy together with an sRSM that formally certifies probability 1 stability, both learned as neural networks. Our experimental evaluation shows that our learning procedure can successfully learn provably stabilizing policies in practice.

InCoder: A Generative Model for Code Infilling and Synthesis
Daniel Fried,Armen Aghajanyan,Jessy Lin,Sida Wang,Eric Wallace,Freda Shi,Ruiqi Zhong,Scott Yih,Luke Zettlemoyer,Mike Lewis
Code is seldom written in a single left-to-right pass and is instead repeatedly edited and refined. We introduce InCoder, a unified generative model that can perform program synthesis (via left-to-right generation) as well as editing (via masking and infilling). InCoder is trained to generate code files from a large corpus of permissively licensed code, where regions of code have been randomly masked and moved to the end of each file, allowing code infilling with bidirectional context. Our model is the first large generative code model that is able to infill arbitrary regions of code, which we evaluate in a zero-shot setting on challenging tasks such as type inference, comment generation, and variable re-naming. We find that the ability to condition on bidirectional context substantially improves performance on these tasks, while still performing comparably on standard program synthesis benchmarks in comparison to left-to-right only models pretrained at similar scale. Our models and code will be publicly released.
****

Bridge the Inference Gaps of Neural Processes via Expectation Maximization
Qi Wang,Marco Federici,Herke van Hoof
The neural process (NP) is a family of computationally efficient models for learning distributions over functions. However, it suffers from under-fitting and shows suboptimal performance in practice. Researchers have primarily focused on incorporating diverse structural inductive biases, e.g. attention or convolution, in modeling. The topic of inference suboptimality and an analysis of the NP from the optimization objective perspective has hardly been studied in earlier work. To fix this issue, we propose a surrogate objective of the target log-likelihood of the meta dataset within the expectation maximization framework. The resulting model, referred to as the Self-normalized Importance weighted Neural Process (SI-NP), can learn a more accurate functional prior and has an improvement guarantee concerning the target log-likelihood. Experimental results show the competitive performance of SI-NP over other NPs objectives and illustrate that structural inductive biases, such as attention modules, can also augment our method to achieve SOTA performance.
****

Generated Graph Detection
Yihan Ma,Zhikun Zhang,Ning Yu,Xinlei He,Michael Backes,Yun Shen,Yang Zhang
Graph generative models become increasingly effective for data distribution approximation and data augmentation. Although still in sandboxes, they have aroused public concerns about their malicious misuses or misinformation broadcasts, just as what Deepfake visual and auditory media has been delivering to society. It is never too early to regulate the prevalence of generated graphs. As a preventive response, we pioneer to formulate the generated graph detection problem to distinguish generated graphs from real ones. We propose the first framework to systematically investigate a set of sophisticated models and their performance in four classification scenarios. Each scenario switches between seen and unseen datasets/generators during testing to get closer to real world settings and progressively challenge the classifiers. Extensive experiments evidence that all the models are qualified for generated graph detection, with specific models having advantages in specific scenarios. Resulting from the validated generality and oblivion of the classifiers to unseen datasets/generators, we draw a safe conclusion that our solution can sustain for a decent while to curb generated graph misuses.
****

Neural Embeddings for Text
Oleg Vasilyev,John Bohannon

We propose a new kind of embedding for natural language text that deeply represents semantic meaning. Standard text embeddings use the vector output of a pretrained language model. In our method, we let a language model learn from the text and then literally pick its brain, taking the actual weights of the model's neurons to generate a vector. We call this representation of the text a neural embedding. With analysis of its behavior on several datasets, we confirm the ability of this representation to reflect semantics of the text. We also compare neural embeddings with GPT sentence (SGPT) embeddings. We observe that neural embeddings achieve comparable performance with a far smaller model, and that the embeddings respond to semantics differently.

****

Find Your Friends: Personalized Federated Learning with the Right Collaborators
Yi Sui,Junfeng Wen,Yenson Lau,Brendan Leigh Ross,Jesse C Cresswell

In the traditional federated learning setting, a central server coordinates a network of clients to train one global model. However, the global model may serve many clients poorly due to data heterogeneity. Moreover, there may not exist a trusted central party that can coordinate the clients to ensure that each of them can benefit from others. To address these concerns, we present a novel decentralized framework, FedeRiCo, where each client can learn as much or as little from other clients as is optimal for its local data distribution. Based on expectation-maximization, FedeRiCo estimates the utilities of other participants’ models on each client’s data so that everyone can select the right collaborators for learning. As a result, our algorithm outperforms other federated, personalized, and/or decentralized approaches on several benchmark datasets, being the only approach that consistently performs better than training with local data only.

****

Masked Vision and Language Modeling for Multi-modal Representation Learning
Gukyeong Kwon,Zhaowei Cai,Avinash Ravichandran,Erhan Bas,Rahul Bhotika,Stefano Soatto

In this paper, we study how to use masked signal modeling in vision and language (V+L) representation learning. Instead of developing masked language modeling (MLM) and masked image modeling (MIM) independently, we propose to build joint masked vision and language modeling, where the masked signal of one modality is reconstructed with the help from another modality. This is motivated by the nature of image-text paired data that both of the image and the text convey almost the same information but in different formats. The masked signal reconstruction of one modality conditioned on another modality can also implicitly learn cross-modal alignment between language tokens and image patches. Our experiments on various V+L tasks show that the proposed method, along with common V+L alignment losses, not only achieves state-of-the-art performance by using a large amount of data but also outperforms the other competitors by a significant margin in the regimes of limited training data.

Quantum Fourier Networks for solving Parametric PDEs
Nishant Jain,Jonas Landman,Natansh Mathur,Iordanis Kerenidis

Many real-world problems like modelling environment dynamics, physical processes, time series etc., involve solving Partial Differential Equations (PDEs) parameterized by problem-specific conditions. Recently, a deep learning architecture called Fourier Neural Operator (FNO) proved to be capable of learning solutions of given PDE families, for any initial conditions as input. Given the advancements in quantum hardware and the recent results in quantum machine learning methods, we propose three quantum circuits, inspired by the FNO, to learn this functional mapping for PDEs. The proposed algorithms are distinguished based on the trade-off between depth and their similarity to the classical FNO. At their core, we make use of unary encoding paradigm and orthogonal quantum layers, and introduce a new quantum Fourier transform in the unary basis. With respect to the number of samples, our quantum algorithm is proven to be substantially faster than the classical counterpart. We benchmark our proposed algorithms on three PDE famili es, namely Burger’s equation, Darcy’s flow equation and the Navier-Stokes equation, and the results show that our quantum methods are comparable in performance to the classical FNO. We also show an analysis of the image classification tasks where our proposed algorithms are able to match the accuracy of the CNNs, thereby showing their applicability to other domains.

Agent-based Graph Neural Networks
Karolis Martinkus,Pál András Papp,Benedikt Schesch,Roger Wattenhofer

We present a novel graph neural network we call AgentNet, which is designed specifically for graph-level tasks. AgentNet is inspired by sublinear algorithms, featuring a computational complexity that is independent of the graph size. The architecture of AgentNet differs fundamentally from the architectures of traditional graph neural networks. In AgentNet, some trained \textit{neural agents} intelligently walk the graph, and then collectively decide on the output. We provide an extensive theoretical analysis of AgentNet: We show that the agents can learn to systematically explore their neighborhood and that AgentNet can distinguish some structures that are even indistinguishable by 2-WL. Moreover, AgentNet is able to separate any two graphs which are sufficiently different in terms of subgraphs. We confirm these theoretical results with synthetic experiments on hard-to-distinguish graphs and real-world graph classification tasks. In both cases, we compare favorably not only to standard GNNs but also to computationally more expensive GNN extensions.

Generating Adversarial Examples with Task Oriented Multi-Objective Optimization
Anh Tuan Bui,Trung Le,He Zhao,Quan Hung Tran,Paul Montague,Dinh Phung

Deep learning models, even the-state-of-the-art ones, are highly vulnerable to adversarial examples. Adversarial training is one of the most efficient methods to improve the model's robustness. The key factor for the success of adversarial training is the capability to generate qualified and divergent adversarial examples which satisfy some objectives/goals (e.g., finding adversarial examples that maximize the model losses for simultaneously attacking multiple models). Therefore, multi-objective optimization (MOO) is a natural tool for adversarial example generation, where we search adversarial examples simultaneously maximizing some objectives/goals. However, we observe that a naive application of MOO tends to maximize all objectives/goals equally, without caring if an objective/goal has been achieved yet. This leads to useless effort to further improve the goal-achieved tasks, while putting less focus on the goal-unachieved tasks. In this paper, we propose \emph{Task Oriented MOO} to address this issue, in the context where we can explicitly define the goal achievement for a task. Our principle is to only maintain the goal-achieved tasks, while letting the optimizer spend more effort on improving the goal-unachieved tasks. We conduct comprehensive experiments for our Task Oriented MOO on various adversarial example generation schemes. The experimental results firmly demonstrate the merit of our proposed approach.

On the Performance of Temporal Difference Learning With Neural Networks
HAOXING TIAN,Ioannis Paschalidis,Alex Olshevsky

Neural Temporal Difference (TD) Learning is an approximate temporal difference method for policy evaluation that uses a neural network for function approximation. Analysis of Neural TD Learning has proven to be challenging. In this paper we provide a convergence analysis of Neural TD Learning with a projection onto $B(\theta_0, \omega)$, a ball of fixed radius ω around the initial point θ_0. We show an approximation bound of $O(\epsilon + 1/\sqrt{m})$ where ϵ is the approximation quality of the best neural network in $B(\theta_0, \omega)$ and m is the width of all hidden layers in the network.

Certified Defences Against Adversarial Patch Attacks on Semantic Segmentation
Maksym Yatsura,Kaspar Sakmann,N. Grace Hua,Matthias Hein,Jan Hendrik Metzen

Adversarial patch attacks are an emerging security threat for real world deep learning applications. We present Demasked Smoothing, the first approach (up to our knowledge) to certify the robustness of semantic segmentation models against t his threat model. Previous work on certifiably defending against patch attacks has mostly focused on image classification task and often required changes in the model architecture and additional training which is undesirable and computationally expensive. In Demasked Smoothing, any segmentation model can be applied without particular training, fine-tuning, or restriction of the architecture. Using different masking strategies, Demasked Smoothing can be applied both for certified detection and certified recovery. In extensive experiments we show that Demasked Smoothing can on average certify 63% of the pixel predictions for a 1% patch in the detection task and 46% against a 0.5% patch for the recovery task on the ADE20K dataset.

Markup-to-Image Diffusion Models with Scheduled Sampling

Yuntian Deng,Noriyuki Kojima,Alexander M Rush

Building on recent advances in image generation, we present a fully data-driven approach to rendering markup into images. The approach is based on diffusion models, which parameterize the distribution of data using a sequence of denoising operations on top of a Gaussian noise distribution. We view the diffusion denoising process a sequential decision making process, and show that it exhibits compounding errors similar to exposure bias issues in imitation learning problems. To mitigate these issues, we adapt the scheduled sampling algorithm to diffusion training. We conduct experiments on four markup datasets: formulas (LaTeX), table layouts (HTML), sheet music (LilyPond), and molecular images (SMILES). These experiments each verify the effectiveness of diffusion and the use of scheduled sampling to fix generation issues. These results also show that the markup-to-image task presents a useful controlled compositional setting for diagnosing and analyzing generative image models.

Efficient Reward Poisoning Attacks on Online Deep Reinforcement Learning

Yinglun Xu,Qi Zeng,Gagandeep Singh

We study reward poisoning attacks on online deep reinforcement learning (DRL), where the attacker is oblivious to the learning algorithm used by the agent and does not necessarily have full knowledge of the environment. We demonstrate the intrinsic vulnerability of state-of-the-art DRL algorithms by designing a general, black-box reward poisoning framework called adversarial MDP attacks. We instantiate our framework to construct several new attacks which only corrupt the rewards for a small fraction of the total training timesteps and make the agent learn a low-performing policy. Our key insight is that state-of-the-art DRL algorithms strategically explore the environment to find a high-performing policy. Our attacks leverage this insight to construct a corrupted environment where (a) the agent learns a high-performing policy that has low performance in the original environment and (b) the corrupted environment is similar to the original one so that the attacker's budget is reduced. We provide a theoretical analysis of the efficiency of our attack and perform an extensive evaluation. Our results show that our attacks efficiently poison agents learning with a variety of state-of-the-art DRL algorithms, such as DQN, PPO, SAC, etc., under several popular classical control and MuJoCo environments.

How Much Space Has Been Explored? Measuring the Chemical Space Covered by Databases and Machine-Generated Molecules

Yutong Xie,Ziqiao Xu,Jiaqi Ma,Qiaozhu Mei

Forming a molecular candidate set that contains a wide range of potentially effective compounds is crucial to the success of drug discovery. While most databases and machine-learning-based generation models aim to optimize particular chemical properties, there is limited literature on how to properly measure the coverage of the chemical space by those candidates included or generated. This problem is challenging due to the lack of formal criteria to select good measures of the chemical space. In this paper, we propose a novel evaluation framework for measures of the chemical space based on two analyses: an axiomatic analysis with three intuitive axioms that a good measure should obey, and an empirical analysis on the correlation between a measure and a proxy gold standard. Using this frame work, we are able to identify #Circles, a new measure of chemical space coverage, which is superior to existing measures both analytically and empirically. We further evaluate how well the existing databases and generation models cover the chemical space in terms of #Circles. The results suggest that many generation models fail to explore a larger space over existing databases, which leads to new opportunities for improving generation models by encouraging exploration.

D-CIPHER: Discovery of Closed-form Partial Differential Equations
Krzysztof Kacprzyk,Zhaozhi Qian,Mihaela van der Schaar
Closed-form differential equations, including partial differential equations and higher-order ordinary differential equations, are one of the most important tools used by scientists to model and better understand natural phenomena. Discovering these equations directly from data is challenging because it requires modeling relationships between various derivatives that are not observed in the data (equation-data mismatch) and it involves searching across a huge space of possible equations. Current approaches make strong assumptions about the form of the equation and thus fail to discover many well-known systems. Moreover, many of them resolve the equation-data mismatch by estimating the derivatives, which makes them inadequate for noisy and infrequently sampled systems. To this end, we propose D-CIPHER, which is robust to measurement artifacts and can uncover a new and very general class of differential equations. We further design a novel optimization procedure, CoLLie, to help D-CIPHER search through this class efficiently. Finally, we demonstrate empirically that it can discover many well-known equations that are beyond the capabilities of current methods.

Towards Identification of Microaggressions in real-life and Scripted conversations, using Context-Aware Machine Learning Techniques.
Mikel K. Ngueajio,Ivan Hernandez,Kelsi Cornett,Gloria Washington,darryl parsons
The advent and rapid proliferation of social media have brought with it an exponential growth in hate speech and overt offensive language, with one of the most subtle yet pervasive subcategories of hate speech being Microaggressions (MA). MAs are unintentional, hostile, derogatory, or negative prejudicial slights and insults toward any group, particularly culturally marginalized communities and growing bodies of research are linking long-term MA exposure to serious health problems. The scarcity of studies leveraging AI techniques to identify MAs in text and in spoken conversations, coupled with the lack of investigative analysis on the impact of context on the performance of algorithms used for this task, makes this a relevant topic for the AI community. In this paper, we explore the degree of effectiveness of MAs detection often found in spoken human communications across various contexts (e.g., workplace, social media, conversations) using Machine Learning models. We further examine the extent that art may imitate life, by comparing the ability of these models trained on real-life conversations to infer MAs, occurring in scripted Television shows. We apply a Support Vector Machine (SVM) classifier using N-grams and contextual modeling representation, using the Robustly Optimized Bidirectional Encoder Representation for Transformer (RoBERTa) model, whose performance is evaluated based on its pretraining size and ability to accurately detect hate speeches, with comparative results from BERT based-uncased and the HateBERT model respectively.
Overall, the results show that contextual transformer models outperform simpler context-free approaches to classifying MAs collected from surveys and online blogs. We also found that these models trained on real-life conversations could infer MAs in scripted TV settings, though at reduced levels, and equal rates, suggesting there may be a disconnect between contexts of MA found in art and those from real life.

UNIFIED-IO: A Unified Model for Vision, Language, and Multi-modal Tasks
Jiasen Lu,Christopher Clark,Rowan Zellers,Roozbeh Mottaghi,Aniruddha Kembhavi
We propose Unified-IO, a model that performs a large variety of AI tasks spanning classical computer vision tasks, including pose estimation, object detection,

depth estimation and image generation, vision-and-language tasks such as region captioning and referring expression, to natural language processing tasks such as question answering and paraphrasing. Developing a single unified model for such a large variety of tasks poses unique challenges due to the heterogeneous inputs and outputs pertaining to each task, including RGB images, per-pixel maps, binary masks, bounding boxes, and language. We achieve this unification by homogenizing every supported input and output into a sequence of discrete vocabulary tokens. This common representation across all tasks allows us to train a single transformer-based architecture, jointly on over 90 diverse datasets in the vision and language fields. Unified-IO is the first model capable of performing all 7 tasks on the GRIT benchmark and produces strong results across 16 diverse benchmarks like NYUv2-Depth, ImageNet, VQA2.0, OK-VQA, Swig, VizWizGround, BoolQ, and SciTail, with no task-specific fine-tuning. Code and pre-trained models will be made publicly available.

Benchmarking Offline Reinforcement Learning on Real-Robot Hardware

Nico Gürtler,Sebastian Blaes,Pavel Kolev,Felix Widmaier,Manuel Wuthrich,Stefan Bauer,Bernhard Schölkopf,Georg Martius

Learning policies from previously recorded data is a promising direction for real-world robotics tasks, as online learning is often infeasible. Dexterous manipulation in particular remains an open problem in its general form. The combination of offline reinforcement learning with large diverse datasets, however, has the potential to lead to a breakthrough in this challenging domain analogously to the rapid progress made in supervised learning in recent years. To coordinate the efforts of the research community toward tackling this problem, we propose a benchmark including: i) a large collection of data for offline learning from a dexterous manipulation platform on two tasks, obtained with capable RL agents trained in simulation; ii) the option to execute learned policies on a real-world robotic system and a simulation for efficient debugging. We evaluate prominent open-sourced offline reinforcement learning algorithms on the datasets and provide a reproducible experimental setup for offline reinforcement learning on real systems.

****

CUDA: Curriculum of Data Augmentation for Long-tailed Recognition

Sumyeong Ahn,Jongwoo Ko,Se-Young Yun

Class imbalance problems frequently occur in real-world tasks, and conventional deep learning algorithms are well known for performance degradation on imbalanced training datasets. To mitigate this problem, many approaches have aimed to balance among given classes by re-weighting or re-sampling training samples. These re-balancing methods increase the impact of minority classes and reduce the influence of majority classes on the output of models. However, the extracted representations may be of poor quality owing to the limited number of minority samples. To handle this restriction, several methods have been developed that increase the representations of minority samples by leveraging the features of the majority samples. Despite extensive recent studies, no deep analysis has been conducted on determination of classes to be augmented and strength of augmentation has been conducted. In this study, we first investigate the correlation between the degree of augmentation and class-wise performance, and find that the proper degree of augmentation must be allocated for each class to mitigate class imbalance problems. Motivated by this finding, we propose a simple and efficient novel curriculum, which is designed to find the appropriate per-class strength of data augmentation, called CUDA: CUrriculum of Data Augmentation for long-tailed recognition. CUDA can simply be integrated into existing long-tailed recognition methods. We present the results of experiments showing that CUDA effectively achieves better generalization performance compared to the state-of-the-art method on various imbalanced datasets such as CIFAR-100-LT, ImageNet-LT, and iNaturalist 2018.

Understanding new tasks through the lens of training data via exponential tiltin g

Subha Maity,Mikhail Yurochkin,Moulinath Banerjee,Yuekai Sun

Deploying machine learning models on new tasks is a major challenge due to differences in distributions of the train (source) data and the new (target) data. However, the training data likely captures some of the properties of the new task. We consider the problem of reweighing the training samples to gain insights into the distribution of the target task. Specifically, we formulate a distribution shift model based on the exponential tilt assumption and learn train data importance weights minimizing the KL divergence between labeled train and unlabeled target datasets. The learned train data weights can then be used for downstream tasks such as target performance evaluation, fine-tuning, and model selection. We demonstrate the efficacy of our method on Waterbirds and Breeds benchmarks.

Neighborhood Gradient Clustering: An Efficient Decentralized Learning Method for Non-IID Data Distributions

Sai Aparna Aketi,Sangamesh Kodge,Kaushik Roy

Decentralized learning algorithms enable the training of deep learning models over large distributed datasets generated at different devices and locations, without the need for a central server. In practical scenarios, the distributed datasets can have significantly different data distributions across the agents. The current state-of-the-art decentralized algorithms mostly assume the data distributions to be Independent and Identically Distributed (IID). This paper focuses on improving decentralized learning over non-IID data distributions with minimal compute and memory overheads. We propose Neighborhood Gradient Clustering (NGC), a novel decentralized learning algorithm that modifies the local gradients of each agent using self- and cross-gradient information. Cross-gradients for a pair of neighboring agents are the derivatives of the model parameters of an agent with respect to the dataset of the other agent. In particular, the proposed method replaces the local gradients of the model with the weighted mean of the self-gradients, model-variant cross-gradients (derivatives of the received neighbors’ model parameters with respect to the local dataset - computed locally), and data-variant cross-gradients (derivatives of the local model with respect to its neighbors’ datasets - received through communication). The data-variant cross-gradients are aggregated through an additional communication round without breaking the privacy constraints of the decentralized setting. Further, we present CompNGC, a compressed version of NGC that reduces the communication overhead by $32 \times$ by compressing the cross-gradients. We demonstrate the empirical convergence and efficiency of the proposed technique over non-IID data distributions sampled from the CIFAR-10 dataset on various model architectures and graph topologies. Our experiments demonstrate that NGC and CompNGC outperform the existing state-of-the-art (SoTA) decentralized learning algorithm over non-IID data by $1-5\%$ with significantly less compute and memory requirements. Further, we also show that the proposed NGC method outperforms the baseline by $5-40\%$ with no additional communication.

****

Equilibrium-finding via exploitability descent with learned best-response functions

Carlos Martin,Tuomas Sandholm

There has been great progress on equilibrium-finding research over the last 20 years. Most of that work has focused on games with finite, discrete action spaces. However, many games involving space, time, money, etc. have continuous action spaces. We study the problem of computing approximate Nash equilibria of games with continuous strategy sets. The main measure of closeness to Nash equilibrium is exploitability, which measures how much players can benefit from unilaterally changing their strategy. We propose a new method that minimizes an approximation of exploitability with respect to the strategy profile. This approximation is computed using learned best-response functions, which take the current strategy profile as input and return learned best responses. The strategy profile and best-response functions are trained simultaneously, with the former trying to minimize exploitability while the latter try to maximize it. We evaluate our method on various continuous games, showing that it outperforms prior methods.

****

A Unified Framework for Comparing Learning Algorithms

Harshay Shah,Sung Min Park,Andrew Ilyas,Aleksander Madry

We propose a framework for {\em (learning) algorithm comparisons}, wherein the goal is to find similarities and differences between models trained with two different learning algorithms. We begin by formalizing the goal of algorithm comparison as finding {\em distinguishing feature transformations}, input transformations that change the predictions of models trained with one learning algorithm but not the other. We then present a two-stage method for algorithm comparisons based on comparing how models use the training data, leveraging the recently proposed datamodel representations [Ilyas et al., 2022]. We demonstrate our framework through three case studies that compare models trained with/without standard data augmentation, with/without pre-training, and with different optimizer hyperparameters.

Neural Network Approximations of PDEs Beyond Linearity: Representational Perspective

Tanya Marwah,Zachary Chase Lipton,Jianfeng Lu,Andrej Risteski

A burgeoning line of research has developed deep neural networks capable of approximating the solutions to high dimensional PDEs, opening related lines of theoretical inquiry focused on explaining how it is that these models appear to evade the curse of dimensionality. However, most theoretical analyses thus far have been limited to simple linear PDEs. In this work, we take a step towards studying the representational power of neural networks for approximating solutions to nonlinear PDEs. We focus on a class of PDEs known as nonlinear elliptic variational PDEs, whose solutions minimize an Euler-Lagrange energy functional $\mathcal{E}(u) = \int_\Omega L(\nabla u) dx$. We show that if composing a function with Barron norm b with L produces a function of Barron norm at most $B_L b^p$, the solution to the PDE can be ϵ-approximated in the L^2 sense by a function with Barron norm $O\left(\left(dB_L\right)^{p^{\log(1/\epsilon)}}\right)$. By a classical result due to \cite{barron1993universal}, this correspondingly bounds the size of a 2-layer neural network needed to approximate the solution. Treating p, ϵ, B_L as constants, this quantity is polynomial in dimension, thus showing neural networks can evade the curse of dimensionality. Our proof technique involves neurally simulating (preconditioned) gradient in an appropriate Hilbert space, which converges exponentially fast to the solution of the PDE, and such that we can bound the increase of the Barron norm at each iterate. Our results subsume and substantially generalize analogous prior results for linear elliptic PDEs.

Calibrating Sequence likelihood Improves Conditional Language Generation

Yao Zhao,Mikhail Khalman,Rishabh Joshi,Shashi Narayan,Mohammad Saleh,Peter J Liu

Conditional language models are predominantly trained with maximum likelihood estimation (MLE), giving probability mass to sparsely observed target sequences. While MLE trained models assign high probability to plausible sequences given the context, the model probabilities often do not accurately rank-order generated sequences by quality. This has been empirically observed in beam search decoding as output quality degrading with large beam sizes, and decoding strategies benefiting from heuristics such as length normalization and repetition-blocking. In this work, we introduce sequence likelihood calibration (SLiC) where the likelihood of model generated sequences are calibrated to better align with reference sequences in the model’s latent space. With SLiC, decoding heuristics become unnecessary and decoding candidates’ quality significantly improves regardless of the decoding method. Furthermore, SLiC shows no sign of diminishing returns with model scale, and presents alternative ways to improve quality with limited training and inference budgets. With SLiC, we exceed or match SOTA results on a wide range of generation tasks spanning abstractive summarization, question generation, abstractive question answering and data-to-text generation, even with modest-sized models.

Masked inverse folding with sequence transfer for protein representation learning

Kevin K Yang,Hugh Yeh,Niccolò Zanichelli

Self-supervised pretraining on protein sequences has led to state-of-the art performance on protein function and fitness prediction.
However, sequence-only methods ignore the rich information contained in experimental and predicted protein structures.
Meanwhile, inverse folding methods reconstruct a protein's amino-acid sequence given its structure, but do not take advantage of sequences that do not have known structures.
In this study, we train a masked inverse folding protein language model parameterized as a structured graph neural network.
We then show that using the outputs from a pretrained sequence-only protein masked language model as input to the inverse folding model further improves pretraining perplexity.
We evaluate both of these models on downstream protein engineering tasks and analyze the effect of using information from experimental or predicted structures on performance.

****

Convolutions are competitive with transformers for protein sequence pretraining

Kevin K Yang,Alex Xijie Lu,Nicolo Fusi

Pretrained protein sequence language models largely rely on the transformer architecture. However, transformer run-time and memory requirements scale quadratically with sequence length. We investigate the potential of a convolution-based architecture for protein sequence masked language model pretraining and subsequent finetuning. CNNs are competitive on the pretraining task with transformers across several orders of magnitude in parameter size while scaling linearly with sequence length. More importantly, CNNs are competitive with and occasionally superior to transformers across an extensive set of downstream evaluations, including structure prediction, zero-shot mutation effect prediction, and out-of-domain generalization. We also demonstrate strong performance on sequences longer than the positional embeddings allowed in the current state-of-the-art transformer protein masked language models. Finally, we close with a call to disentangle the effects of pretraining task and model architecture when studying pretrained protein sequence models.

****

Learning differentiable solvers for systems with hard constraints

Geoffrey Négiar,Michael W. Mahoney,Aditi Krishnapriyan

We introduce a practical method to enforce partial differential equation (PDE) constraints for functions defined by neural networks (NNs), up to a desired tolerance. By combining methods in differentiable optimization and applications of the implicit function theorem to NN models, we develop a differentiable PDE-constrained layer that can be incorporated into a NN. Inspired by dictionary learning, our model learns a family of functions, each of which defines a mapping from PDE parameters to PDE solutions. At inference time, the model finds an optimal linear combination of the functions in the learned family by solving a PDE-constrained optimization problem. Our method provides continuous solutions over the domain of interest that accurately satisfy desired physical constraints. Our results show that incorporating hard constraints directly into the NN architecture achieves much lower test error when compared to training on an unconstrained objective.

FedDAR: Federated Domain-Aware Representation Learning

Aoxiao Zhong,Hao He,Zhaolin Ren,Na Li,Quanzheng Li

Cross-silo Federated learning (FL) has become a promising tool in machine learning applications for healthcare. It allows hospitals/institutions to train models with sufficient data while the data is kept private. To make sure the FL model is robust when facing heterogeneous data among FL clients, most efforts focus on personalizing models for clients. However, the latent relationships between cli ents' data are ignored. In this work, we focus on a special non-iid FL problem, called Domain-mixed FL, where each client's data distribution is assumed to be a mixture of several predefined domains. Recognizing the diversity of domains and the similarity within domains, we propose a novel method, FedDAR, which learns a domain shared representation and domain-wise personalized prediction heads in a decoupled manner. For simplified linear regression settings, we have theoretically proved that FedDAR enjoys a linear convergence rate. For general settings, we have performed intensive empirical studies on both synthetic and real-world medical datasets which demonstrate its superiority over prior FL methods. Our code is available at https://github.com/zlz0414/FedDAR.

Learning to Estimate Shapley Values with Vision Transformers

Ian Connick Covert,Chanwoo Kim,Su-In Lee

Transformers have become a default architecture in computer vision, but understanding what drives their predictions remains a challenging problem. Current explanation approaches rely on attention values or input gradients, but these provide a limited view of a model’s dependencies. Shapley values offer a theoretically sound alternative, but their computational cost makes them impractical for large, high-dimensional models. In this work, we aim to make Shapley values practical for vision transformers (ViTs). To do so, we first leverage an attention masking approach to evaluate ViTs with partial information, and we then develop a procedure to generate Shapley value explanations via a separate, learned explainer model. Our experiments compare Shapley values to many baseline methods (e.g., attention rollout, GradCAM, LRP), and we find that our approach provides more accurate explanations than existing methods for ViTs.

****

No Double Descent in PCA: Training and Pre-Training in High Dimensions

Daniel Gedon,Antonio H. Ribeiro,Thomas B. Schön

With the recent body of work on overparameterized models the gap between theory and practice in contemporary machine learning is shrinking. While many of the present state-of-the-art models have an encoder-decoder architecture, there is little theoretical work for this model structure. To improve our understanding in this direction, we consider linear encoder-decoder models, specifically PCA with linear regression on data from a low-dimensional manifold. We present an analysis for fundamental guarantees of the risk and asymptotic results for isotropic data when the model is trained in a supervised manner. The results are also verified in simulations. Furthermore, we extend our analysis to the popular setting where parts of the model are pre-trained in an unsupervised manner by pre-training the PCA encoder with subsequent supervised training of the linear regression. We show that the overall risk depends on the estimates of the eigenvectors in the encoder and present a sample complexity requirement through a concentration bound. The results highlight that using more pre-training data decreases the overall risk only if it improves the eigenvector estimates. Therefore, we stress that the eigenvalue distribution determines whether more pre-training data is useful or not.

Predicting Drug Repurposing Candidates and Their Mechanisms from A Biomedical Knowledge Graph

Chunyu Ma,Zhihan Zhou,Han Liu,David Koslicki

Computational drug repurposing is a cost- and time-efficient method to identify new indications of approved or experimental drugs/compounds. It is especially critical for emerging and/or orphan diseases due to its cheaper investment and shorter research cycle compared with traditional wet-lab drug discovery approaches. However, the underlying mechanisms of action between repurposed drugs and their target diseases remain largely unknown, which is still an unsolved issue in existing repurposing methods. As such, computational drug repurposing has not been widely adopted in clinical settings. In this work, based on a massive biomedical knowledge graph, we propose a computational drug repurposing framework that not only predicts the treatment probabilities between drugs and diseases but also predicts the path-based, testable mechanisms of action (MOAs) as their biomedical

explanations. Specifically, we utilize the GraphSAGE model in an unsupervised manner to integrate each entity’s neighborhood information and employ a Random Forest model to predict the treatment probabilities between pairs of drugs and diseases. Moreover, we train an adversarial actor-critic reinforcement learning model to predict the potential MOA for explaining drug purposing. To encourage the model to find biologically reasonable paths, we utilize the curated molecular interactions of drugs and a PubMed-publication-based concept distance to extract potential drug MOA paths from the knowledge graph as ”demonstration paths” to guide the model during the process of path-finding. Comprehensive experiments and case studies show that the proposed framework outperforms state-of-the-art baselines in both predictive performance of drug repurposing and explanatory performance of recapitulating human-curated DrugMechDB-based paths.
****

Interval Bound Interpolation for Few-shot Learning with Few Tasks

Shounak Datta,Sankha Subhra Mullick,Anish Chakrabarty,Swagatam Das

Few-shot learning aims to transfer the knowledge acquired from training on a diverse set of tasks to unseen tasks from the same task distribution, with a limited amount of labeled data. The underlying requirement for effective few-shot generalization is to learn a good representation of the task manifold. This becomes more difficult when only a limited number of tasks are available for training. In such a few-task few-shot setting, it is beneficial to explicitly preserve the local neighborhoods from the task manifold and exploit this to generate artificial tasks for training. To this end, we introduce the notion of interval bounds from the provably robust training literature to few-shot learning. The interval bounds are used to characterize neighborhoods around the training tasks. These neighborhoods can then be preserved by minimizing the distance between a task and its respective bounds. We then use a novel strategy to artificially form new tasks for training by interpolating between the available tasks and their respective interval bounds. We apply our framework to both model-agnostic meta-learning as well as prototype-based metric-learning paradigms. The efficacy of our proposed approach is evident from the improved performance on several datasets from diverse domains in comparison to recent methods.
****

A framework for benchmarking Class-out-of-distribution detection and its application to ImageNet

Ido Galil,Mohammed Dabbah,Ran El-Yaniv

When deployed for risk-sensitive tasks, deep neural networks must be able to detect instances with labels from outside the distribution for which they were trained.

In this paper we present a novel framework to benchmark the ability of image classifiers to detect class-out-of-distribution instances

(i.e., instances whose true labels do not appear in the training distribution) at various levels of detection difficulty.

We apply this technique to ImageNet, and benchmark 525 pretrained, publicly available, ImageNet-1k classifiers.

The code for generating a benchmark for any ImageNet-1k classifier, along with the benchmarks prepared for the above-mentioned 525 models is available at https://github.com/mdabbah/COOD_benchmarking.

The usefulness of the proposed framework and its advantage over alternative existing benchmarks is demonstrated by analyzing the results obtained for these models, which reveals numerous novel observations including:

(1) knowledge distillation consistently improves class-out-of-distribution (C-OOD) detection performance; (2) a subset of ViTs performs better C-OOD detection than any other model; (3) the language–-vision CLIP model achieves good zero-shot detection performance, with its best instance outperforming 96% of all other models evaluated; (4) accuracy and in-distribution ranking are positively correlated to C-OOD detection; and

(5) we compare various confidence functions for C-OOD detection.

Our companion paper, also published in ICLR 2023 (What Can We Learn From The Sel ective Prediction And Uncertainty Estimation Performance Of 523 Imagenet Classifiers), examines the uncertainty estimation performance (ranking, calibration, and selective prediction performance) of these classifiers in an in-distribution setting.

Data Poisoning Attacks Against Multimodal Encoders

Ziqing Yang,Xinlei He,Zheng Li,Michael Backes,Mathias Humbert,Pascal Berrang,Yang Zhang

Traditional machine learning (ML) models, e.g., image classifiers, usually rely on large-scale labeled datasets to achieve strong performance. However, such labeled datasets are often challenging and expensive to obtain. Also, the predefined categories limit the model's ability to generalize to other visual concepts as additional labeled data is required. On the contrary, the newly emerged multimodal model, which contains both visual and linguistic modalities, learns the concept of images from the raw text. It is a promising way to solve the above problems as it can use easy-to-collect image-text pairs to construct the training dataset and the raw texts contain almost unlimited categories according to their semantics. However, learning from a large-scale unlabeled dataset also exposes the model to the risk of potential poisoning attacks, whereby the adversary aims to perturb the model's training dataset to trigger malicious behaviors in it. Previous work mainly focuses on the visual modality. In this paper, we instead focus on answering two questions: (1) Is the linguistic modality also vulnerable to poisoning attacks? and (2) Which modality is most vulnerable? To answer the two questions, we conduct three types of poisoning attacks against CLIP, the most representative multimodal contrastive learning framework. Extensive evaluations on different datasets and model architectures show that all three attacks can perform well on the linguistic modality with only a relatively low poisoning rate and limited epochs. Also, we observe that the poisoning effect differs between different modalities, i.e., with lower MinRank in the visual modality and with higher Hit@K when K is small in the linguistic modality. To mitigate the attacks, we propose both pre-training and post-training defenses. We empirically show that both defenses can significantly reduce the attack performance while preserving the model's utility.

SlotFormer: Unsupervised Visual Dynamics Simulation with Object-Centric Models

Ziyi Wu,Nikita Dvornik,Klaus Greff,Thomas Kipf,Animesh Garg

Understanding dynamics from visual observations is a challenging problem that requires disentangling individual objects from the scene and learning their interactions. While recent object-centric models can successfully decompose a scene into objects, modeling their dynamics effectively still remains a challenge. We address this problem by introducing SlotFormer -- a Transformer-based autoregressive model operating on learned object-centric representations. Given a video clip, our approach reasons over object features to model spatio-temporal relationships and predicts accurate future object states. In this paper, we successfully apply SlotFormer to perform video prediction on datasets with complex object interactions. Moreover, the unsupervised SlotFormer's dynamics model can be used to improve the performance on supervised downstream tasks, such as Visual Question Answering (VQA), and goal-conditioned planning. Compared to past works on dynamics modeling, our method achieves significantly better long-term synthesis of object dynamics, while retaining high quality visual generation. Besides, SlotFormer enables VQA models to reason about the future without object-level labels, even outperforming counterparts that use ground-truth annotations. Finally, we show its ability to serve as a world model for model-based planning, which is competitive with methods designed specifically for such tasks.

Simplifying Model-based RL: Learning Representations, Latent-space Models, and Policies with One Objective

Raj Ghugare,Homanga Bharadhwaj,Benjamin Eysenbach,Sergey Levine,Russ Salakhutdinov

While reinforcement learning (RL) methods that learn an internal model of the en vironment have the potential to be more sample efficient than their model-free counterparts, learning to model raw observations from high dimensional sensors can be challenging.

Prior work has addressed this challenge by learning low-dimensional representation of observations through auxiliary objectives, such as reconstruction or value prediction. However, the alignment between these auxiliary objectives and the RL objective is often unclear.

In this work, we propose a single objective which jointly optimizes a latent-space model and policy to achieve high returns while remaining self-consistent. This objective is a lower bound on expected returns. Unlike prior bounds for model-based RL on policy exploration or model guarantees, our bound is directly on the overall RL objective. We demonstrate that the resulting algorithm matches or improves the sample-efficiency of the best prior model-based and model-free RL methods. While sample efficient methods typically are computationally demanding, our method attains the performance of SAC in about 50\% less wall-clock time.

****

Tessellated Neural Networks: A Robust Defence against Adversarial Attacks

Chinmay Jain,Pabitra Mitra,Debasis Ganguly

Data-driven deep learning approaches for image classification are prone to adversarial attacks. An adversarial image which is sufficiently close (visually indistinguishable) from a true image of its representative class can often be misclassified to be a member of a different class. It is possible for attackers to exploit the high dimensionality of image representations, as learned by the neural models, to identify adversarial perturbations. To mitigate this problem, we propose a novel divide-and-conquer based approach of tessellating a base network architecture (e.g., a ResNet used in our experiments). The tessellated network learns the parameterized representations of each non-overlapping sub-region or tiles within an image, independently, and then learns how to combine these representations to finally estimate the class of the input image. We investigate two different modes of tessellation, namely periodic, comprised of regular square-shaped tiles, and aperiodic, comprised of rectangles of different dimensions. Experiments demonstrate that the tessellated extension of two standard deep neural models leads to a better defence against a number of standard adversarial attacks. We observed that the decrease in post-attack accuracy values relative to the accuracy of the uncompromised networks is smaller for our proposed tessellated approach.

Retrieval-based Controllable Molecule Generation

Zichao Wang,Weili Nie,Zhuoran Qiao,Chaowei Xiao,Richard Baraniuk,Anima Anandkumar

Generating new molecules with specified chemical and biological properties via generative models has emerged as a promising direction for drug discovery. However, existing methods require extensive training/fine-tuning with a large dataset, often unavailable in real-world generation tasks. In this work, we propose a new retrieval-based framework for controllable molecule generation. We use a small set of exemplar molecules, i.e., those that (partially) satisfy the design criteria, to steer the pre-trained generative model towards synthesizing molecules that satisfy the given design criteria. We design a retrieval mechanism that retrieves and fuses the exemplar molecules with the input molecule, which is trained by a new self-supervised objective that predicts the nearest neighbor of the input molecule. We also propose an iterative refinement process to dynamically update the generated molecules and retrieval database for better generalization. Our approach is agnostic to the choice of generative models and requires no task-specific fine-tuning. On various tasks ranging from simple design criteria to a challenging real-world scenario for designing lead compounds that bind to the SARS-CoV-2 main protease, we demonstrate our approach extrapolates well beyond the retrieval database, and achieves better performance and wider applicability than previous methods.

ELRT: Towards Efficient Low-Rank Training for Compact Neural Networks

Yang Sui,Miao Yin,Wanzhao Yang,Yu Gong,Jinqi Xiao,Huy Phan,Ding Ding,Xiaozhong Xu,Shan Liu,Zhenzhong Chen,Bo Yuan

Low-rank compression, a popular model compression technique that produces compact convolutional neural networks (CNNs) with low rankness, has been well studied in the literature. On the other hand, low-rank training, as an alternative way to train low-rank CNNs from scratch, is little exploited yet. Unlike low-rank compression, low-rank training does not need pre-trained full-rank models and the entire training phase is always performed on the low-rank structure, bringing attractive benefits for practical applications. However, the existing low-rank training solutions are still very limited and do not demonstrate their effectiveness for training modern low-rank CNN models in the large-scale dataset from scratch. In this paper, we perform a systematic investigation on low-rank CNN training. By identifying the proper low-rank format and performance-improving strategy, we propose ELRT, an efficient low-rank training solution for high-accuracy high-compactness low-rank CNN models. Our extensive evaluation results for training various CNNs on different datasets demonstrate the effectiveness of ELRT.

InfoOT: Information Maximizing Optimal Transport

Ching-Yao Chuang,Stefanie Jegelka,David Alvarez-Melis

Optimal transport aligns samples across distributions by minimizing the transportation cost between them, e.g., the geometric distances. Yet, it ignores coherence structure in the data such as clusters, does not handle outliers well, and cannot integrate new data points. To address these drawbacks, we propose InfoOT, an information-theoretic extension of optimal transport that maximizes the mutual information between domains while minimizing geometric distances. The resulting objective can still be formulated as a (generalized) optimal transport problem, and can be efficiently solved by projected gradient descent. This formulation yields a new projection method that is robust to outliers and generalizes to unseen samples. Empirically, InfoOT improves the quality of alignments across benchmarks in domain adaptation, cross-domain retrieval, and single-cell alignment.

Posterior Sampling Model-based Policy Optimization under Approximate Inference

Chaoqi Wang,Yuxin Chen,Kevin Patrick Murphy

Model-based reinforcement learning algorithms (MBRL) hold tremendous promise for improving the sample efficiency in online RL. However, many existing popular MBRL algorithms cannot deal with exploration and exploitation properly. Posterior sampling reinforcement learning (PSRL) serves as a promising approach for automatically trading off the exploration and exploitation, but the theoretical guarantees only hold under exact inference. In this paper, we show that adopting the same methodology as in exact PSRL can be fairly suboptimal under approximate inference. Motivated by the analysis, we propose an improved factorization for the posterior distribution of polices by removing the conditional independence between the policy and data given the model. By adopting such a posterior factorization, we further propose a general algorithmic framework for PSRL under approximate inference and a practical instantiation of it. Empirically, our algorithm can surpass the baseline methods by a significant margin on both dense rewards and sparse rewards tasks from DM control suite, OpenAI Gym and Metaworld benchmarks.

Causal discovery from conditionally stationary time series

Carles Balsells Rodas,Ruibo Tu,Hedvig Kjellstrom,Yingzhen Li

Causal discovery, i.e., inferring underlying causal relationships from observational data, has been shown to be highly challenging for AI systems. In time series modeling context, traditional causal discovery methods mainly consider constrained scenarios with fully observed variables and/or data from stationary time-series. We develop a causal discovery approach to handle a wide class of non-stationary time-series that are conditionally stationary, where the non-stationary behaviour is modeled as stationarity conditioned on a set of (possibly hidden) state variables. Named state-dependent causal inference (SDCI), our approach is able to recover the underlying causal dependencies, provably with fully-observed st ates and empirically with hidden states. The latter is confirmed by experiments on synthetic linear system and nonlinear particle interaction data, where SDCI achieves superior performance over baseline causal discovery methods. Improved results over non-causal RNNs on modeling NBA player movements demonstrate the potential of our method and motivate the use causality-driven methods for forecasting.

Learning for Edge-Weighted Online Bipartite Matching with Robustness Guarantees

Pengfei Li,Jianyi Yang,Shaolei Ren

Many real-world problems, such as online ad display, can be formulated as online bipartite matching. The crucial challenge lies in the nature of sequentially-revealed online item information, based on which we make irreversible matching decisions at each step. While numerous expert online algorithms have been proposed with bounded worst-case competitive ratios, they may not offer satisfactory performance in average cases. On the other hand, reinforcement learning (RL) has been applied to improve the average performance, but they lack robustness and can perform arbitrarily badly. In this paper, we propose a novel RL-based approach to edge-weighted online bipartite matching with robustness guarantees (LOMAR), achieving both good average-case and good worst-case performance. The key novelty of LOMAR is a new online switching operation which, based on a judiciously-designed condition to hedge against future uncertainties, decides whether to follow the expert's decision or the RL decision for each online item arrival. We prove that for any $\rho \in [0,1]$, LOMAR is ρ-competitive against any given expert online algorithm. To improve the average performance, we train the RL policy by explicitly considering the online switching operation. Finally, we run empirical experiments to demonstrate the advantages of LOMAR compared to existing baselines.

Tangential Wasserstein Projections

Florian Gunsilius,Meng Hsuan Hsieh,Myung Jin Lee

We develop a notion of projections between sets of probability measures using the geometric properties of the 2-Wasserstein space. It is designed for general multivariate probability measures, is computationally efficient to implement, and provides a unique solution in regular settings. The idea is to work on regular tangent cones of the Wasserstein space using generalized geodesics. Its structure and computational properties make the method applicable in a variety of settings, from causal inference to the analysis of object data. An application to estimating causal effects yields a generalization of the notion of synthetic controls for systems with general heterogeneity described via multivariate probability measures, as well as a way to estimate optimal weights jointly over all time periods.

****

Data Drift Correction via Time-varying Importance Weight Estimator

Rasool Fakoor,Jonas Mueller,Zachary Chase Lipton,Pratik Chaudhari,Alex Smola

Real-world deployment of machine learning models is challenging when data evolves over time. And data does evolve over time. While no model can work when data evolves in an arbitrary fashion, if there is some pattern to these changes, we might be able to design methods to address it. This paper addresses situations when data evolves gradually. We introduce a novel time-varying importance weight estimator that can detect gradual shifts in the distribution of data. Such an importance weight estimator allows the training method to selectively sample past data---not just similar data from the past like a standard importance weight estimator would but also data that evolved in a similar fashion in the past. Our time-varying importance weight is quite general. We demonstrate different ways of implementing it that exploit some known structure in the evolution of data. We demonstrate and evaluate this approach on a variety of problems ranging from supervised learning tasks (multiple image classification datasets) where the data undergoes a sequence of gradual shifts of our design to reinforcement learning tasks (robotic manipulation and continuous control) where data undergoes a shift organically as the policy or the task changes.

Analytical Composition of Differential Privacy via the Edgeworth Accountant
Hua Wang,Sheng Gao,Huanyu Zhang,Milan Shen,Weijie J Su

Many modern machine learning algorithms are composed of simple private algorithms; thus, an increasingly important problem is to efficiently compute the overall privacy loss under composition. In this study, we introduce the Edgeworth Accountant, an analytical approach to composing differential privacy guarantees of private algorithms. The Edgeworth Accountant starts by losslessly tracking the privacy loss under composition using the f-differential privacy framework, which allows us to express the privacy guarantees using privacy-loss log-likelihood ratios (PLLRs). As the name suggests, this accountant next uses the Edgeworth expansion to the upper and lower bounds the probability distribution of the sum of the PLLRs. Moreover, by relying on a technique for approximating complex distributions using simple ones, we demonstrate that the Edgeworth Accountant can be applied to the composition of any noise-addition mechanism. Owing to certain appealing features of the Edgeworth expansion, the (ϵ, δ)-differential privacy bounds offered by this accountant are non-asymptotic, with essentially no extra computational cost, as opposed to the prior approaches, wherein the running times increase with the number of compositions. Finally, we demonstrate that our upper and lower (ϵ, δ)-differential privacy bounds are tight in federated analytics and certain regimes of training private deep learning models.

Policy-Induced Self-Supervision Improves Representation Finetuning in Visual RL
Séb Arnold,Fei Sha

We study how to transfer representations pretrained on source tasks to target tasks in visual percept based RL. We analyze two popular approaches: freezing or finetuning the pretrained representations. Empirical studies on a set of popular tasks reveal several properties of pretrained representations. First, finetuning is required even when pretrained representations perfectly capture the information required to solve the target task. Second, finetuned representations improve learnability and are more robust to noise.

Third, pretrained bottom layers are task-agnostic and readily transferable to new tasks, while top layers encode task-specific information and require adaptation. Building on these insights, we propose a self-supervised objective that \emph{clusters representations according to the policy they induce}, as opposed to traditional representation similarity measures which are policy-agnostic (\eg Euclidean norm, cosine similarity). Together with freezing the bottom layers, this objective results in significantly better representation than frozen, finetuned, and self-supervised alternatives on a wide range of benchmarks.

Deep Generative Symbolic Regression
Samuel Holt,Zhaozhi Qian,Mihaela van der Schaar

Symbolic regression (SR) aims to discover concise closed-form mathematical equations from data, a task fundamental to scientific discovery. However, the problem is highly challenging because closed-form equations lie in a complex combinatorial search space. Existing methods, ranging from heuristic search to reinforcement learning, fail to scale with the number of input variables. We make the observation that closed-form equations often have structural characteristics and invariances (e.g. the commutative law) that could be further exploited to build more effective symbolic regression solutions. Motivated by this observation, our key contribution is to leverage pre-trained deep generative models to capture the intrinsic regularities of equations, thereby providing a solid foundation for subsequent optimization steps. We show that our novel formalism unifies several prominent approaches of symbolic regression and offers a new perspective to justify and improve on the previous ad hoc designs, such as the usage of cross-entropy loss during pre-training. Specifically, we propose an instantiation of our framework, Deep Generative Symbolic Regression (DGSR). In our experiments, we show that DGSR achieves a higher recovery rate of true equations in the setting of a larger number of input variables, and it is more computationally efficient at infe

rence time than state-of-the-art RL symbolic regression solutions.

What Can we Learn From The Selective Prediction And Uncertainty Estimation Performance Of 523 Imagenet Classifiers?
Ido Galil,Mohammed Dabbah,Ran El-Yaniv
When deployed for risk-sensitive tasks, deep neural networks must include an uncertainty estimation mechanism.
Here we examine the relationship between deep architectures and their respective training regimes, with their corresponding selective prediction and uncertainty estimation performance. We consider some of the most popular estimation performance metrics previously proposed including AUROC, ECE, AURC as well as coverage for selective accuracy constraint.
We present a novel and comprehensive study of selective prediction and the uncertainty estimation performance of 523 existing pretrained deep ImageNet classifiers that are available in popular repositories.
We identify numerous and previously unknown factors that affect uncertainty estimation and examine the relationships between the different metrics. We find that distillation-based training regimes consistently yield better uncertainty estimations than other training schemes such as vanilla training, pretraining on a larger dataset and adversarial training.
Moreover, we find a subset of ViT models that outperform any other models in terms of uncertainty estimation performance.
For example, we discovered an unprecedented 99% top-1 selective accuracy on ImageNet at 47% coverage
(and 95% top-1 accuracy at 80%) for a ViT model, whereas a competing EfficientNet-V2-XL cannot obtain these accuracy constraints at any level of coverage.
Our companion paper, also published in ICLR 2023 (A framework for benchmarking class-out-of-distribution detection and its application to ImageNet), examines the performance of these classifiers in a class-out-of-distribution setting.

Solving and Learning non-Markovian Stochastic Control problems in continuous-time with Neural RDEs
Melker Höglund,Emilio Ferrucci,Camilo Hernández,Aitor Muguruza Gonzalez,Cristopher Salvi,Leandro Sánchez-Betancourt,Yufei Zhang
We propose a novel framework for solving continuous-time, non-Markovian stochastic control problems with the use of neural rough differential equations (Neural RDEs). By parameterising the control process as the solution of a Neural RDE driven by the state process, we show that the control-state joint dynamics are governed by an uncontrolled RDE with structured vector fields, allowing for efficient trajectories simulation, Monte-Carlo estimation of the value function and backpropagation. To deal with input paths of infinite 1-variation, we refine the existing universal approximation result to a probabilistic density result for Neural RDEs driven by random rough paths. Experiments on various non-Markovian problems indicate how the proposed framework is time-resolution-invariant and capable of learning optimal solutions with higher accuracy than traditional RNN-based approaches. Finally, we discuss possible extensions of this framework to the setting of non-Markovian continuous-time reinforcement learning and provide promising empirical evidence in this direction.

Spatio-temporal Self-Attention for Egocentric 3D Pose Estimation
Jinman Park,Kimathi Kaai,Saad Hossain,Norikatsu Sumi,Sirisha Rambhatla,Paul W. Fieguth
Vision-based ego-centric 3D human pose estimation (ego-HPE) is essential to support critical applications of xR-technologies. However, severe self-occlusions and strong distortion introduced by the fish-eye view from the head mounted camera, make ego-HPE extremely challenging. While current state-of-the-art (SOTA) methods try to address the distortion, they still suffer from large errors in the most critical joints (such as hands) due to self-occlusions. To this end, we propose a spatio-temporal transformer model that can attend to semantically rich feature maps obtained from popular convolutional backbones. Leveraging the complex s

patio-temporal information encoded in ego-centric videos, we design a spatial concept called feature map tokens (FMT) which can attend to all the other spatial units in our spatio-temporal feature maps. Powered by this FMT-based transformer, we build Egocentric Spatio-Temporal Self-Attention Network (Ego-STAN), which uses heatmap-based representations and spatio-temporal attention specialized to address distortions and self-occlusions in ego-HPE.

Our quantitative evaluation on the contemporary sequential xR-EgoPose dataset, achieves a 38.2% improvement on the highest error joints against the SOTA ego-HPE model, while accomplishing a 22% decrease in the number of parameters. Finally, we also demonstrate the generalization capabilities of our model to real-world HPE tasks beyond ego-views.

RNAS-CL: Robust Neural Architecture Search by Cross-Layer Knowledge Distillation

Utkarsh Nath,Yancheng Wang,Yingzhen Yang

Deep Neural Networks are vulnerable to adversarial attacks. Neural Architecture Search (NAS), one of the driving tools of deep neural networks, demonstrates superior performance in prediction accuracy in various machine learning applications. However, it is unclear how it performs against adversarial attacks. Given the presence of a robust teacher, it would be interesting to investigate if NAS would produce robust neural architecture by inheriting robustness from the teacher. In this paper, we propose Robust Neural Architecture Search by Cross-Layer Knowledge Distillation (RNAS-CL), a novel NAS algorithm that improves the robustness of NAS by learning from a robust teacher through cross-layer knowledge distillation. Unlike previous knowledge distillation methods that encourage close student/teacher output only in the last layer, RNAS-CL automatically searches for the best teacher layer to supervise each student layer. Experimental result evidences the effectiveness of RNAS-CL and shows that RNAS-CL produces small and robust neural architecture.

Multi-Agent Policy Transfer via Task Relationship Modeling

Rong-Jun Qin,Feng Chen,Tonghan Wang,Lei Yuan,Xiaoran Wu,Yipeng Kang,Zongzhang Zhang,Chongjie Zhang,Yang Yu

Team adaptation to new cooperative tasks is a hallmark of human intelligence, which has yet to be fully realized in learning agents. Previous works on multi-agent transfer learning accommodate teams of different sizes, but heavily rely on the generalization ability of neural networks for adapting to unseen tasks. We posit that the relationship among tasks provides the key information for policy adaptation. To utilize such relationship for efficient transfer, we try to discover and exploit the knowledge among tasks from different teams, propose to learn effect-based task representations as a common latent space among tasks, and use it to build an alternatively fixed training scheme. We demonstrate that the task representation can capture the relationship among teams and generalize to unseen tasks. As a result, the proposed method can help transfer learned cooperation knowledge to new tasks after training on a few source tasks, and the learned transferred policies can also help solve tasks that are hard to learn from scratch.

Predictor-corrector algorithms for stochastic optimization under gradual distribution shift

Subha Maity,Debarghya Mukherjee,Moulinath Banerjee,Yuekai Sun

Time-varying stochastic optimization problems frequently arise in machine learning practice (e.g., gradual domain shift, object tracking, strategic classification). Often, the underlying process that drives the distribution shift is continuous in nature. We exploit this underlying continuity by developing predictor-corrector algorithms for time-varying stochastic optimization that anticipates changes in the underlying data generating process through a predictor-corrector term in the update rule. The key challenge is the estimation of the predictor-corrector term; a naive approach based on sample-average approximation may lead to non-convergence. We develop a general moving-average based method to estimate the predictor-corrector term and provide error bounds for the iterates, both in presence of pure and noisy access to the queries from the relevant derivatives of th e loss function. Furthermore, we show (theoretically and empirically in several examples) that our method outperforms non-predictor corrector methods that do not anticipate changes in the data generating process.

AIM: Adapting Image Models for Efficient Video Action Recognition

Taojiannan Yang,Yi Zhu,Yusheng Xie,Aston Zhang,Chen Chen,Mu Li

Recent vision transformer based video models mostly follow the ``image pre-training then finetuning" paradigm and have achieved great success on multiple video benchmarks. However, fully finetuning such a video model could be computationally expensive and unnecessary, given the pre-trained image transformer models have demonstrated exceptional transferability. In this work, we propose a novel method to Adapt pre-trained Image Models (AIM) for efficient video understanding. By freezing the pre-trained image model and adding a few lightweight Adapters, we introduce spatial adaptation, temporal adaptation and joint adaptation to gradually equip an image model with spatiotemporal reasoning capability. We show that our proposed AIM can achieve competitive or even better performance than prior arts with substantially fewer tunable parameters on four video action recognition benchmarks. Thanks to its simplicity, our method is also generally applicable to different image pre-trained models, which has the potential to leverage more powerful image foundation models in the future. The project webpage is https://adapt-image-models.github.io/.

Impossibly Good Experts and How to Follow Them

Aaron Walsman,Muru Zhang,Sanjiban Choudhury,Dieter Fox,Ali Farhadi

We consider the sequential decision making problem of learning from an expert that has access to more information than the learner. For many problems this extra information will enable the expert to achieve greater long term reward than any policy without this privileged information access. We call these experts ``Impossibly Good'' because no learning algorithm will be able to reproduce their behavior. However, in these settings it is reasonable to attempt to recover the best policy possible given the agent's restricted access to information. We provide a set of necessary criteria on the expert that will allow a learner to recover the optimal policy in the reduced information space from the expert's advice alone. We also provide a new approach called Elf Distillation (Explorer Learning from Follower) that can be used in cases where these criteria are not met and environmental rewards must be taken into account. We show that this algorithm performs better than a variety of strong baselines on a challenging suite of Minigrid and Vizdoom environments.

On Convergence of Average-Reward Off-Policy Control Algorithms in Weakly-Communicating MDPs

Yi Wan,Richard S. Sutton

We show two average-reward off-policy control algorithms, Differential Q Learning (Wan, Naik, \& Sutton 2021a) and RVI Q Learning (Abounadi Bertsekas \& Borkar 2001), converge in weakly-communicating MDPs. Weakly-communicating MDPs are the most general class of MDPs that a learning algorithm with a single stream of experience can guarantee obtaining a policy achieving optimal reward rate. The original convergence proofs of the two algorithms require that all optimal policies induce unichains, which is not necessarily true for weakly-communicating MDPs. To the best of our knowledge, our results are the first showing average-reward off-policy control algorithms converge in weakly-communicating MDPs. As a direct extension, we show that average-reward options algorithms introduced by (Wan, Naik, \& Sutton 2021b) converge if the Semi-MDP induced by options is weakly-communicating.

****

Distributionally Robust Post-hoc Classifiers under Prior Shifts

Jiaheng Wei,Harikrishna Narasimhan,Ehsan Amid,Wen-Sheng Chu,Yang Liu,Abhishek Kumar

The generalization ability of machine learning models degrades significantly when the test distribution shifts away from the training distribution. We investiga te the problem of training models that are robust to shifts caused by changes in the distribution of class-priors or group-priors. The presence of skewed training priors can often lead to the models overfitting to spurious features. Unlike existing methods, which optimize for either the worst or the average performance over classes or groups, our work is motivated by the need for finer control over the robustness properties of the model. We present an extremely lightweight post-hoc approach that performs scaling adjustments to predictions from a pre-trained model, with the goal of minimizing a distributionally robust loss around a chosen target distribution. These adjustments are computed by solving a constrained optimization problem on a validation set and applied to the model during test time. Our constrained optimization objective is inspired from a natural notion of robustness to controlled distribution shifts. Our method comes with provable guarantees and empirically makes a strong case for distributional robust post-hoc classifiers. An empirical implementation is available at https://github.com/weijiaheng/Drops.

Transformer Meets Boundary Value Inverse Problems

Ruchi Guo,Shuhao Cao,Long Chen

A Transformer-based deep direct sampling method is proposed for electrical impedance tomography, a well-known severely ill-posed nonlinear boundary value inverse problem. A real-time reconstruction is achieved by evaluating the learned inverse operator between carefully designed data and the reconstructed images. An effort is made to give a specific example to a fundamental question: whether and how one can benefit from the theoretical structure of a mathematical problem to develop task-oriented and structure-conforming deep neural networks? Specifically, inspired by direct sampling methods for inverse problems, the 1D boundary data in different frequencies are preprocessed by a partial differential equation-based feature map to yield 2D harmonic extensions as different input channels. Then, by introducing learnable non-local kernels, the direct sampling is recast to a modified attention mechanism. The new method achieves superior accuracy over its predecessors and contemporary operator learners and shows robustness to noises in benchmarks.

This research shall strengthen the insights that, despite being invented for natural language processing tasks, the attention mechanism offers great flexibility to be modified in conformity with the a priori mathematical knowledge, which ultimately leads to the design of more physics-compatible neural architectures.

Diagnosing and exploiting the computational demands of videos games for deep reinforcement learning

Lakshmi Narasimhan Govindarajan,Rex G Liu,Drew Linsley,Alekh Karkada Ashok,Max Reuter,Michael Frank,Thomas Serre

Humans learn by interacting with their environments and perceiving the outcomes of their actions. A landmark in artificial intelligence has been the development of deep reinforcement learning (dRL) algorithms capable of doing the same in video games, on par with or better than humans. However, it remains unclear whether the successes of dRL models reflect advances in visual representation learning, the effectiveness of reinforcement learning algorithms at discovering better policies, or both. To address this question, we introduce the Learning Challenge Diagnosticator (LCD), a tool that separately measures the perceptual and reinforcement learning demands of a task. We use LCD to discover a novel taxonomy of challenges in the Procgen benchmark, and demonstrate that these predictions are both highly reliable and can instruct algorithmic development. More broadly, the LCD reveals multiple failure cases that can occur when optimizing dRL algorithms over entire video game benchmarks like Procgen, and provides a pathway towards more efficient progress.

NeuralPCG: Learning Preconditioner for Solving Partial Differential Equations with Graph Neural Network

Yichen Li,Tao Du,Peter Yichen Chen,Wojciech Matusik

Fast and accurate partial differential equation (PDE) solvers empower scientific and engineering research. Classic numerical solvers provide unparalleled accuracy but often require extensive computation time. Machine learning solvers are significantly faster but lack convergence and accuracy guarantees. We present Neural-Network-Preconditioned Conjugate Gradient, or NeuralPCG, a novel linear second-order PDE solver that combines the benefits of classic iterative solvers and machine learning approaches. Our key observation is that both neural-network PDE solvers and classic preconditioners excel at obtaining fast but inexact solutions. NeuralPCG proposes to use neural network models to \emph{precondition} PDE systems in classic iterative solvers. Compared with neural-network PDE solvers, NeuralPCG achieves converging and accurate solutions (e.g.,1e-12 precision) by construction. Compared with classic solvers, NeuralPCG is faster via data-driven preconditioners. We demonstrate the efficacy and generalizability of NeuralPCG by conducting extensive experiments on various 2D and 3D linear second-order PDEs.

Learning Dynamic Query Combinations for Transformer-based Object Detection and Segmentation
Yiming Cui,Linjie Yang,Haichao Yu

Transformer-based detection and segmentation methods use a list of learned detection queries to retrieve information from the transformer network and learn to predict the location and category of one specific object from each query. We empirically find that random convex combinations of the learned queries are still good queries for the corresponding models. We then propose to learn a convex combination with dynamic coefficients based on the high-level semantics of the image. The generated dynamic queries better capture the prior of object locations and categories in the different images. Equipped with our dynamic queries, a wide range of DETR-based models achieve consistent and superior performance across multiple tasks (object detection, instance segmentation, panoptic segmentation) and on different benchmarks (MS COCO, CityScapes, YoutubeVIS).

Cross-Quality Few-Shot Transfer for Alloy Yield Strength Prediction: A New Material Science Benchmark and An Integrated Optimization Framework
Xuxi Chen,Tianlong Chen,Everardo Yeriel Olivares,Kate Elder,Scott K. McCall,Aurelien Pierre Philippe Perron,Joseph T. McKeown,Bhavya Kailkhura,Zhangyang Wang,Brian Gallagher

Discovering high-entropy alloys (HEAs) with high yield strength is an important yet challenging task in material science. However, the yield strength can only be accurately measured by very expensive and time-consuming real-world experiments, hence cannot be acquired at scale. Learning-based methods could facilitate the discovery process, but the lack of a comprehensive dataset on HEA yield strength has created barriers. We present X-Yield, a large-scale material science benchmark with 240 experimentally measured ("high-quality") and over 100K simulated (imperfect or "low-quality") HEA yield strength annotations. Due to the scarcity of experimental annotations and the quality gap in imperfectly simulated data, existing transfer learning methods cannot generalize well on our dataset. We address this cross-quality few-shot transfer problem by leveraging model sparsification "twice" --- as a noise-robust feature learning regularizer at the pre-training stage, and as a data-efficient learning regularizer at the few-shot transfer stage. While the workflow already performs decently with ad-hoc sparsity patterns tuned independently for either stage, we take a step further by proposing a bi-level optimization framework termed Bi-RPT, that jointly learns optimal masks and automatically allocates sparsity levels for both stages. The optimization problem is solved efficiently using gradient unrolling, which is seamlessly integrated with the training process. The effectiveness of Bi-RPT is validated through extensive experiments on our new challenging X-Yield dataset, alongside other synthesized testbeds. Specifically, we achieve an 8.9~19.8% reduction in terms of the test mean squared error and 0.98~1.53% in terms of test accuracy, merely using 5-10% of the experimental data. Codes and sample data are in the supplement.
****

Robust Reinforcement Learning with Distributional Risk-averse formulation

Pierre Clavier,Stephanie Allassonniere,Erwan Le Pennec

The purpose of robust reinforcement learning is to make predictions more robust to changes in the dynamics or rewards of the system. This problem is particularly important when dynamics and rewards of the environment are estimated from the data. However, without constraints, this problem is intractable. In this paper, we approximate the Robust Reinforcement Learning constrained with a f-divergence using an approximate Risk-Averse formulation. We show that the classical Reinforcement Learning formulation can be robustified using a standard deviation penalization of the objective. Two algorithms based on Distributional Reinforcement Learning, one for discrete and one for continuous action spaces, are proposed and tested in a classical Gym environment to demonstrate the robustness of the algorithms.

Unicom: Universal and Compact Representation Learning for Image Retrieval

Xiang An,Jiankang Deng,Kaicheng Yang,Jaiwei Li,Ziyong Feng,Jia Guo,Jing Yang,Tongliang Liu

Modern image retrieval methods typically rely on fine-tuning pre-trained encoders to extract image-level descriptors.

However, the most widely used models are pre-trained on ImageNet-1K with limited classes. The pre-trained feature representation is therefore not universal enough to generalize well to the diverse open-world classes.

In this paper, we first cluster the large-scale \laion{} into one million pseudo classes based on the joint textual and visual features extracted by the CLIP model. Due to the confusion of label granularity, the automatically clustered dataset inevitably contains heavy inter-class conflict. To alleviate such conflict, we randomly select partial inter-class prototypes to construct the margin-based softmax loss. To further enhance the low-dimensional feature representation, we randomly select partial feature dimensions when calculating the similarities between embeddings and class-wise prototypes. The dual random partial selections are with respect to the class dimension and the feature dimension of the prototype matrix, making the classification conflict-robust and the feature embedding compact. Our method significantly outperforms state-of-the-art unsupervised and supervised image retrieval approaches on multiple benchmarks. The code and pre-trained models are released to facilitate future research \url{https://github.com/deepglint/unicom}.

****

The Reward Hypothesis is False

Joar Max Viktor Skalse,Alessandro Abate

The reward hypothesis is the hypothesis that "all of what we mean by goals and purposes can be well thought of as the maximisation of the expected value of the cumulative sum of a received scalar signal". In this paper, we will argue that this hypothesis is false. We will look at three natural classes of reinforcement learning tasks (multi-objective reinforcement learning, risk-averse reinforcement learning, and modal reinforcement learning), and then prove mathematically that these tasks cannot be expressed using any scalar, Markovian reward function. We thus disprove the reward hypothesis by providing many examples of tasks which are both natural and intuitive to describe, but which are nonetheless impossible to express using reward functions. In the process, we provide necessary and sufficient conditions for when a multi-objective reinforcement learning problem can be reduced to ordinary, scalar reward reinforcement learning. We also call attention to a new class of reinforcement learning problems (namely those we call "modal" problems), which have so far not been given any systematic treatment in the reinforcement learning literature.

Convergence of Generative Deep Linear Networks Trained with Bures-Wasserstein Loss

Pierre Bréchet,Katerina Papagiannouli,Jing An,Guido Montufar

We consider a deep matrix factorization model of covariance matrices trained with the Bures-Wasserstein distance. While recent works have made important advances in the study of the optimization problem for overparametrized low-rank matrix approximation, much emphasis has been placed on discriminative settings and the square loss. In contrast, our model considers another interesting type of loss and connects with the generative setting. We characterize the critical points and minimizers of the Bures-Wasserstein distance over the space of rank-bounded matrices. For low-rank matrices the Hessian of this loss can blow up, which creates challenges to analyze convergence of optimizaton methods. We establish convergence results for gradient flow using a smooth perturbative version of the loss and convergence results for finite step size gradient descent under certain assumptions on the initial weights

Diffusion Probabilistic Fields

Peiye Zhuang,Samira Abnar,Jiatao Gu,Alex Schwing,Joshua M. Susskind,Miguel Ángel Bautista

Diffusion probabilistic models have quickly become a major approach for generative modeling of images, 3D geometry, video and other domains. However, to adapt diffusion generative modeling to these domains the denoising network needs to be carefully designed for each domain independently, oftentimes under the assumption that data lives in a Euclidean grid. In this paper we introduce Diffusion Probabilistic Fields (DPF), a diffusion model that can learn distributions over continuous functions defined over metric spaces, commonly known as fields. We extend the formulation of diffusion probabilistic models to deal with this field parametrization in an explicit way, enabling us to define an end-to-end learning algorithm that side-steps the requirement of representing fields with latent vectors as in previous approaches (Dupont et al., 2022a; Du et al., 2021). We empirically show that, while using the same denoising network, DPF effectively deals with different modalities like 2D images and 3D geometry, in addition to modeling distributions over fields defined on non-Euclidean metric spaces.

Improving Information Retention in Large Scale Online Continual Learning

zhipeng cai,Vladlen Koltun,Ozan Sener

Given a stream of data sampled from non-stationary distributions, online continual learning (OCL) aims to adapt efficiently to new data while retaining existing knowledge. The typical approach to address information retention (the ability to retain previous knowledge) is keeping a replay buffer of a fixed size and computing gradients using a mixture of new data and the replay buffer. Surprisingly, the recent work (Cai et al., 2021) suggests that information retention remains a problem in large scale OCL even when the replay buffer is unlimited, \emph{i.e.}, the gradients are computed using all past data. This paper focuses on this peculiarity to understand and address information retention. To pinpoint the source of this problem, we theoretically show that, given limited computation budgets at each time step, even without strict storage limit, naively applying SGD with constant or constantly decreasing learning rates fail to optimize information retention in the long term. We propose using a moving average family of methods to improve optimization for non-stationary objectives. Specifically, we design an adaptive moving average (AMA) optimizer and a moving-average-based learning rate schedule (MALR). We demonstrate the effectiveness of AMA+MALR on large scale benchmarks, including Continual Localization (CLOC), Google Landmarks and ImageNet. Code
will be released upon publication.

Landscape Learning for Neural Network Inversion

Ruoshi Liu,Chengzhi Mao,Purva Tendulkar,Hao Wang,Carl Vondrick

Many machine learning methods operate by inverting a neural network at inference time, which has become a popular technique for solving inverse problems in computer vision, robotics, and graphics. However, these methods often involve gradient descent through a highly non-convex loss landscape, causing the optimization process to be unstable and slow. We introduce a method that learns a loss landscape where gradient descent is efficient, bringing massive improvement and acceleration to the inversion process. We demonstrate this advantage on a number of methods for both generative and discriminative tasks, including GAN inversion, adv

ersarial defense, and 3D human pose reconstruction.

Stochastic Multi-Person 3D Motion Forecasting

Sirui Xu,Yu-Xiong Wang,Liangyan Gui

This paper aims to deal with the ignored real-world complexity in prior work on human motion forecasting, emphasizing the social properties of multi-person motion, the diversity of motion and social interactions, and the complexity of articulated motion. To this end, we introduce a novel task of stochastic multi-person 3D motion forecasting. We propose a dual-level generative modeling framework that separately models independent individual motion at the local level and social interactions at the global level. Notably, this dual-level modeling mechanism can be achieved within a shared generative model, through introducing learnable latent codes that represent intents of future motion and switching the codes' modes of operation at different levels. Our framework is general, and we instantiate it with various multi-person forecasting models. Extensive experiments on CMU-Mocap, MuPoTS-3D, and SoMoF benchmarks show that our approach produces diverse and accurate multi-person predictions, significantly outperforming the state of the art.

ON INJECTING NOISE DURING INFERENCE

Milad Khademi Nori,Yiqun GE,IL MIN KIM

We study activation noise in a generative energy-based modeling setting during training for the purpose of regularization. We prove that activation noise is a general form of dropout. Then, we analyze the role of activation noise at inference time and demonstrate it to be utilizing sampling. Thanks to the activation noise we observe about 200% improvement in performance (classification accuracy). Later, we not only discover, but also prove that the best performance is achieved when the activation noise follows the same distribution both during training and inference. To explicate this phenomenon, we provide theoretical results that illuminate the roles of activation noise during training, inference, and their mutual influence on the performance. To further confirm our theoretical results, we conduct experiments for five datasets and seven distributions of activation noise.

LEARNING THE SPECTROGRAM TEMPORAL RESOLUTION FOR AUDIO CLASSIFICATION

Haohe Liu,Xubo Liu,Qiuqiang Kong,Wenwu Wang,Mark D Plumbley

The audio spectrogram is a time-frequency representation that has been widely used for audio classification. The temporal resolution of a spectrogram depends on hop size. Previous works generally assume the hop size should be a constant value such as ten milliseconds. However, a fixed hop size or resolution is not always optimal for different types of sound. This paper proposes a novel method, DiffRes, that enables differentiable temporal resolution learning to improve the performance of audio classification models. Given a spectrogram calculated with a fixed hop size, DiffRes merges non-essential time frames while preserving important frames. DiffRes acts as a "drop-in" module between an audio spectrogram and a classifier, and can be end-to-end optimized. We evaluate DiffRes on the mel-spectrogram, followed by state-of-the-art classifier backbones, and apply it to five different subtasks. Compared with using the fixed-resolution mel-spectrogram, the DiffRes-based method can achieve the same or better classification accuracy with at least 25% fewer temporal dimensions on the feature level, which alleviates the computational cost at the same time. Starting from a high-temporal-resolution spectrogram such as one-millisecond hop size, we show that DiffRes can improve classification accuracy with the same computational complexity.

Beyond calibration: estimating the grouping loss of modern neural networks

Alexandre Perez-Lebel,Marine Le Morvan,Gael Varoquaux

The ability to ensure that a classifier gives reliable confidence scores is essential to ensure informed decision-making. To this end, recent work has focused on miscalibration, i.e., the over or under confidence of model scores. Yet calibration is not enough: even a perfectly calibrated classifier with the best possib le accuracy can have confidence scores that are far from the true posterior probabilities. This is due to the grouping loss, created by samples with the same confidence scores but different true posterior probabilities. Proper scoring rule theory shows that given the calibration loss, the missing piece to characterize individual errors is the grouping loss. While there are many estimators of the calibration loss, none exists for the grouping loss in standard settings. Here, we propose an estimator to approximate the grouping loss. We show that modern neural network architectures in vision and NLP exhibit grouping loss, notably in distribution shifts settings, which highlights the importance of pre-production validation.

Hybrid RL: Using both offline and online data can make RL efficient

Yuda Song,Yifei Zhou,Ayush Sekhari,Drew Bagnell,Akshay Krishnamurthy,Wen Sun

We consider a hybrid reinforcement learning setting (Hybrid RL), in which an agent has access to an offline dataset and the ability to collect experience via real-world online interaction. The framework mitigates the challenges that arise in both pure offline and online RL settings, allowing for the design of simple and highly effective algorithms, in both theory and practice. We demonstrate these advantages by adapting the classical Q learning/iteration algorithm to the hybrid setting, which we call Hybrid Q-Learning or Hy-Q. In our theoretical results, we prove that the algorithm is both computationally and statistically efficient whenever the offline dataset supports a high-quality policy and the environment has bounded bilinear rank. Notably, we require no assumptions on the coverage provided by the initial distribution, in contrast with guarantees for policy gradient/iteration methods. In our experimental results, we show that Hy-Q with neural network function approximation outperforms state-of-the-art online, offline, and hybrid RL baselines on challenging benchmarks, including Montezuma’s Revenge.

Spotting Expressivity Bottlenecks and Fixing Them Optimally

Manon Verbockhaven,Guillaume Charpiat

Machine learning tasks are generally formulated as optimization problems, where one searches for an optimal function within a certain functional space. In practice, parameterized functional spaces are considered, in order to be able to perform gradient descent. Typically, a neural network architecture is chosen and fixed, and its parameters (connection weights) are optimized, yielding an architecture-dependent result. This way of proceeding however forces the evolution of the function during training to lie within the realm of what is expressible with the chosen architecture, and prevents any optimization across possible architectures. Costly architectural hyper-parameter optimization is often performed to compensate for this. Instead, we propose to adapt the architecture on the fly during training. We show that the information about desirable architectural changes, due to expressivity bottlenecks when attempting to follow the functional gradient, can be extracted from the back-propagation. To do this, we propose a new mathematically well-grounded method to detect expressivity bottlenecks on the fly and solve them by adding suitable neurons when and where needed. Thus, while the standard approach requires large networks, in terms of number of neurons per layer, for expressivity and optimization reasons, we are able to start with very small neural networks and let them grow appropriately. As a proof of concept, we show convincing results on the MNIST dataset, matching large neural network accuracy, with competitive training time, while removing the need for standard architectural hyper-parameter optimization.

Scalable and Privacy-enhanced Graph Generative Model for Graph Neural Networks

Minji Yoon,Yue Wu,John Palowitch,Bryan Perozzi,Russ Salakhutdinov

As the field of Graph Neural Networks (GNN) continues to grow, it experiences a corresponding increase in the need for large, real-world datasets to train and test new GNN models on challenging, realistic problems. Unfortunately, such graph datasets are often generated from online, highly privacy-restricted ecosystems,

which makes research and development on these datasets hard, if not impossible. This greatly reduces the amount of benchmark graphs available to researchers, causing the field to rely only on a handful of publicly-available datasets. To address this dilemma, we introduce a novel graph generative model, Computation Graph Transformer (CGT) that can learn and reproduce the distribution of real-world graphs in a privacy-enhanced way. Our proposed model (1) generates effective benchmark graphs on which GNNs show similar task performance as on the source graphs, (2) scales to process large-scale real-world graphs, (3) guarantees privacy for end-users. Extensive experiments across a vast body of graph generative models show that only our model can successfully generate privacy-controlled, synthetic substitutes of large-scale real-world graphs that can be effectively used to evaluate GNN models.

Model ensemble instead of prompt fusion: a sample-specific knowledge transfer method for few-shot prompt tuning
XIANGYU PENG,Chen Xing,Prafulla Kumar Choubey,Chien-Sheng Wu,Caiming Xiong
Prompt tuning approaches, which learn task-specific soft prompts for a downstream task conditioning on frozen pre-trained models, have attracted growing interest due to its parameter efficiency. With large language models and sufficient training data, prompt tuning performs comparably to full-model tuning. However, with limited training samples in few-shot settings, prompt tuning fails to match the performance of full-model fine-tuning. In this work, we focus on improving the few-shot performance of prompt tuning by transferring knowledge from soft prompts of source tasks with abundant training samples. Recognizing the good generalization capabilities of ensemble methods in low-data regime, we first experiment and show that a simple ensemble of model predictions based on different source prompts, outperforms existing multi-prompt knowledge transfer approaches such as source prompt fusion in the few-shot setting. Motivated by this observation, we further investigate model ensembles and propose Sample-specific Ensemble of Source Models (SESoM). SESoM learns to adjust the contribution of each source model for each target sample separately when ensembling source model outputs. Through this way, SESoM inherits the superior generalization of ensemble methods and simultaneously captures the sample-specific competence of each source prompt. We conduct experiments across a diverse set of eight NLP tasks using models of different scales (T5-\{base, large, XL\}) and find that SESoM consistently outperforms the existing models of the same as well as larger parametric scale by a large margin.

Entropy-Regularized Model-Based Offline Reinforcement Learning
Soroush Ghandi,Maryam Tavakol
Model-based approaches to offline Reinforcement Learning (RL) aim to remedy the problem of sample complexity in offline learning via first estimating a pessimistic Markov Decision Process (MDP) from offline data, followed by freely exploring in the learned model for policy optimization. Recent advances in model-based RL techniques mainly rely on an ensemble of models to quantify the uncertainty of the empirical MDP which is leveraged to penalize out-of-distribution state-action pairs during the policy learning. However, the performance of ensembles for uncertainty quantification highly depends on how they are implemented in practice, which can be a limiting factor. In this paper, we propose a systematic way to measure the epistemic uncertainty and present \abbrv, an Entropy-regularized Model-based Offline RL approach, to provide a smooth error estimation when leaving the support of data toward uncertain areas. Subsequently, we optimize a single neural architecture that maximizes the likelihood of offline data distribution while regularizing the transitions that are outside of the data support. Empirical results demonstrate that our framework achieves competitive performance compared to state-of-the-art offline RL methods on D4RL benchmark datasets.

Sign and Basis Invariant Networks for Spectral Graph Representation Learning
Derek Lim,Joshua David Robinson,Lingxiao Zhao,Tess Smidt,Suvrit Sra,Haggai Maron,Stefanie Jegelka

We introduce SignNet and BasisNet---new neural architectures that are invariant to two key symmetries displayed by eigenvectors: (i) sign flips, since if v is an eigenvector then so is -v; and (ii) more general basis symmetries, which occur in higher dimensional eigenspaces with infinitely many choices of basis eigenvectors. We prove that under certain conditions our networks are universal, i.e., they can approximate any continuous function of eigenvectors with the desired invariances. When used with Laplacian eigenvectors, our networks are provably more expressive than existing spectral methods on graphs; for instance, they subsume all spectral graph convolutions, certain spectral graph invariants, and previously proposed graph positional encodings as special cases. Experiments show that our networks significantly outperform existing baselines on molecular graph regression, learning expressive graph representations, and learning neural fields on triangle meshes. Our code is available at https://github.com/cptq/SignNet-BasisNet.

Diffusing Graph Attention
Daniel Glickman,Eran Yahav
The dominant paradigm for machine learning on graphs uses Message Passing Graph Neural Networks~(MP-GNNs), in which node representations are updated by aggregating information in their local neighborhood. Recently, there have been increasingly more attempts to adapt the Transformer architecture to graphs in an effort to solve some known limitations of MP-GNN. A challenging aspect of designing Graph Transformers is integrating the arbitrary graph structure into the architecture. We propose \emph{Graph Diffuser}~(GD) to address this challenge. GD learns to extract structural and positional relationships between distant nodes in the graph, which it then uses to direct the Transformer's attention and node representation. We demonstrate that existing GNNs and Graph Transformers struggle to capture long-range interactions and how Graph Diffuser does so while admitting intuitive visualizations. Experiments on eight benchmarks show Graph Diffuser to be a highly competitive model, outperforming the state-of-the-art in a diverse set of domains.

Sequential Latent Variable Models for Few-Shot High-Dimensional Time-Series Forecasting
Xiajun Jiang,Ryan Missel,Zhiyuan Li,Linwei Wang
Modern applications increasingly require learning and forecasting latent dynamics from high-dimensional time-series. Compared to univariate time-series forecasting, this adds a new challenge of reasoning about the latent dynamics of an unobserved abstract state. Sequential latent variable models (LVMs) present an attractive solution, although existing works either struggle with long-term forecasting or have difficulty learning across diverse dynamics. In this paper, we first present a conceptual framework of sequential LVMs to unify existing works, contrast their fundamental limitations, and identify an intuitive solution to long-term forecasting for diverse dynamics via meta-learning. We then present the first framework of few-shot forecasting for high-dimensional time-series: instead of learning a single dynamic function, we leverage data of diverse dynamics and learn to adapt latent dynamic functions to few-shot support series. This is realized via Bayesian meta-learning underpinned by: 1) a latent dynamic function conditioned on knowledge derived from few-shot support series, and 2) a meta-model that learns to extract such dynamic-specific knowledge via feed-forward embedding of support set. We compared the presented framework with a comprehensive set of baseline models trained 1) globally on the large meta-training set with diverse dynamics, and 2) individually on single dynamics, both with and without fine-tuning to k-shot support series used by the meta-models. We demonstrated that the presented framework is agnostic to the latent dynamic function of choice and, at meta-test time, is able to forecast for new dynamics given variable-shot of support series.

Code Translation with Compiler Representations
Marc Szafraniec,Baptiste Roziere,Hugh James Leather,Patrick Labatut,Francois Cha

rton,Gabriel Synnaeve

In this paper, we leverage low-level compiler intermediate representations (IR) code translation. Traditional transpilers rely on syntactic information and handcrafted rules, which limits their applicability and produces unnatural-looking code. Applying neural machine translation (NMT) approaches to code has successfully broadened the set of programs on which one can get a natural-looking translation. However, they treat the code as sequences of text tokens, and still do not differentiate well enough between similar pieces of code which have different semantics in different languages. The consequence is low quality translation, reducing the practicality of NMT, and stressing the need for an approach significantly increasing its accuracy. Here we propose to augment code translation with IRs, specifically LLVM IR, with results on the C++, Java, Rust, and Go languages. Our method improves upon the state of the art for unsupervised code translation, increasing the number of correct translations by 11% on average, and up to 79% for the Java → Rust pair with greedy decoding. With beam search, it increases the number of correct translations by 5.5% in average. We extend previous test sets for code translation, by adding hundreds of Go and Rust functions. Additionally, we train models with high performance on the problem of IR decompilation, generating programming source code from IR, and study using IRs as intermediary pivot for translation.

GAIN: On the Generalization of Instructional Action Understanding

Junlong Li,Guangyi Chen,Yansong Tang,Jinan Bao,Kun Zhang,Jie Zhou,Jiwen Lu

Despite the great success achieved in instructional action understanding by deep learning and mountainous data, deploying trained models to the unseen environment still remains a great challenge, since it requires strong generalizability of models from in-distribution training data to out-of-distribution (OOD) data. In this paper, we introduce a benchmark, named GAIN, to analyze the GeneralizAbility of INstructional action understanding models. In GAIN, we reassemble steps of existing instructional video training datasets to construct the OOD tasks and then collect the corresponding videos. We evaluate the generalizability of models trained on in-distribution datasets with the performance on OOD videos and observe a significant performance drop. We further propose a simple yet effective approach, which cuts off the excessive contextual dependency of action steps by performing causal inference, to provide a potential direction for enhancing the OOD generalizability. In the experiments, we show that this simple approach can improve several baselines on both instructional action segmentation and detection tasks. We expect the introduction of the GAIN dataset will promote future in-depth research on the generalization of instructional video understanding.

Deep Reinforcement learning on Adaptive Pairwise Critic and Asymptotic Actor

Huihui Zhang

Maximum entropy deep reinforcement learning has displayed great potential on a range of challenging continuous tasks. The maximum entropy is able to encourage policy exploration, however, it has a tradeoff between the efficiency and stability, especially when employed on large-scale tasks with high state and action dimensionality.

Sometimes the temperature hyperparameter of maximum entropy term is limited to remain stable at the cost of slower and lower convergence.

Besides, the function approximation errors existing in actor-critic learning are known to induce estimation errors and suboptimal policies.

In this paper, we propose an algorithm based on adaptive pairwise critics, and adaptive asymptotic maximum entropy combined.

Specifically, we add a trainable state-dependent weight factor to build an adaptive pairwise target Q-value to serve as the surrogate policy objective.

Then we adopt a state-dependent adaptive temperature to smooth the entropy policy exploration, which introduces an asymptotic maximum entropy.

The adaptive pairwise critics can effectively improve the value estimation, preventing overestimation or underestimation errors. Meanwhile, the adaptive asymptotic entropy can adapt to the tradeoff between efficiency and stability, which pr ovides more exploration and flexibility.

We evaluate our method on a set of Gym tasks, and the results show that the proposed algorithms have better performance than several baselines on continuous control.

Model-based Value Exploration in Actor-critic Deep Reinforcement Learning

Huihui Zhang

Off-policy method has demonstrated great potential on model-free deep reinforcement learning due to the sample-efficient advantage. However, it suffers extra instability due to some mismatched distributions from observations. Model-free on-policy counterparts usually have poor sample efficiency. Model-based algorithms, in contrast, are highly dependent on the goodness of expert demonstrations or learned dynamics.

In this work, we propose a method which involves training the dynamics to accelerate and gradually stabilize learning without adding sample-complexity. The dynamics model prediction can provide effective target value exploration, which is essentially different from the methods on-policy exploration, by adding valid diversity of transitions.

Despite the existence of model bias, the model-based prediction can avoid the overestimation and distribution mismatch errors in off-policy learning, as the learned dynamics model is asymptotically accurate.

Besides, to generalize the solution to large-scale reinforcement learning problems, we use global gaussian and deterministic function approximation to model the transition probability and reward function, respectively. To minimize the negative impact of potential model bias brought by the estimated dynamics, we adopt one-step global prediction for the model-based part of target value. By analyses and proofs, we show how the model-based prediction provides value exploration and asymptotical performance to the overall network. It can also be concluded that the convergence of proposed algorithm only depends on the accuracy of learnt dynamics model.

Omnigrok: Grokking Beyond Algorithmic Data

Ziming Liu,Eric J Michaud,Max Tegmark

Grokking, the unusual phenomenon for algorithmic datasets where generalization happens long after overfitting the training data, has remained elusive. We aim to understand grokking by analyzing the loss landscapes of neural networks, identifying the mismatch between training and test losses as the cause for grokking. We refer to this as the "LU mechanism" because training and test losses (against model weight norm) typically resemble "L" and "U", respectively. This simple mechanism can nicely explain many aspects of grokking: data size dependence, weight decay dependence, the emergence of representations, etc. Guided by the intuitive picture, we are able to induce grokking on tasks involving images, language and molecules, although the grokking signals are sometimes less dramatic. We attribute the dramatic nature of grokking for algorithmic datasets to representation learning.

ManyDG: Many-domain Generalization for Healthcare Applications

Chaoqi Yang,M Brandon Westover,Jimeng Sun

The vast amount of health data has been continuously collected for each patient, providing opportunities to support diverse healthcare predictive tasks such as seizure detection and hospitalization prediction. Existing models are mostly trained on other patients’ data and evaluated on new patients. Many of them might suffer from poor generalizability. One key reason can be overfitting due to the unique information related to patient identities and their data collection environments, referred to as patient covariates in the paper. These patient covariates usually do not contribute to predicting the targets but are often difficult to remove. As a result, they can bias the model training process and impede generalization. In healthcare applications, most existing domain generalization methods assume a small number of domains. In this paper, considering the diversity of patient covariates, we propose a new setting by treating each patient as a separa te domain (leading to many domains). We develop a new domain generalization method ManyDG, that can scale to such many-domain problems. Our method identifies the patient do- main covariates by mutual reconstruction, and removes them via an orthogonal projection step. Extensive experiments show that ManyDG can boost the generalization performance on multiple real-world healthcare tasks (e.g., 3.7% Jaccard improvements on MIMIC drug recommendation) and support realistic but challenging settings such as insufficient data and continuous learning. The code is available at https://github.com/ycq091044/ManyDG.

Adversarial Detector for Decision Tree Ensembles Using Representation Learning

Gal Braun,Lior Rokach

Research on adversarial evasion attacks focuses mainly on neural network models. Among other reasons, this is because of their popularity in certain fields (e.g., computer vision and NLP) and the models' properties, making it easier to search for adversarial examples with minimal input change. Decision trees and tree ensembles are still very popular due to their high
performance in fields dominated by tabular data and their explainability. In recent years, several works have defined new adversarial attacks targeting decision trees and tree ensembles. As a result, several papers were published focusing on robust versions of tree ensembles. This research aims to create an adversarial detector for attacks on an ensemble of decision trees. While several previous works have demonstrated the generation of more robust tree ensembles, the process of considering evasion attacks during ensemble generation can affect model performance. We demonstrate a method to detect adversarial samples without affecting either the target model structure or its original performance. We showed that by using representation learning based on the structure of the trees, we achieved better detection rates than the state-of-the-art technique and better than using the original representation of the dataset to train an adversarial detector.

****

Learning with Instance-Dependent Label Noise: Balancing Accuracy and Fairness

Donna Tjandra,Jenna Wiens

Incorrect labels hurt model performance when the model overfits to noise. Many state-of-the-art approaches that address label noise assume that label noise is independent from the input features. In practice, however, label noise is often feature or instance-\textit{dependent}, and therefore is biased (i.e., some instances are more likely to be mislabeled than others). Approaches that ignore this dependence can produce models with poor discriminative performance, and depending on the task, can exacerbate issues around fairness. In light of these limitations, we propose a two-stage approach to learn from datasets with instance-dependent label noise. Our approach utilizes \textit{anchor points}, a small subset of data for which we know the ground truth labels. On many tasks, our approach leads to consistent improvements over the state-of-the-art in discriminative performance (AUROC) while balancing model fairness (area under the equalized odds curve, AUEOC). For example, when predicting acute respiratory failure onset on the MIMIC-III dataset, the harmonic mean of the AUROC and AUEOC of our approach is 0.84 (SD 0.01) while that of the next best baseline is 0.81 (SD 0.01). Overall, our approach leads to learning more accurate and fair models compared to existing approaches in the presence of instance-dependent label noise.

Flow Annealed Importance Sampling Bootstrap

Laurence Illing Midgley,Vincent Stimper,Gregor N. C. Simm,Bernhard Schölkopf,José Miguel Hernández-Lobato

Normalizing flows are tractable density models that can approximate complicated target distributions, e.g. Boltzmann distributions of physical systems. However, current methods for training flows either suffer from mode-seeking behavior, use samples from the target generated beforehand by expensive MCMC methods, or use stochastic losses that have high variance. To avoid these problems, we augment flows with annealed importance sampling (AIS) and minimize the mass-covering α-divergence with $\alpha=2$, which minimizes importance weight variance. Our method, Flow AIS Bootstrap (FAB), uses AIS to generate samples in regions wher e the flow is a poor approximation of the target, facilitating the discovery of new modes. We apply FAB to multimodal targets and show that we can approximate them very accurately where previous methods fail. To the best of our knowledge, we are the first to learn the Boltzmann distribution of the alanine dipeptide molecule using only the unnormalized target density, without access to samples generated via Molecular Dynamics (MD) simulations: FAB produces better results than training via maximum likelihood on MD samples while using 100 times fewer target evaluations. After reweighting the samples, we obtain unbiased histograms of dihedral angles that are almost identical to the ground truth.

****

DecAF: Joint Decoding of Answers and Logical Forms for Question Answering over Knowledge Bases

Donghan Yu,Sheng Zhang,Patrick Ng,Henghui Zhu,Alexander Hanbo Li,Jun Wang,Yiqun Hu,William Yang Wang,Zhiguo Wang,Bing Xiang

Question answering over knowledge bases (KBs) aims to answer natural language questions with factual information such as entities and relations in KBs. Previous methods either generate logical forms that can be executed over KBs to obtain final answers or predict answers directly. Empirical results show that the former often produces more accurate answers, but it suffers from non-execution issues due to potential syntactic and semantic errors in the generated logical forms. In this work, we propose a novel framework DecAF that jointly generates both logical forms and direct answers, and then combines the merits of them to get the final answers. Moreover, different from most of the previous methods, DecAF is based on simple free-text retrieval without relying on any entity linking tools --- this simplification eases its adaptation to different datasets. DecAF achieves new state-of-the-art accuracy on WebQSP, FreebaseQA, and GrailQA benchmarks, while getting competitive results on the ComplexWebQuestions benchmark.

NANSY++: Unified Voice Synthesis with Neural Analysis and Synthesis

Hyeong-Seok Choi,Jinhyeok Yang,Juheon Lee,Hyeongju Kim

Various applications of voice synthesis have been developed independently despite the fact that they generate “voice” as output in common. In addition, most of the voice synthesis models still require a large number of audio data paired with annotated labels (e.g., text transcription and music score) for training. To this end, we propose a unified framework of synthesizing and manipulating voice signals from analysis features, dubbed NANSY++. The backbone network of NANSY++ is trained in a self-supervised manner that does not require any annotations paired with audio. After training the backbone network, we efficiently tackle four voice applications - i.e. voice conversion, text-to-speech, singing voice synthesis, and voice designing - by partially modeling the analysis features required for each task. Extensive experiments show that the proposed framework offers competitive advantages such as controllability, data efficiency, and fast training convergence, while providing high quality synthesis. Audio samples: tinyurl.com/8tnsy3uc.

Causality Compensated Attention for Contextual Biased Visual Recognition

Ruyang Liu,Jingjia Huang,Thomas H. Li,Ge Li

Visual attention does not always capture the essential object representation desired for robust predictions. Attention modules tend to underline not only the target object but also the common co-occurring context that the module thinks helpful in the training. The problem is rooted in the confounding effect of the context leading to incorrect causalities between objects and predictions, which is further exacerbated by visual attention. In this paper, to learn causal object features robust for contextual bias, we propose a novel attention module named Interventional Dual Attention (IDA) for visual recognition. Specifically, IDA adopts two attention layers with multiple sampling intervention, which compensates the attention against the confounder context. Note that our method is model-agnostic and thus can be implemented on various backbones. Extensive experiments show our model obtains significant improvements in classification and detection with lower computation. In particular, we achieve the state-of-the-art results in mul ti-label classification on MS-COCO and PASCAL-VOC.

A unified optimization framework of ANN-SNN Conversion: towards optimal mapping from activation values to firing rates

Haiyan Jiang,Srinivas Anumasa,Giulia De Masi,Huan Xiong,Bin Gu

Spiking Neural Networks (SNNs) have attracted great attention as a primary candidate for running large-scale deep artificial neural networks (ANNs) in real-time due to their distinctive properties of energy-efficient and event-driven fast computation. Training an SNN directly from scratch is usually difficult because of the discreteness of spikes. Converting an ANN to an SNN, i.e., ANN-SNN conversion, is an alternative method to obtain deep SNNs.

The performance of the converted SNN is determined by both the ANN performance and the conversion error. The existing ANN-SNN conversion methods usually redesign the ANN with a new activation function instead of the regular ReLU, train the tailored ANN and convert it to an SNN. The performance loss between the regular ANN with ReLU and the tailored ANN has never been considered, which will be inherited to the converted SNN.

In this work, we formulate the ANN-SNN conversion as a unified optimization problem which considers the performance loss between the regular ANN and the tailored ANN, as well as the conversion error simultaneously. Following the unified optimization framework, we propose the SlipReLU activation function to replace the regular ReLU activation function in the tailored ANN. The SlipReLU is a weighted sum of the threhold-ReLU and the step function, which improves the performance of either as an activation function alone.

The SlipReLU method covers a family of activation functions mapping from activation values in source ANNs to firing rates in target SNNs; most of the state-of-the-art optimal ANN-SNN conversion methods are special cases of our proposed SlipReLU method. We demonstrate through two theorems that the expected conversion error between SNNs and ANNs can theoretically be zero on a range of shift values $\delta \in [-\frac{1}{2},\frac{1}{2}]$ rather than a fixed shift term $\frac{1}{2}$, enabling us to achieve converted SNNs with high accuracy and ultra-low latency. We evaluate our proposed SlipReLU method on CIFAR-10 dataset, and the results show that the SlipReLU outperforms the state-of-the-art ANN-SNN conversion in both accuracy and latency. To our knowledge, this is the first work to explore high-performance ANN-SNN conversion method considering the ANN performance and the conversion error simultaneously.
